Constant-permeability materials are required for applications where a constant inductance is essential for electrical filters or in loading coils for telephone lines. The original materials were

in the ternary Fe/Ni/Co series but more recently they have been replaced by the 40–50% nickel Isoperms. They have an addition of 5–15% copper and by cold rolling and heat treatment a preferred orientation is produced. The permeability of 50–60 is constant over a range of fields up to $8\,\mathrm{kA\,m^{-1}}$.

20.5   Magnetic powder core materials

The thickness of laminations of ferromagnetic alloy cores must be reduced as the operating frequency is increased above audio range if the increasing loss and reducing permeability caused by eddy currents are to be avoided. However, reduction of thickness of laminations causes increased cost. This may be avoided for many applications up to 200 kHz by the use of magnetic powder cores.[3]

The Permalloys are used in the form of compressed insulated powder cores, the effect of subdivision being to reduce eddy current losses to a minimum. The permeability is also reduced but is made extremely constant, becoming within a small percentage independent of magnetising force and unaffected by magnetic shock. The properties of such materials are in many ways similar to the constant permeability alloys described in the preceding section. *Sendust*, a brittle alloy of aluminium, silicon and iron, has been similarly used in Japan and Germany. Carbonyl iron powder is used for powder cores mainly at radio frequencies, specially low eddy current losses being obtained on account of the characteristic fine particle size. Some details of these materials are given in Table 20.13.

Table 20.13   MAGNETIC POWDER CORE MATERIALS

Material	Composition	*Effective initial relative permeability* μ_e	*Typical power loss* kw/m³ (*at* 50 kHz, 100 mT, 25°C)	*Typical applications*
Molybdenum Permalloy	80% Ni–Fe +Mo	125 60	230 500	High Q fixed inductors 0.1 to 200 kHz
Radiometal (high flux)	50% Ni–Fe	125	600	Switch mode power supply chokes and transformers to 250 kHz
		69	650	Mains chokes and filters for suppression of radio frequency interference
Carbonyl iron powder (high frequency)	99.9% Fe	5–25	—	High Q fixed inductors 1–300 MHz. Wide band signal transformers up to 10 GHz. Chokes for RF suppression
Electrolytic iron powder (low frequency)	99% Fe	45–90	3 300	Switch mode power supply chokes to 50 kHz. Main chokes for RF suppression
			2 400	Dimmer chokes 50 Hz DC electromagnets
Sendust	9.5% Si, 5.5% Al, balance Fe	60	2 000	Chokes and inductors

20.6   Magnetic temperature-compensating materials

Alloys having a marked variation of permeability with temperature are used to compensate for errors in electrical instruments caused by changes in the ambient temperature.

The magnetic permeability of iron and iron alloys decreases with temperature (except for low values of the field), and this causes the readings of electrical meters which depend upon the fluxes maintained by a constant voltage or current or by a permanent magnet, to decrease with the ambient temperature. To compensate for such errors it is customary to shunt a certain proportion of the magnetic flux passing through the magnetic circuit of the meter by means of an alloy having an unusually high negative temperature coefficient between 0 and 100°C, so that, as the ambient temperature increases, the proportion of the shunted flux decreases, causing more flux to pass through the working air gap of the instrument than otherwise would be the case. By correctly proportioning

the shunt component it is possible to render the readings almost completely independent of ambient temperature changes.

Compensation may also be provided for the changes of resistivity of eddy current devices. These alloys have a major application in the compensation of changes in the resistivity with temperature of the copper drag cup in speedometers.

The alloys used are in the nickel–iron series, about 30% nickel, sometimes with additions of chromium, manganese and/or silicon. Details of the characteristics of the alloy are given in Table 20.14.

Table 20.14 THERMOMAGNETIC TEMPERATURE COMPENSATING MATERIALS

	Magnetic flux density at $H = 8 \times 10^3 \, A \, m^{-1}$ T								
	Temperature °C								
Material	−40	−20	0	20	40	60	80	100	120
Telecon 2799	0.53	0.43	0.33	0.22	0.13	0.05	—	—	—

20.7   Non-magnetic steels and cast irons

For certain constructional purposes in electrical engineering where magnetic shunting effects have to be avoided there arises a requirement for almost non-magnetic materials possessing certain minimum mechanical properties.

The materials available comprise non-magnetic cast irons, austenitic steels, and certain other sensibly non-magnetic alloys; the choice of materials for any particular purpose is dependent upon the mechanical properties required; e.g. certain intricate stationary parts of electrical machinery would be suitably made from non-magnetic cast iron, while armature straps for high-speed rotors would be made in a high-tensile austenitic alloy steel in order to withstand the dynamic stresses encountered in practice. A high resistivity is sometimes beneficial as well as the possession of virtually non-magnetic properties.

There are two well-known non-magnetic cast irons, one called *Nomag*, a manganese-silicon-nickel-iron with a permeability of 1.04, and a resistivity of 1.40 microhm *m*, and the other *Ni-Resist*, containing lower proportions of manganese and silicon, but a higher proportion of nickel, also a little chromium and copper. These irons with flake graphite are brittle, and can only be used for parts of a simple nature, such as supports which are not subjected to severe mechanical stress. These non-magnetic irons are also made in the spheroidal graphite form e.g. *Nodumag* and *S. G. Ni-Resist*, having the characteristically improved mechanical properties of this type of cast iron.

As examples of austenitic steels. Hadfields 13% manganese steel and the chromium–nickel steels have found considerable use. The stainless steels of the chromium–nickel type are normally non-magnetic but if they are subjected to cold working appreciable magnetic properties may appear. This disadvantage can be overcome by using steels with higher alloy content than the well-known 18/8 type. Besides these materials other non-magnetic austenitic steels have been specially developed to give improved mechanical properties.

Although the originators of some of these steels and cast irons are no longer in business, it is possible to get steelmakers or foundries to produce them to order. Table 20.15 gives details of the non-magnetic cast irons and a number of non-magnetic cast steels.[37]

Table 20.15   NON-MAGNETIC STEELS AND CAST IRONS

Material	Nominal composition	Relative permeability	Resistivity $\mu\Omega\,m$	Condition	Mechanical properties				
					Hardness HB	Proof stress MPa	Max stress MPa	Elongation $L=4\sqrt{A}$ %	Reduction in area %
Wrought steels									
18/8 Stainless	8% Ni, 18% Cr and various minor constituents	1.06 or greater	0.72	Austenised	170	278	618	45	50
18/8 Stainless	8% Ni, 18% Cr and various minor constituents	1.4	—	20% cold reduction	280	—	927	25	—
18/8 Stainless	8% Ni, 18% Cr and various minor constituents	about 10.0	—	50% cold reduction	330	—	1 313	10	—

Appendix

Units and definitions

Magnetic poles

The concept of magnetic poles is used to explain the behaviour of magnetised bodies acting on one another and in the earth's magnetic field. Like magnetic poles repel each other and unlike poles attract.

Magnetic dipole

A magnetic dipole is an elementary pair of unlike poles and can be represented by an infinitesimal current loop.

Magnetic moment m

For a magnetic dipole the magnetic moment is the product of the current and the loop area. For a magnetised body the magnetic moment is the sum of all the magnetic dipole moments and is equal to ml where l is the distance between the poles.

Magnetic field strength H

The magnetic field strength H at a point is an axial vector quantity associated with the magnetic flux density in a magnetic field. The unit of magnetic field is the ampere per metre ($A\,m^{-1}$), which is the (axial) field inside an infinitely long solenoid of one turn per metre carrying a current of one ampere.

Magnetisation M

When a magnetic field is applied to a magnetic material the material becomes magnetised. The magnitude of this magnetisation M is equal to the total magnetic moment divided by the volume. The units of M are ampere per metre ($A\,m^{-1}$).

Polarisation J

This is the name given to the product $\mu_0 M$, and it has the units of tesla (T).

Saturation magnetisation M$_s$ *and polarisation* J$_s$

These are the maximum possible values of the magnetisation and polarisation for a given material at a given temperature. The saturation polarisation J_s is sometimes called B_s.

Magnetisation per unit mass σ

The value of σ is usually the saturation value and is equal to M/ρ where ρ is the density. The units are joule/(tesla kg).

Magnetic flux density B (or magnetic induction)

The magnetic flux density B at a point is a vector quantity arising from the magnetic field and the magnetisation of the medium. It is given by:

$$B = \mu_0 H + \mu_0 M$$

or

$$B = \mu_0 H + J$$

where μ_0 is the magnetic constant. The units of B are tesla (T) or weber/(metre)^2 ($Wb\,m^{-2}$).

Magnetic constant μ$_0$

This constant μ_0 is equal to $4\pi \times 10^{-7}$ Henries m^{-1}. For practical purposes this constant when multiplied by the field strength equals the flux density in vacuo. (It was in the past called the permeability of free space.)

Magnetic flux φ

The magnetic flux ϕ is the sum over an area A of the magnetic flux density and $\phi = BA$. The unit of flux is the weber (Wb).

Magnetic susceptibility κ

The magnetic susceptibility κ of a material is the ratio of the magnetisation M to the magnetic field H producing it. This quantity κ is the magnetic susceptibility per unit volume and is dimensionless.

Mass susceptibility χ

The magnetic susceptibility per unit mass or mass susceptibility χ is given by κ/ρ, where ρ is the density of the material. It has the units of $m^3\,kg^{-1}$.

Magnetic permeability μ

The permeability μ of a medium is the ratio of the magnetic flux B to the magnetic field H producing it. For practical purposes the value of μ is divided by the magnetic constant μ_0 to give the relative magnetic permeability μ_r which is dimensionless. For strongly magnetic materials the value of μ_r varies with the value of the magnetic field. The values of μ_i, the initial permeability, and μ_{max}, the maximum permeability, are widely quoted parameters for magnetic materials.

Curie point T$_c$

The Curie point, or temperature, (T_c) is the temperature below which a material is ferromagnetic or ferrimagnetic and above which it is paramagnetic.

Néel point N$_c$

The Neel point or temperature is the temperature below which a material is antiferromagnetic and above which it is paramagnetic.

Magnetic hysteresis

This is a phenomenon by which the magnetisation of a material depends not only on the magnetising field but also on the previous magnetic history. The magnetic flux B always lags behind magnetic field H in a material showing hysteresis. The complete B–H curve, or loop, produced by increasing H from zero to a maximum value, reducing to zero and then repeating with H in the negative sense is termed the hysteresis loop, and the dissipation of energy associated with it, the hysteresis loss. The hysteresis loss per unit volume is given by (area of the loop in $B \times H$) joules.

Remanence B$_r$

This is the value of the magnetic flux density remaining in a material in a closed magnetic circuit following magnetisation to saturation and subsequent removal of the magnetic field.

Coercivity H$_c$

This is the magnetic field strength when a material is brought from saturation to the point where the flux density B or magnetisation M is reduced to zero. In a graphical representation it is the value corresponding to the intersection of the B curve or the M with the H axis. Two cases must be distinguished. When the value of B is reduced to zero the coercivity is called H_{cB} and when the value of M (or J) is reduced to zero the value is called H_{cM} (or H_{cJ}). The quantity H_{cJ} is sometimes called H_{ci}.

Energy Product and (BH)$_{max}$

The energy product is the product of the flux density and the field strength at any point of a demagnetisation curve for a permanent magnet. The maximum value of the product is called $(BH)_{max}$. It is directly related to the stored energy per unit volume of the material. The units of $(BH)_{max}$ are joules/(metre)^3.

Magnetostriction

Elastic deformation which accompanies a change in the magnetisation of a material. This results in changes of length or volume.

Magnetic units and conversion factors

Authors and publishers of current literature on magnetism and magnetic materials have been very slow in adopting SI (systeme international) units in place of the centimetre gram second (c.g.s.) electromagnetic units previously used. Conversion of magnetic units between the two systems are therefore frequently required, as well as care in using equations which are different for the two systems. The relation between the relevant c.g.s. electromagnetic units and the SI (rationalised m.k.s.) units is given in Table 20.16.

Table 20.16   RELATION BETWEEN SI UNITS AND .C.G.S. UNITS OF MAGNETIC QUANTITIES

Quantity	*c.g.s. unit*	*SI unit*	*Conversion factor**
Magnetic field H	Oersted (Oe)	amperes per metre ($A\,m^{-1}$)	$\times 10^3/4\pi$
Magnetic flux ϕ	Maxwell (or line)	Weber (Wb)	$\times 10^{-8}$
Flux density B	Gauss (Gs)	Tesla (T)	$\times 10^{-4}$
Magnetomotive force	Oersted cm or Gilbert	amperes	$\times 10/4\pi$
Polarisation	*I or J* e.m.u.	*J* Tesla (T)	$\times 4\pi \cdot 10^{-4}$
Magnetisation	*I or J* e.m.u.	*M* amperes per metre	$\times 10^3$
Maximum energy product $(BH)_{max}$	M Gs Oe	$J\,m^{-3}$ or $T\,A\,m^{-1}$	$\times 10^5/4\pi$
Magnetic moment m	e.m.u.	Weber metre (Wb m)	$\times 4\pi 10^{-10}$
Magnetic constant μ_0	1	Henry m^{-1} ($H\,m^{-1}$)	$\times 4\pi 10^{-7}$
Resistivity ρ	ohm $\cdot$ cm	ohm $\cdot$ m	$\times 10^{-2}$

*The number by which the quantity in c.g.s. units must be multiplied to obtain the quantity in SI units.

Standards

38. A series of International (IEC) and equivalent British Standards (BS) have been published for the Classification, Specification and Methods of Test for Magnetic Materials. The IEC series are numbered 404 and the equivalent BS series are 6404. In addition BS 4727, part I Group 07, 1991 is the standard for 'Magnetism terminology' and BS 5884, 1987. Methods for determination of relative magnetic permeability of feebly magnetic materials.

21   Mechanical testing

21.1   Hardness testing

Hardness tests are a quick and simple method to characterise a metal's resistance to deformation and can in some cases be related to an equivalent yield strength. A number of different hardness tests exist, which differ in the type of indenter used, the load applied, and the means used to quantify the extent of permanent deformation. Further information concerning the hardness of metals and hardness testing may be found in Refs [1–3]. Hardness values for some common metals and alloys are given in Chapter 22.

21.1.1   Brinell hardness

Relevant standards: ASTM E10-01, BS EN 10003-1:1996
An indenter comprising a hardened steel ball of diameter D mounted in a suitable holder is pushed into the material under test by a force F. The diameter of the indentation left in the surface of the material after removal of the load is measured in two directions at right angles. The area of the curved surface of the indentation is calculated from the mean diameter, d, the indentation being considered as a segment of a sphere of diameter D. The Brinell hardness is the quotient obtained by dividing the load, symbol f, expressed in kilograms-force, by the surface area of the indentation expressed in square millimetres.

Symbols:

F = force (N)
f = load symbol (kgf)
D = diameter of ball in millimetres (mm)
d = mean diameter of indentation in millimetres (mm)

$$\mathrm{HBW} = \mathrm{Brinell\ Hardness} = \frac{0.102 \times 2F}{\pi D[D - \sqrt{D^2 - d^2}]} = \frac{2f}{\pi D[D - \sqrt{D^2 - d^2}]}$$

$$h = \mathrm{depth\ of\ indentation\ in\ millimetres} = \frac{f}{\pi D(\mathrm{HBW})}\ (\mathrm{mm})$$

The symbol HBW is supplemented by numbers indicating the diameter of the ball used and the load applied. Thus 226 HBW 10/3 000 indicates that a Brinell hardness of 226 was obtained by using a 10 mm diameter ball with a load symbol of 3 000 kgf. If the time of duration of load differs from the standard 10–15 sec, a further number is added to show the duration of the load in seconds.

RELATION OF LOAD TO BALL DIAMETER

The choice of force and ball diameter to be used in a Brinell test is determined by two factors:

1. the value of the ratio f/D^2, and
2. the size of the indentation which provides optimum accuracy.

The same value of f/D^2 will, in principle, give the same hardness value for different loads and the load used in practice depends on the nature and the hardness of the material under test. Five standard values of f/D^2, i.e. 30, 10, 5, 2.5 and 1, have been adopted. Recommended combinations of load and diameter for different materials are given in BS EN 10003-1:1996.

21.1.2   Rockwell hardness

Relevant standards: ASTM E18-00, BS EN ISO 6508-1:1999
An indenter of the standard type comprising a diamond cone or hardened steel ball mounted rigidly in a suitable holder, is forced into the test piece under a preliminary load F_0. When equilibrium has been reached, an indicating device which follows the movement of the indenter and so responds to changes in depth of penetration of the indenter is set to a datum position.

While the preliminary load is still applied, it is augmented by an additional load with resulting increase in penetration of the indenter. When equilibrium has again been reached, the additional load is removed but the preliminary load is maintained.

Removal of the additional load allows a partial recovery, so reducing the depth of penetration. The permanent increase in depth of penetration, e, resulting from application and removal of the additional load is used to deduce the Rockwell hardness number by means of the equation:

$$HR = E - e$$

where:

HR = Rockwell hardness number
E = a constant depending on the form of indenter:
    100 units when a diamond cone indenter is used
    130 units when a steel ball indenter is used

A variety of indenters and loads are used to give several scales of hardness, e.g. 60 HRC represents a Rockwell hardness of 60 on scale C. The various scales are defined in Table 21.1.

Table 21.1   ROCKWELL HARDNESS SCALES

Scale symbol		Total test force		Dial figures	Typical applications of scales
		kN	kgf		
B	$\frac{1}{16}$ in (1.588 mm) ball	0.98	100	Red	Copper alloys, soft steels, aluminium alloys, malleable iron, etc.
C	Diamond	1.47	150	Black	Steel, hard cast irons, pearlitic malleable iron, titanium, deep case hardened steel and other materials harder than HRB100
A	Diamond	0.59	60	Black	Cemented carbides, thin steel, and shallow case-hardened steel
D	Diamond	0.98	100	Black	Thin steel and medium case hardened steel, and pearlitic malleable iron
E	$\frac{1}{8}$ in (3.175 mm) ball	0.98	100	Red	Cast iron, aluminium and magnesium alloys, bearing metals
F	$\frac{1}{16}$ in (1.588 mm) ball	0.59	60	Red	Annealed copper alloys, thin soft sheet metals

Notes: (1) The preliminary load is 10 kgf for all scales.
      (2) The diamond indenter is conical with an included angle of $120 \pm 0.1°$ with a tip rounded to a radius of 0.20 mm.
      (3) ASTM E18-00 standard gives values in kgf. Newton values are conversions.

21.1.3   Rockwell superficial hardness

Relevant standards: ASTM E18-00, BS EN ISO 6508-1:1999
This test is similar in principle to the Rockwell test, but in order to keep the depth of impression small the minor load is restricted to 3 kg. It is used for thin specimens and for nitrided steels, etc. The following scales are used.

Table 21.2   ROCKWELL SUPERFICIAL HARDNESS SCALES

Scale	Penetrator	Preliminary Test Force		Total Test Force	
		kgf	N	kgf	kN
15-N	Diamond cone	3	29.4	15	0.14
30-N	Diamond cone	3	29.4	30	0.29
45-N	Diamond cone	3	29.4	45	0.44
15-T	$\frac{1}{16}$ in (1.588 mm) steel ball	3	29.4	15	0.14
30-T	$\frac{1}{16}$ in (1.588 mm) steel ball	3	29.4	30	0.29
45-T	$\frac{1}{16}$ in (1.588 mm) steel ball	3	29.4	45	0.44

21.1.4   Vickers hardness test

Relevant standards: BS EN ISO 6507-1:1998, ASTM E92-82 (1997)
A diamond indenter, in the form of a right pyramid with a square base and an angle of 136° between opposite faces, is forced into the material under a load F. The two diagonals, d_1 and d_2 of the indentation left in the surface of the material after removal of the load are measured and their arithmetic mean d calculated. The area of the sloping surface of the indentation is calculated, the indentation being considered as a right pyramid with a square base of diagonal d and vertex angle of 136°.

The Vickers hardness is the quotient obtained by dividing the load F, expressed in kilograms-force, by the sloping area of the indentation expressed in square millimetres.

Symbols:
F = load in kilograms force (kgf) where $1\,\text{kgf} = 9.806\,65\,\text{N}$
d = arithmetic mean of the two diagonals d_1 and d_2 in millimetres (mm)
HV = Vickers hardness
     = $2F \sin(136°/2)d^2$
     = $1.854F/d^2$

The loads employed vary from 1 to 100 kgf and are maintained from 10 to 15 seconds. Hardness numbers are expressed as 440 HV30 for example where a hardness of 440 is measured using a 30 kgf load.

21.1.5   Micro-indentation hardness testing

Relevant standards: ASTM E 384-99, BS EN ISO 6507-1:1997
Micro-indentation hardness testing is performed according to principles similar to the Vickers hardness test, but with considerably lower loads that produce microscopic indentations (typically 10–200 μm). Micro-indentation hardness testing, also referred to as 'microhardness' testing, is commonly used to measure hardness in very local areas, e.g. different microstructural phases or surface layers. As in the Vickers test, a diamond indenter with a specific geometry is impressed into the specimen surface with a known, calibrated force for a duration of 10–15 sec. Forces range from 1–1 000 gf. The indenter is removed from the surface and the size of the impression is measured using a microscope. Micro-indentation hardness testers are sold commercially.

Two indenter shapes are employed. The Vickers indenter is a square-based pyramid with face angles of 136°. The lengths of the two diagonals of the resulting square indent are averaged and the hardness, HV, is calculated according to:

$$HV = 1\,854.4\,P/d^2$$

where P is the applied force in gf and d is the mean diagonal length.

The Knoop indenter is a rhombic-based pyramid with included longitudinal edge angles of 172.5° and 130°; the long diagonal is approximately seven times the length of the short diagonal. The long diagonal is measured, and the hardness, HK, is calculated according to:

$$HK = 14\,229\,P/d^2$$

The narrow width of the Knoop indent makes it better suited for measuring steep hardness gradients since the indents can be more closely spaced.

Vickers hardness values are reported in the form: *value* HV_{force}, for example, $650\,HV_{100}$ corresponds to a Vickers hardness of 600 measured with a 100 gf force. The same form is used for Knoop hardness with HK instead of HV. In the European standard, force is reported in units of kgf.

When selecting the force to be used for testing, it is important to recognise that the measured hardness is not necessarily independent of test force, especially for forces less than 100 gf. Larger indents produce better accuracy due to reduced error in length measurement. The size of the indent, however, must be considerably smaller than the area of interest. In addition, the indenter must be perpendicular to the test piece, and the surface being measured must be free of deformation and damage resulting from preparation (e.g. grinding and polishing). Ref. [4] provides further information on microindentation hardness testing.

Recently, the techniques of microhardness indentation testing have been extended to smaller scales using lower loads and more precise instrumentation. This class of testing is referred to as nanohardness testing, nanoindentation testing, or instrumented indentation testing. These test techniques commonly employ a three-sided pyramidal indenter, rather than the four-sided Vickers indenter, and include the ability to measure and record the force on the indenter along with its vertical displacement. The latter feature of nanoindentation testing allows it to used to characterise a number of properties of surfaces and thin films, including elastic modulus, yield stress and strain-hardening behaviour, fracture toughness of brittle materials, and creep behaviour. Ref. [5] provides further information and references related to nanoindentation testing.

21.1.6   Hardness conversion tables

Table 21.3 only applies to steel of uniform chemical composition and uniform heat treatment, and is not recommended for non-ferrous metals or for case-hardened steels.

21.2   Tensile testing

21.2.1   Standard test pieces

Relevant standards: ASTM E 8-00 and E 8M-00, BS EN 10002-1 through -5.

The tensile test is the most commonly used mechanical test for metals. A specimen is extended under a uniaxial tensile force until separation occurs. The force required to deform the specimen is recorded as a function of extension, and from these data a number of intrinsic properties may be derived, which include: modulus of elasticity, yield and ultimate tensile strengths, ductility, and strain hardening behaviour. Further information regarding the tensile behaviour of metals and tensile testing may be found in Refs [6–9]. Tensile properties of common metals and alloys are presented in Chapter 22.

A wide variety of specimen geometries may be employed. For certain product shapes (e.g. strips and bars), a full cross-section of the product may be tested. In most cases, however, a part of the product is machined into a specimen which has a central section of reduced area and grip zones at either end. Cross-sections of the reduced area are usually circular or rectangular. In the reduced section, a gauge length is defined, from which measurements are made to determine ductility (Fig. 21.1).

In the European test standard, two types of 'proportional' test pieces are defined, regardless of the cross-section shape. For these specimens the gauge length L_0 and cross-sectional area A_0 are related by:

$$L_0 = 5.65\sqrt{A_0} \text{ and}$$
$$L_0 = 11.3\sqrt{A_0}$$

Non-proportional test pieces are also defined for various shapes.
Figure 21.1   *Tensile test specimen*
Figure 21.2   *Typical engineering stress–strain curve*   **Figure 21.3**   *Offset method for determining yield stress*
In the ASTM standard, specific dimensions are defined for the different cross-sectional shapes. The standard gage length and diameter for cylindrical specimens are 2.0 inch and 0.5 inch, respectively, while for rectangular cross-sections the gage length is 2.0 inch, the gage width 0.5 inch, and the thickness is variable. Sub-standard specimens proportionally based on the standard specimens are also defined. ASTM E 8M defines similarly sized specimens using metric units.

Several different grip end configurations are available. The specimen may be threaded, wedge-clamped, button-ended, or pin-loaded. The primary consideration for grips is that the specimen must not fail within the grip. The ability to maintain proper specimen alignment, so that the load is purely axial, is also important. Proper choice of grip arrangement is most critical for metals with limited ductility. If the specimen is machined from a product piece, the orientation of the long axis with respect to significant axes in the product (e.g. rolling direction) should be defined.

The force-extension data is gathered in a tensile test from transducers attached to the load frame and specimen. Strain-gauge based load cells built into the test frames are nearly exclusively used for force measurement. Extension is measured within the gauge length of the specimen, either mechanically (using clip-on strain gauges or linear variable differential transducers) or optically. Tensile behaviour is usually reported in terms of engineering stress and strain, which are calculated from the force and initial cross-sectional area (stress) and the extension and initial gauge length (strain). A typical stress–strain curve, shown in Fig. 21.2, shows an initial elastic region where stress and strain are linearly related, followed by non-linear plastic deformation at higher strains. Tensile behaviour may also be reported as true stress and strain, which are defined based on actual gauge length and area at a given applied force.

The strength of metal in a tensile test is quantified in terms of the yield strength and ultimate tensile strength (UTS). The yield strength reflects the stress needed to cause permanent plastic deformation; the exact value obtained from a given stress–strain curve depends on the definition used. The most common definition is the 0.2% offset strength, which is obtained from the intersection of the stress–strain curve and a line parallel to the initial elastic region but offset 0.2% in strain (Fig. 21.3). A second definition is the extension under load (EUL) which is defined as the stress needed to result in a given strain (typically 0.5%). The ultimate tensile strength is derived from the maximum load achieved in the tensile test, the highest point in the engineering stress–strain curve (see Fig. 21.2). For metals in which necking, a localised reduction in cross-section, occurs, the load on the specimen drops with continued extension beyond the UTS. The true stress in the neck does not diminish after the UTS is reached.

There are two measures of ductility assessed in a tensile test, elongation and reduction in area. Elongation is the increase in gauge length of the test piece after testing divided by the original gauge length. The increase may be manually measured by placing the two broken halves of the specimen back together and measuring the distance between gauge length marks placed on the specimen before testing, or by directly reading the extension at failure with an extensometer on the specimen. The two methods do not give equivalent results. Elongation values obtained are dependent on the initial gauge length of the specimen. This effect is particularly pronounced in materials which exhibit extensive necking. It is therefore important to report the gauge length along with tensile results.

Reduction in area is the difference between the original cross-sectional area and the smallest cross-sectional area after testing, expressed as a percentage of the original area. Reduction in area is not affected by gauge length differences, since measurements of area after testing are performed on any necked region.

The speed at which the test is conducted is an important parameter in tensile testing. Metal properties can exhibit a strong strain rate dependence, particularly at elevated temperatures. The strain rate is typically controlled through the rate of test machine cross-head displacement or the rate of stress increase, both of which can be roughly correlated with the strain rate. ASTM standard E 8 requires that the rate of stress increase be controlled to between 1.1 and 11 MPa/sec when determining the yield point. In any case, the speed of test (strain rate, stress rate, or cross-head displacement rate) should be reported with the tensile test data.

21.3   Impact testing of notched bars

Impact tests represent a simple way of measuring the toughness of a metal under rapid loading conditions and were the first fracture toughness tests devised. Despite the empirical nature of the data obtained, impact testing is still frequently used as a quality control measure and as a technique for determining the transition temperature from ductile to brittle behaviour in low-carbon steels. Further details on impact testing and the impact behaviour of metals may be found in Refs [6,10,11]. Data on impact energies for a number of common metals and alloys are presented in Chapter 22.

Table 21.8 DIMENSIONS OF IZOD IMPACT TEST PIECES—BRITISH STANDARD BS 131:PART 1:1961 (1996) AND AMERICAN STANDARD ASTM E23-01

Item	Square section		Circular section	
	Nominal dimension			
	mm	in *equivalent*	in	mm *equivalent*
Minimum overall length of test piece				
1 Notch	70[(1)]	2.75	2.8[(1)]	71
2 Notch	98	3.86	3.9	99
3 Notch	126[(2)]	4.96	5.0[(3)]	127
Width	10	0.394 ⎱		
Thickness	10	0.394 ⎰	0.45 dia.	11.48 dia.
Root radius of notch	0.25	0.010	0.010	0.25
Maximum depth below notch	8	0.315	0.32	8.1
Distance of plane of symmetry of notch from free end of test piece and from the adjacent notch	28	1.1	1.1	28
Angle of notch	45°		45°	

Notes: (1) American Standard overall length 75 mm (2.952 in).
     (2) American Standard overall length 131 mm (5.157 in).
     (3) American Standard overall length 137 mm (5.375 in).

21.3.1 Izod test

Relevant standards: ASTM E23-01, BS 131:Part 1:1961 (1996)
The test consists of measuring the energy absorbed in breaking a notched test piece by one blow from a striker carried by a pendulum. The test piece is gripped vertically with the root of the notch in the same plane as the upper face of the grips. The blow is struck on the same face as the notch and at a fixed height above it. Tests are usually performed at the ambient temperature of the test house.

TEST PIECES

The standard test pieces are either 10 mm square or 0.45 inches (11.4 mm) diameter cross-section. Complete dimensions are shown in Table 21.8. The notch profile is shown in Figure 21.2.

PRESENTATION OF RESULTS

When standard test pieces are used the following symbols are used in reporting the results of Izod tests:

    I for Izod
    S for square section
    Rs for circular cross-section with straight notch
    E.G. I120S: x ft lbf

   An energy of x ft lbf was obtained from an Izod test with a striking energy of 120 ft lbf using a square section test piece.[†]

21.3.2 Charpy test

Relevant standards: ASTM E23-01, BS EN 10045-1:1990
The test consists of measuring the energy absorbed in breaking by one blow from a pendulum a test piece notched in the middle and supported at each end.

[†] BS 131:Part 2:1972 uses SI units with 1 J ≈ 4/3 ft lbf for striking energies (1 ft lbf = 1.355 82 J).
Figure 21.4   *Standard notch profiles for impact test pieces—see Tables 21.8 and 21.9*

Table 21.9   DIMENSIONS OF CHARPY IMPACT TEST PIECES—BRITISH STANDARDS BS EN 10045-1:1990; AMERICAN STANDARD ASTM E23-01

Item	Nominal dimension	
	mm	in *equivalent*
Length	55	2.165
Width standard test piece	10	0.394
subsidiary test piece[1]	7.5	0.295
subsidiary test piece	5.0	0.197
subsidiary test piece	2.5	0.098
Thickness	10	0.394
Root radius of V notch	0.25	0.010
Depth below V notch	8	0.315
Root radius of U notch	1	0.039
Depth below U notch	8 (2 mm notch)[2,3]	0.315
	7 (3 mm notch)[2,3]	0.276
	5 (5 mm notch)	0.197
Distance of notch from one end of test piece	27.5	1.083
Angle between plane of symmetry of notch and longitudinal axis of test piece	90°	
Angle of V notch	45°	

Notes: (1) Additional subsidiary test pieces are permitted by ASTM E23-01 as follows: 5 mm thick with 4 mm depth below the notch and 5, 10 or 20 mm width and 3 mm thick with 0.094 in (2.39 mm) depth below notch and 10 mm width.
    (2) Not specified in ASTM E23-01.
    (3) The 2, 3 and 5 mm notches are sometimes referred to as 'Mesnager', 'DVM' and 'Charpy', respectively.

TEST PIECES

The standard test piece has a 10 mm square cross-section with one of the three notch profiles shown in Figure 21.4. The test piece dimensions are shown in Table 21.9. Sub-standard test pieces are used where material thicknesses do not permit full-size specimens. It should be noted that the values obtained from subsidiary specimens cannot be compared with full-size specimens nor can the values obtained from different notches be compared. The current EN standard only includes the V- and U-notch profiles.
Figure 21.5   *Single-notch bend specimen*
Figure 21.6   *Compact tension specimen*

PRESENTATION OF RESULTS

The report of the tests should include the following information:
Type of test: Charpy V or U notch; striking energy of the machine; size of test piece if sub-standard.
Nominal depth of notch and form ('U' or 'keyhole').
The energy absorbed (J) and the test temperature:

> e.g. C160V : x J at y °C

An energy of x J was recorded from a Charpy V notch specimen tested at y °C with a striking energy of 160 J:

> e.g. C320U2 : x J at y °C

In this case the specimen was a Charpy with a U notch 2 mm deep and the striking energy was 320 J.
Note: The above reporting form is used for the BS EN 10045-1 standard; there is no specified reporting form in ASTM E23-01.

21.4   Fracture toughness testing

Fracture toughness tests provide quantification of a material's resistance to crack extension using the principles of fracture mechanics in both linear-elastic and elastic–plastic forms. Tests are performed on specimens containing sharp, pre-existing defects formed by fatigue loading and are typically conducted at relatively slow loading rates (in contrast to impact tests, section 21.3). Information obtained in fracture toughness tests is used to determine the load-bearing capacity of materials and structures with defects. The following sections present information on common standardised fracture toughness tests for metals. Further information on fracture toughness testing is presented in Ref. [12]; the applicable standards must be conducted for complete test requirements.

21.4.1   Linear-elastic (K_{Ic})

Relevant standards: ASTM E 399-90, BS EN ISO 12737:1996
Linear elastic fracture toughness tests are used to measure resistance to crack extension for metals which are relatively strong and have relatively low toughness. For this case, the region of plastic deformation associated with the crack is small relative to the dimensions of the crack and the test specimen, and linear elastic fracture mechanics (LEFM) principles may be applied. In LEFM, the local stress field ahead of the tip of a sharp crack is characterised by the stress intensity parameter, K, which is dependent on the crack length, geometry, and applied load. The standard test measures K_{Ic}, the critical value of K for unstable crack propagation in an opening mode (mode I) with high constraint (plane-strain conditions). K_{Ic} is considered an intrinsic material property, and is believed to represent the lower limiting value of fracture toughness. For details on fracture mechanics and the applicability and use of K_{Ic}, consult Refs [13,14]. A limited amount of fracture toughness data is presented in Chapter 22.

Two specimen geometries are commonly used in fracture toughness testing, the single edge-notched bend and the compact tension specimens. These specimen names are abbreviated in ASTM standards as SE(B) and C(T), respectively; schematic diagrams of the two specimens are shown in Figs. 21.5 and 21.6. ASTM E 399 also defines three other specimen geometries with arc shapes
Figure 21.7 *Yield strength versus fracture toughness data for several alloy systems at 20° C. The upper scale of the diagram indicates the minimum thickness requirement for a given strength and toughness by projection of the line joining the origin and data point. (Source: Fulmer Materials Optimiser, Fulmer Laboratories Ltd, UK)*

Table 21.10 RECOMMENDED THICKNESS AND CRACK LENGTH FOR FRACTURE TOUGHNESS TEST PIECES

σ_Y/E	*Minimum recommended thickness and crack length*	
	mm	in
up to 0.005 0	100	4.0
0.005 0–0.005 7	75	3.0
0.005 7–0.006 2	63	2.5
0.006 2–0.006 5	50	2.0
0.006 5–0.007 1	38	1.5
0.007 1–0.008 0	25	1.0
0.008 0–0.009 5	13	0.5
0.009 5 or greater	6.5	0.25

that are less commonly used. All specimen types incorporate a sharp machined notch from which a fatigue crack may be grown. The SE(B) specimen requires more material for a given thickness than the C(T) specimen, but is simpler to machine.

The size of the specimen used is an important consideration, since certain size requirements must be met for the K_{Ic} test to be valid. The key dimensions of both specimen types are the thickness, B, and crack length, a (these are nominally equal). In order for a test to be valid, both must be larger than $2.5[(K_{Ic})/(\sigma_Y)]^2$, where σ_Y is the 0.2% yield stress for the material under the conditions of test, e.g. orientation, temperature, and loading rate. This requirement insures that the plastic zone ahead of the crack tip is sufficiently small with respect to these dimensions. Hence an initial measurement of σ_Y and an estimate of K_{Ic} must be made prior to selecting specimen size. Figure 21.7 can be used as a graphic guide to selection of thickness. In the absence of this information, the ratio of yield strength to elastic modulus may also be used to estimate specimen thickness (Table 21.10).

Prior to the actual fracture toughness test, a fatigue precrack must be grown from the starter notch. The standards define requirements for the length of fatigue crack which must be grown and the load

levels used. The objective of fatigue precracking is to obtain a microscopically sharp crack with an insignificant region of plastic deformation ahead of the crack tip.

The test itself involves monotonically increasing the specimen load until fracture occurs. The load and displacement are recorded and used to generate a plot of load versus displacement. Displacement is measured at the crack mouth using a clip gauge. After the test, the load-displacement record is analyzed to determine P_Q, a load from which K_Q is computed. K_Q serves as a provisional value of K_{Ic} until the validity requirements have been demonstrated. A secant line through the origin is drawn with a slope 5% less than the original linear region of the load-displacement curve. The load P_Q is defined as the intersection of the secant line with the load-displacement curve, or any higher recorded value prior to the intersection. K_Q is computed using the equation:

$$K_Q = P \, f(a/W)/B\sqrt{W}$$

Expressions for $f(a/W)$ for the different specimen geometries are given in the standards. The crack length a is measured on the broken halves of the specimen at the end of the fatigue precrack.

A number of validity requirements must be met before the provisional K_Q may be accepted as K_{Ic}. In addition to the size requirements above (in which K_Q is substituted for K_{Ic}), the maximum load in the test must not exceed P_Q by more than 10%. This requirement limits the amount of stable crack extension. There are other requirements relating to the shape of the crack front and precracking load levels. The standards should be consulted for complete details.

21.4.2   K–R curve

Relevant standard: ASTM E 561-98
The K–R curve test provides a characterisation of fracture resistance for materials and specimen geometries in which stable, ductile crack extension occurs under elastic conditions. In the test, a plot of K, the stress intensity factor needed to drive the crack, as a function of crack extension, Δa, is developed, which is referred to as the R curve. An example R-curve is shown in Fig. 21.8. Once established, the R curve may be used to determine a value of K_c, the plane-stress fracture toughness, for various crack lengths and specimen geometries. The K–R test is frequently used to measure the fracture toughness of sheet materials, for which the thickness requirements (which ensure plane-strain conditions) of the K_{Ic} test (Section 21.4.1 above) may not be met. It is important to note that
Figure 21.8   *Typical K–R curve*
Figure 21.9   *Middle-cracked tension specimen*

results obtained in K–R curve testing are dependent on specimen thickness—therefore all results are given for a specified thickness.

The test involves loading a notched specimen with a fatigue precrack in tension to cause stable crack growth. The load is plotted as a function of crack mouth displacement. The effective crack length (accounting for plasticity ahead of the crack tip) is determined either by physical measurement or from the load-displacement record. The load and effective crack length are used to calculate K for a series of increasing effective crack lengths, which are then plotted as a function of crack extension (total effective crack length minus initial crack length). Specimens with the compact tension C(T) or middle cracked tension M(T) geometries may be used with this technique. The M(T) geometry is used for sheet materials—a schematic diagram is shown in Fig. 21.9.

An alternative technique for K–R curve determination allowed in the standard is the use of a crack-line-wedge-loaded compact specimen C(W). The geometry is similar to the C(T) specimen, except that the loading is applied via a wedge driven into the crack mouth, resulting in displacement-controlled loading. This loading technique is useful for lower-toughness materials. Full details on the use of this specimen may be found in the standard.

Data obtained in R-curve testing under this standard must be principally in the elastic loading regime. This requirement is expressed for the C(T) and C(W) specimens as:

$$b = (W - a) \geq (4/\pi)/(K_{max} \sigma Y)^2$$

where b is the uncracked ligament and K_{max} is the maximum level of K reached in the test. For the M(T) specimen the net section stress based on the uncracked ligament must be less than the yield stress.

21.4.3 Elastic-Plastic (J_{Ic}, CTOD)

Relevant standards: ASTM E 1820-01, BS 7448-1:1991, BS 7448-4:1997

For low strength, high-toughness materials (such as low-carbon steels) the requirements of LEFM (K_{Ic}) testing are not easily satisfied as extensive ductile crack extension with associated plasticity occurs prior to failure. To quantify the toughness behaviour in this regime, elastic-plastic fracture mechanics tests have been developed. Several separate tests which use similar specimen geometries and techniques exist. These tests have been recently consolidated by the ASTM (along with K_{Ic} testing) into a single test standard, E 1820-01. Two British Standards covering the same test procedures exist. The tests provide different measures of the conditions for initiation of stable crack extension (similar to K_{Ic}) and the resistance to further crack extension (R-curve behaviour). Details of the tests are found in the standards and Ref. [12].

The two parameters used in elastic-plastic fracture toughness testing are the J integral and the crack tip opening displacement (CTOD or δ). The J integral is a non-linear measure of the driving force available to extend a crack,[14] and is analogous to G, the strain energy release rate in the linear regime. The J integral is useful because it can be accurately calculated from experimental data or using numerical methods. The CTOD is the opening at the position of the original crack tip, a parameter that is believed to characterise the fracture process.[13] The CTOD is calculated from the measured displacement at the crack mouth (CMOD), which is simple to measure experimentally. Due to simplicity, the CTOD was the first parameter used to measure the fracture behaviour of materials beyond the LEFM regime. Its use, however, has to a large extent been superseded by the J integral, because of the assumptions which must be made in calculation of CTOD from CMOD.

Two specimen geometries are allowed in the standards—the C(T) and SE(B) specimens, both essentially identical to the geometries used for K_{Ic} testing. The notch of the C(T) specimen is widened for J-integral testing to allow for displacement measurements to be made along the load line. In addition, specimens used in J-integral testing may incorporate side grooves to keep the crack in its original plane. All specimens are tested after creation of a sharp precrack using fatigue loading, as is performed in K_{Ic} testing.

The basic test procedure for both J-integral and CTOD tests involves loading the precracked specimen while monitoring the CMOD and/or load-line displacement until unstable fracture occurs or a desired displacement level is reached. Depending on the behaviour of the material and the information desired, a number of different fracture parameters may be obtained. The exact test and analysis procedures are complex, and the applicable standards must be consulted for details.

The fracture toughness parameters measured in J-integral or CTOD testing are useful for comparing the behaviour of different materials or as a quality control measure, and may also serve as a basis for defect tolerance assessment of structural materials. However, particular caution must be used when applying data obtained with laboratory test specimens to actual service conditions.

21.5   Fatigue testing

Fatigue tests measure the resistance of a material to failure by application of cyclic stresses. A very broad range of stresses and number of cycles to failure are encountered, from less than 100 cycles for stresses well in excess of the yield strength, to millions of cycles for low, elastic stresses. Historical tests have used specimens with smooth surfaces or relatively blunt notches in which the number of cycles to initiate and propagate a crack resulting in failure were measured. With the advent of fracture mechanics and damage-tolerant design principles, tests to measure sub-critical crack propagation rates under cyclic loading were developed and are commonly used today.

This section presents basic information concerning fatigue tests which have been standardised, describing properties measured, specimen and machine requirements, basic test procedures, and important considerations in testing. The reader should always refer to the relevant test standard for complete details. For further information concerning the fatigue behaviour of metals, consults Refs [15–17]. Fatigue data for a number of common metals and alloys are presented in Chapter 22.

21.5.1   Load-controlled smooth specimen tests

Relevant standards: ASTM E 466-96, BS 3518-12:1962 (1997), BS 3518-3:1963 (1997)
Load-controlled fatigue tests are typically performed at stresses in the elastic range, resulting in relatively long fatigue lives (greater than 10^5 cycles to failure). The specimen surfaces are polished smooth or contain machined notches. Each fatigue test measures the number of cycles to failure at a single stress level; failure is nearly always defined as complete specimen separation. Several fatigue tests at different stress levels are required to define the fatigue behaviour in terms of a S-N curve, a plot of cycles to failure (x-axis) versus stress range (y-axis). The curve defines stress levels below which failure in a given number of cycles will not occur. The S-N curve may be used to derive a 'fatigue strength', or stress level below which failure does not occur in a very high number of cycles, usually 10^7 or 10^8.

Load-controlled fatigue tests are typically performed at cyclic frequencies greater than 10 Hz and sometimes as high as 1000 Hz to achieve failure in reasonable times. Loading may be either in simple tension or rotating bending. A number of different machine designs are commercially available, including servo-hydraulic and electromechanical. Rotating-bend tests are favoured for high frequencies, since these are easily achieved and the test machine is relatively simple and inexpensive, allowing a number of machines to be obtained and used simultaneously. Very high frequency tests ($\sim 10^4$ Hz) can be performed using ultrasonic excitation of the specimen.[18]

The applied load usually follows a sinusoidal waveform. The maximum and minimum loads in the cycle define the mean load applied, and the load ratio, R ($=P_{max}/P_{min}$). In the case of fully-reversed (equal tensile and compressive, R $= -1$) loads the mean load is zero. Most S-N curves are produced with fully-reversed loading; other types of diagrams may be constructed to account for the effect of non-zero mean loads.[17] Note that the waveform for rotating-bend tests is always sinusoidal and fully-reversed.

Dogbone-shaped specimens very similar in shape to the tensile specimens described in section 21.3 are defined in the standards. Cross-sections may be circular (necessary for rotating bend) or rectangular. The gauge sections of fatigue specimens need not be straight, but may incorporate a shallow radius as shown in Fig. 21.10. Because fatigue cracks are frequently surface-initiated, the
Figure 21.10   *Strain-controlled fatigue test specimen with continuous radius between ends*

finish of the specimen is very important. The standards define allowable machining removal rates and final polished roughness. The grip arrangement for fatigue specimens is also important, more so than in tensile tests. Threaded grip attachments are not recommended since the notches may initiate cracks.

Specimen alignment is critical in axial fatigue tests. The load must purely axial without the presence of significant bending stresses. Limits on the amount of bending stress are defined in the standards. Alignment is usually verified by loading a dummy specimen with several strain gages on the surface and comparing strain readings.

Load-controlled fatigue tests may be conducted at any desired temperature, provided that the gauge section of the specimen is uniformly heated or cooled. Several different furnace designs are available for use with fatigue testing machines, including clamshell resistance furnaces, induction furnaces, and radiative (lamp) furnaces. If the grips are heated or cooled along with the specimen they must be constructed from suitable materials. Temperature measurement of the specimen must be performed with care, so that surface defects are not introduced by the attachment of thermocouples.

The actual test procedure is simple, involving placing the specimen in the grips, applying a known cyclic force, and recording the elapsed cycles until failure occurs. A number of variables may influence the results obtained in load-controlled fatigue testing, and it is important to ensure that the conditions of test closely match those of the intended application. Variables to consider include: temperature, environment, humidity, specimen size, frequency, surface finish, and stress concentrators. Because of the statistical nature of fatigue phenomena, several specimens should be tested for each condition to assess the extent of scatter. This is especially important for lower-stress, longer-life conditions.

21.5.2 Strain-controlled smooth specimen tests

Relevant standards: ASTM E 606-92, BS 7270:1990
Tests in the so-called low cycle fatigue (LCF) regime usually involve significant plastic deformation of the specimen and are conducted with axial loading in strain control using servohydraulic testing machines. The use of strain as the test parameter is accomplished using extensometers attached to the specimen for feedback control of the test machine. Details on extensometry and testing machines used for LCF testing may be found in Refs [19–21]. The tests are otherwise similar to load-controlled tests, in that each specimen gives a single data point of cycles to failure at the applied strain range. Failure is not always defined as complete specimen separation, however, but may also be a specified drop in maximum load, observation of crack initiation, or a change in modulus ratio. Plots of cycles to failure as a function of applied strain range are constructed.

In addition to the number of cycles to failure, the cyclic stress–strain behaviour of the specimen may also be reported. This takes the form of hysteresis loops, plots of stress versus strain for a single fatigue cycle (Fig. 21.11). Changes in the hysteresis loop from the beginning to end of the test indicates whether material hardens or softens under cyclic loading. Instead of full hysteresis loops, the maximum and minimum loads may also be recorded. The load range at 50% of the cycles to failure is commonly reported.

LCF tests are typically performed at relatively low frequencies, less than 1 Hz, and at elevated temperatures. Strain waveforms are usually triangular rather than sinusoidal, so that loading is accomplished at a constant strain rate. Strain-rate effects are important at elevated temperatures due to the addition of creep as a deformation mechanism. Straining in LCF tests is nearly always fully-reversed, with equal tensile and compressive strains. The loads needed to impose these strains may not be equal. Smooth specimen LCF tests may be used to measure creep-fatigue behaviour, in which hold periods of constant strain are imposed in which creep occurs. Details of creep-fatigue testing may be found in Refs [20,21].

Specimens used in LCF testing must be designed in conjunction with the test machine gripping arrangements to ensure that the load profile in the transition from tension to compression is continuous. The grip ends must be securely clamped. As with load-controlled tests, surface finish is important, although it may be less so if significant specimen oxidation occurs at elevated temperatures during testing. Alignment of the specimen is again critical.

21.5.3 Fatigue crack growth testing

Relevant standards: ASTM E 647-00, BS 6835-1:1998
Fatigue crack growth testing measures rate of advance of a fatigue crack in terms of the applied driving force for growth using Linear Elastic Fracture Mechanics (LEFM) principles.[13–15] The range
Figure 21.11   *Typical hysteresis loop obtained in strain-controlled low-cycle fatigue testing*
Figure 21.12   *General plot of crack growth rate versus stress intensity range showing three regimes of crack growth*

of stress intensity factor in the loading cycle (ΔK), is used as the driving force parameter. As described in Section 21.4, K is proportional to the applied load, the square root of the crack length, and a geometric factor. ΔK is simply the difference between the maximum and minimum K in each load cycle, and hence is proportional to the applied load range. The rate of crack growth, da/dN, where a is the crack length and N is the cycle number, is measured over a range of ΔK and a plot constructed. A generic plot of da/dN versus ΔK typical of metals is shown in Fig. 21.12. There are three characteristic regimes, the near-threshold region at low ΔK, the Paris regime where the logarithm of da/dN is linearly dependent on ΔK, and the stage III regime of high crack growth

rates near failure. A threshold value of ΔK below which crack growth does not occur is commonly observed for metals. Further information on the fatigue crack growth behaviour of metals can be found in Ref. [15].

The fatigue test standards describe specimen, test machine, and reporting requirements for measurement of fatigue crack growth rates above 10^{-8} m/cycle. In the ASTM standard, procedures for measurement of fatigue threshold values are also given.

The specimens used in fatigue crack growth testing are identical to those used in other fracture mechanics tests (see section 21.4). In the ASTM standard three specimen types are defined: the compact tension, the single-edge bend, and the center-cracked tension. Similar specimen geometries are defined in the British standard. The specimens contain machined, sharp notches from which fatigue cracks are grown. Prior to the acquisition of valid crack growth rates, the specimens must be precracked to beyond the region of disturbed material at the notch root. Limits are set on the ΔK which may be used for precracking. Standard servo-hydraulic testing machines are used for crack growth testing, frequently equipped with computerised control and data acquisition systems to enable automated testing.

A critical aspect of fatigue crack growth testing is precise measurement of crack length. Three techniques are commonly used for crack length measurement: optical, compliance, and potential drop. In the optical technique the crack is measured at intervals using a travelling microscope. Strobe lighting may be used to allow easy observation of the crack while cycling. This is a historical technique not frequently used today due to the labour involved and lack of very fine resolution needed for threshold measurements. It is simple, however, and does not require computerised equipment.

The optical technique has been largely supplanted by compliance and potential drop techniques. In the compliance technique, the compliance of the specimen is computed from the crack-mouth opening displacement (measured with a clip-gauge mounted to the crack mouth) and the applied load. A calibrated curve of compliance as a function of crack length for the particular specimen geometry is used to derive crack length. In the potential drop method, a large DC current is passed through the specimen, and the potential generated across the crack mouth is measured. The potential drop increases with crack length, which can be quantified, again through a calibration curve. These techniques have the advantage of providing an accurate, essentially continuous measurement of crack length and are highly suited to automated control of the fatigue test. In fact, the complex nature of crack length derivations make automated, computerised measurement essentially a necessity.

Fatigue crack growth data in the higher growth rate regime (greater than 10^{-8} m/cycle) may be simply acquired by growing the crack at a constant load range expected to result in an initial growth rate near 10^{-8} m/cycle. ΔK increases as the crack grows, allowing a wide range of data to be obtained. Fatigue crack growth rates are calculated from the applied load range and crack length versus cycle number data using incremental polynomial or secant techniques.

To obtain near-threshold crack growth rate data (below 10^{-8} m/cycle), ΔK is decreased as the crack grows, a procedure referred to as 'load-shedding.' Proper load-shedding is complex because of three factors: ΔK depends on the crack length; the crack must be grown through the plastic zone of the previous ΔK level before the next reduction; and the threshold level must be reached before the crack has grown through the specimen. These considerations are accounted for in ASTM E 647-00; computerised, automated testing capability is again essential.

The frequencies used in fatigue crack growth testing are typically greater than 10 Hz to allow testing in reasonable timeframes. Fatigue crack growth rates may be a function of several material, environment, and test variables, depending on the metal and the regime of crack growth measured. A few examples include grain size, orientation, humidity, and load range. Requirements for analysing crack growth data and full reporting of fatigue results are given in the relevant standards. Fatigue crack growth testing may be performed at elevated temperatures or specific environments. Compliance and potential drop crack measurement techniques are especially amenable to testing in these situations.

21.6   Creep testing

Relevant standards: ASTM E 139-00, BS EN 10291:2000

Creep is defined as the time-dependent elongation of a metal which occurs at static stresses less than the nominal yield strength. For most metals creep only occurs at temperatures exceeding half of the absolute melting point. Creep testing measures the rate of specimen elongation as a function of applied stress, temperature, and test time. A number of tests must be conducted to fully characterise the behaviour of a given material. Details on the creep behaviour of metals may be found in Refs [22–24], and creep properties of common metals and alloys are presented in Chapter 22.

There are three types of creep tests: creep, creep-rupture, and stress-rupture tests. In a creep test, testing is only performed as long as necessary to obtain the minimum creep rate at the specified stress and temperature; the test is not performed to failure. Creep-rupture refers to a creep test conducted to failure. Creep rates are not measured in stress-rupture testing, only the time to failure under creep loading conditions. All three tests use similar specimens and load frames.

The specimens used for creep testing are essentially identical to those used in simple tensile tests (see Fig. 21.1), although creep specimens may have grooved attachment points on the shoulders of the specimen and longer gauge lengths to permit more accurate strain measurement. Creep testing may also be performed in compression; in this case the specimens may be either cylindrical or parallelepipeds with aspect ratios between 2 and 4.

Creep test frames are simple in design, with a static load applied with weights through a typically 20:1 lever arm. Clamshell-type resistance furnaces are used for heating. Due to the common use of high temperatures (frequently greater than 800°C), extensometers for creep testing are designed to translate the specimen extension out of the hot zone, where measurement is made using standard LVDT transducers. Pull rods, gripping devices, and extensometers must be constructed from suitable high-temperature materials. Due to the long test durations and the necessity to perform several tests to cover a range of stresses and temperatures, a creep testing laboratory usually includes a large number of frames, often with a central data collection system.

The test standards define specimen, load verification, and data reporting requirements for all types of creep tests. As with other axially-loaded mechanical tests, specimen alignment is critical and must be verified to demonstrate that bending stresses are negligible. An important additional parameter to consider in creep testing is the environment, which may have a strong influence at the high test temperatures commonly encountered. Specially designed retort systems are commercially available to enable testing in either inert or vacuum environments.

21.7   Non-destructive testing and evaluation

Non-destructive testing and evaluation (NDT, NDE) techniques permit examination of metal parts or samples without alteration or destruction. NDE encompasses all phases of the production, use, and eventual rejection of components and structures. The initial scope of NDT was the detection of damage in the form of flaws, cracks, inclusions, etc. Since the primary concern has been detection of the smallest possible flaw, sensitivity and probability of detection are important aspects of NDT technology. For materials which have many flaws, however, detecting an individual flaw is immaterial and the overall effect of the flaws on the residual strength of the structure is of greater importance. NDE has been more recently used for process control in manufacturing; a complex application since the inspection equipment must be compatible with process conditions, production equipment, and environment.

Another aspect of NDE, generally not considered, is the integration of NDE into the engineering design process.[25] Despite advances in NDE, it is still primarily used as an after-the-fact testing tool. There are numerous examples where neglecting NDE during the design stage has made its eventual use more costly. Components to be examined are either difficult to access or the available NDE tools are inadequate to perform an exhaustive evaluation. NDE must be an integral part of design to overcome these drawbacks. Various NDT & E techniques and their detection capabilities are listed in Table 21.11.

Table 21.11   BASIC NDT & E TECHNIQUES AND THEIR DETECTION CAPABILITIES

ND technique	Detection capability
Ultrasonic	Cracks, voids, inclusions, corrosion, anisotropy, thickness, elastic constants, grain size, porosity, crack propagation
Radiography	Cracks, voids, density variations, inclusions
Electromagnetic	Cracks, voids, alloy contents, inclusions, corrosion, anisotropy, electrical and thermal conductivity, thickness, heat treatment
Acoustic emission	Cracks, inclusions, plastic zone formation, damage propagation monitoring, leak detection
Thermal	Cracks, inclusions, voids, grain size, porosity, thermal conductivity, composition
Microwave	Thickness measurements, cracks, distributed inhomogeneity

21.7.1 Ultrasonic

Ultrasound is defined as acoustic waves with frequencies above the range of human hearing (>18 MHz). Wave velocity and attenuation are the two parameters measured in ultrasonic examination. Material discontinuities (e.g. voids, cracks, or inclusions) separate an impinging ultrasonic wave into three components: transmitted, reflected, and scattered. Each of these signals carries information about the material, such as stiffness, density, flaw location, and size[26]. An accurate measurement of the time of flight of the wave provides the exact location of the flaw. The reflected intensity is proportionate to the size of the flaw, therefore, measurement of the reflected signal amplitude and its spread effectively estimate the size of the flaw. Basic ultrasonic configurations are shown in Fig. 21.13.

The following relate the wave velocity of the sound to the stiffness E and Poisson's ratio ν of the material:

$$E = \frac{\rho c_L^2 (3c_L^2 - 4c_s^2)}{c_L^2 - c_s^2} \quad \text{and} \quad \nu = \frac{c_L^2 - 2c_s^2}{2(c_L^2 - c_s^2)}$$

where ρ is the density of the medium and c_L and c_S are the longitudinal and shear wave velocities in the medium, respectively. E and ν can be calculated if the two wave velocities are measured accurately.[27,28] Since time, distance, and velocity are related, in a simple experiment at least one of the variables must be known. A variation of this technique, which simultaneously gives both velocity and thickness, is reported in Refs. [29,30]. Ultrasound can also be used to investigate anisotropic materials where the velocity measurements depend on the direction of the wave propagation.[31,32] Waves travelling in the plane of a plate, called Lamb waves or plate waves, are used to measure the elastic properties in the plane of the plate.[33] The scattered acoustic signal has been used to characterise microstructural features in titanium alloys.[34]

21.7.2 Radiography

Radiography is one of the most widely used NDE techniques.[35] The transmission of radiation (x-rays, gamma-rays, or neutrons) through a material is recorded on a photographic plate. Variation in the transmission through the material (due to inhomogeneity, defects, or thickness variations) results in contrast on the film. In determining defect size, magnification in the radiograph due to perspective must be accounted for, as shown in Fig. 21.14.

The radiograph image quality is defined by three factors: contrast, clarity, and graininess. *Contrast* results from varying transmission of the radiation through the object. Higher contrast images are easier to interpret. The edge *clarity* of the imaged feature depends on its size distance from the radiation source. The edges of the feature produce a shadow relative to the finite size of the source resulting in blurred boundaries, as shown in Fig. 21.14. In the last 15 years, advances in radiographic equipment and digital data processing have enabled the detection of features to reach new thresholds. The micro-focus x-ray source with a spot size of 5 microns has resulted in a significant improvement in resolution and clarity. The *graininess* of an image is a property of the imaging film. These fine grain-like spots can decrease the ability to detect small flaws. Digital recording and processing of data and digital enhancement can overcome these problems.[36]

An x-ray simulator (XRSIM) has been recently developed that simulates the entire process of the radiography, starting with a computer model of the object. This simulation aids the operator in deciding proper inspection angles and equipment calibration. The simulation can make NDE an
Figure 21.13 *Basic ultrasonic configurations: (1) reflection, (2) transmission, (3) surface or plate, (4) acoustic microscopy*
Figure 21.14 *Image magnification and shadow effect in radiography*

integral part of component design process, allowing NDE technicians to work with model developers to ascertain that components are easy to test during service.

21.7.3   Electrical and magnetic methods

The fundamental electrical and magnetic properties of materials are electrical conductivity, electrical permittivity, and magnetic permeability. These properties can be related to other characteristics such as microstructure, strength, hardness, and the presence of flaws and inclusions.[37,38] The primary electrical and magnetic NDE testing methods are: magnetic particle, magnetic flux, and eddy current testing.

MAGNETIC PARTICLE TESTING (MT)

This method is accomplished by using a yoke or a coil to induce a magnetic field, or by passing a current through a ferromagnetic material, and then dusting the surface with iron particles (either dry or suspended in liquid). Surface imperfections (defects such as cracks) distort the field. Concentration of iron particles due to field distortion reveals the defects.

MAGNETIC FLUX METHODS

Magnetic field distortion due to defects can be quantitatively assessed with devices such as Hall probes, magnetoresistive sensors, or coils.

EDDY CURRENT METHOD

The principal advantage of the eddy current method is that it does not require surface preparation, as there is no contact between the probe and the object under study.[39] Examples of feature which may be detected and measured using the eddy current method include surface and sub-surface cracks, the thickness of metallic plates, paint thickness on metal surfaces, and corrosion extent. Eddy currents are generated by an alternating magnetic field induced in the specimen with alternating currents in a coil separate from the specimen. The orientation of the coil is determined based on the assumed defect plane to obtain maximum sensitivity of detection. Imperfections or changes in the specimen's conductive properties will interrupt the flow of eddy currents, causing changes in the induced magnetic field that can be recorded.

21.7.4   Acoustic emission testing (AE)

The use of AE testing in the study of metals encompasses detection of crack propagation, yielding and plastic deformation, corrosion, and creep. AE is also used for continuous monitoring of structures like bridges, pipelines, dams, and cables, and for detection of in-service damage or leaks. When a metal is stressed, imperfections or cracking events emit short bursts of acoustic energy–high-frequency (100–300 kHz) transient elastic waves, which may be detected using piezoelectric sensors attached to the specimen. The acoustic emission technique is very sensitive and can easily detect defects that cannot be optically resolved.[40,41] The frequency and amplitude of the acoustic waves can be used to differentiate between different types of events and defects. For example, waves emitted during plastic deformation have low frequencies compared to those emitted during cracking.[42]

21.7.5   Thermal wave imaging

This method is useful in detecting subsurface variations of thermal properties, defects such as cracks or inclusions, and spatial variation of material properties.[43–45] It involves a burst of energy in the form of a flash lamp or a laser light that is impinged on the object under study. The resulting thermal waves are recorded using an infrared lens.

22 Mechanical properties of metals and alloys

The following tables summarise the mechanical properties of important commercial metals and alloys.

The tables of tensile properties at ambient temperatures give the nominal composition of the alloys, followed by the typical specification numbers. Most specifications permit considerable latitude in both composition and properties, but the data given in these tables represent typical average values which would be expected from materials of the nominal composition, unless otherwise stated. For design purposes it is essential to consult the appropriate specifications to obtain minimum and maximum values and special conditions where these apply.

The data in the tables referring to properties at elevated and at sub-normal temperatures, and for creep, fatigue and impact strength have been obtained from a more limited number of tests and sometimes from a single study or test. In these cases the data refer to the particular specimens tested and may not reflect variations arising from sample-to-sample or testing conditions.

22.1 Mechanical properties of aluminium and aluminium alloys

The compositional specifications for wrought aluminium alloys involve a four-digit description of the alloy and is specified in the UK as BS EN 573, 1995. Registration of wrought alloys is administered by the Aluminum Association in Washington, DC. International agreement on temper designations has been achieved, and the standards agreed for the European Union, the Euro-Norms, are replacing the former British Standards. Thus BS EN 515. 1995 specifies in more detail the temper designations to be used for wrought alloys in the UK. At present, there is no Euro-Norm for cast alloys and the old temper designations are still used for cast alloys. While these designations are emphasised here, a cross-listing of some alloys with alternate designations can be found in Chapter 1 of this volume.

22.1.1 Alloy designation system for wrought aluminium

The first of the four digits in the designation indicates the alloy group according to the major alloying elements, as follows: 1XXX—aluminium of 99.0% minimum purity and higher; 2XXX—copper; 3XXX—manganese; 4XXX—silicon; 5XXX—magnesium; 6XXX—magnesium and silicon; 7XXX—zinc; 8XXX—other element, incl. lithium; 9XXX—unused; 1XXX Group—In this group the last two digits indicate the minimum aluminium percentage. Thus 1099 indicates aluminium with a minimum purity of 99.99%. The second digit indicates modifications in impurity or alloying element limits. 0 signifies unalloyed aluminium and integers 1 to 9 are allocated to specific additions; 2XXX—8XXX Groups—In these groups the last two digits are simply used to identify the different alloys in the groups and have no special significance. The second digit indicates alloy modifications, zero being allotted to the original alloy.

National variations of existing compositions are indicated by a letter after the numerical designation, allotted in alphabetical sequence, starting with A for the first national variation registered.

The specifications and properties for Cast Aluminium Alloys are tabulated in Chapter 26.

22.1.2   Temper designation system for aluminium alloys

The following tables use the internationally agreed temper designations for wrought alloys and the more frequently used ones are listed below.

A large number of variants in these tempers has been introduced by adding additional digits to the above designations. For example, the addition of the digit 5 after T1–9 signifies that a stress relieving treatment by stretching has been applied after solution heat-treatment. Some of the more common ones used in the following tables are given below.

T351	Solution heat-treated, stress-relieved by stretching a controlled amount (usually 1–3% permanent set) and then naturally aged. There is no further straightening after stretching. This applies to sheet, plate, rolled rod and bar and ring forging.
T3510	The same as T351 but applied to extruded rod, bar, shapes and tubes.
T3511	As T3510, except that minor straightening is allowed to meet tolerances.
T352	Solution heat-treated, stress-relieved by compressing (1–5% permanent set) and then naturally aged.
T651	Solution heat-treated, stress-relieved by stretching a controlled amount (usually 1–3% permanent set) and then artificially aged. There is no further straightening after stretching. This applies to sheet, plate, rolled rod and bar and ring forging.
T6510	The same as T651 but applied to extruded rod, bar, shapes and tubes.
T6511	As T6510, except that minor straightening is allowed to meet tolerances.
T73	Solution heat-treated and then artificially overaged to improve corrosion resistance.
T7651	Solution heat-treated, stress-relieved by stretching a controlled amount (Again about 1–3% permanent set) and then artificially over-aged in order to obtain a good resistance to exfoliation corrosion. There is no further straightening after stretching. This applies to sheet, plate, rolled rod and bar and to ring forging.
T76510	As T7651 but applied to extruded rod, bar, shapes and tubes.
T76511	As T7510, except that minor straightening is allowed to meet to tolerances.

Table 22.1

Designation	Meaning
F,M	As manufactured or fabricated
H111	Fully soft annealed condition

Strain-hardened alloys

H	Strain hardened non-heat-treatable material
H1x	Strain hardened only
H2x	Strain hardened only and partially annealed to achieve required temper
H3x	Strain hardened only and stabilised by low temperature heat treatment to achieve required temper
H12,H22,H32	Quarter hard, equivalent to about 20–25% cold reduction
H14,H24,H34	Half hard, equivalent to about 35% cold reduction
H16,H26,H36	Three-quarter hard, equivalent to 50–55% cold reduction
H18,H28,H38	Fully hard, equivalent to about 75% cold reduction

Heat-treatable alloys

T1	Cooled from an Elevated Temperature Shaping Process and aged naturally to a substantially stable condition
T2	Cooled from an Elevated Temperature Shaping Process, cold worked and aged naturally to a substantially stable condition
T3	Solution heat-treated, cold worked and aged naturally to a substantially stable condition
T4	Solution heat-treated and aged naturally to a substantially stable condition
T5	Cooled from an Elevated Temperature Shaping Process and then artificially aged
T6	Solution heat-treated and then artificially aged
T7	Solution heat-treated and then stabilised (over-aged)
T8	Solution heat-treated, cold worked and then artificially aged
T9	Solution heat-treated, artificially aged and then cold worked
T10	Cooled from an Elevated cTemperature Shaping Process, artificially aged and then cold worked

22.2   Mechanical properties of copper and copper alloys

A listing of related designations for copper alloys is given in Chapter 1.

Table 22.7   COPPER AND COPPER ALLOYS—TYPICAL MECHANICAL PROPERTIES AT ROOM TEMPERATURE

Condition of material is expressed in accordance with BS Nomenclature, viz:

O	Material in the annealed condition
$\frac{1}{4}$H $\frac{1}{2}$H $\frac{1}{2}$H EH	The various harder tempers produced by cold rolling. For certain of the materials in this schedule, these tempers may be produced by partial annealing
SH ESH	Spring hard tempers produced by cold rolling of thinner material
M	Material in the 'as manufactured' condition. In this schedule confined to hot rolled or extruded material
W	Material which has been solution heat treated and will respond effectively to precipitation treatment
W($\frac{1}{4}$H) W($\frac{1}{2}$H) W(H)	Material which has been solution heat treated and subsequently cold worked to various harder tempers
WP	Material which has been solution heat treated and precipitation treated
W($\frac{1}{4}$H)P W($\frac{1}{2}$H)P W(H)P	Material which has been solution heat treated, cold worked and then precipitation treated

Table 22.8   CAST COPPER—TYPICAL MECHANICAL PROPERTIES AT ROOM TEMPERATURE

Properties vary, dependent on composition, section size and foundry practice.

Material	Composition %	Condition	0.2% Proof stress N mm^{-2}	UTS N mm^{-2}	Elongation on 50 mm %	Brinell hardness
Brass for sand castings	Cu 64 Zn 34 Pb 2	Sand cast	77	232	25	45–60
Leaded gunmetal	Cu 85 Pb 5 Sn 5 Zn 5	Sand cast Continuous cast	108 124	216 254	15 20	65–75 75–95
High tensile brasses	Cu 56 Al 1.5 Fe 1.5 Mn 1.5 Zn 39.5	Sand cast Centrifugal cast	201 224	494 587	20 22	100–150 100–150
	Cu 56 Al 5 Fe 2.5 Mn 2.5 Zn 34	Sand cast Centrifugal cast	386 403	710 757	12 15	150–230 150–230
Gunmetal	Cu 88 Sn 10 Zn 2	Sand cast *Continuous cast	139 147	286 317	18 15	50–70 70–90
Leaded bronze	Cu 80 Sn 10 Pb 10	Sand cast *Continuous cast	108 170	247 293	18 20	65–85 80–90
Phosphor bronze	Cu 90 Sn 10	Sand cast *Centrifugal cast	139 185	293 370	15 16	70–100 100–150
Aluminium bronzes	Cu 87 Al 10 Fe 3	Sand cast *Centrifugal cast	201 216	541 571	25 28	90–140 120–160
	Cu 80 Al 10 Fe 5 Ni 5	Sand cast *Centrifugal cast	263 293	649 695	15 15	140–180 140–180
Aluminium silicon bronze	Cu 95.5 Al 6 Si 2	Sand cast	180	460	20	90–140

* Properties of continuously cast and centrifugally cast materials are generally similar.

Table 22.9   COPPER AND COPPER ALLOYS—TYPICAL TENSILE PROPERTIES AT ELEVATED TEMPERATURES

Limit of proportionality or proof stress is reported under a code, viz:
  LP = Limit of proportionality
  0.1 = 0.1% offset proof stress
  0.2 = 0.2% offset proof stress
  0.5 = 0.5% offset proof stress.

Material	Composition %	Condition (see Table 22.7)	Temperature °C	Limit of proportionality or proof stress		UTS MPa	Elongation on 50 mm %	Remarks	Reference

Table 22.10   COPPER AND COPPER ALLOYS—TYPICAL TENSILE AND IMPACT PROPERTIES AT LOW TEMPERATURES

Limit of proportionality or proof stress is reported under a code, viz:
   LP = Limit of proportionality
   0.1 = 0.1% offset proof stress
   0.2 = 0.2% offset proof stress
   0.5 = 0.5% offset proof stress
Impact values are reported either as C = Charpy, V notch test or I = Izod test.

22.3   Mechanical properties of lead and lead alloys

The mechanical properties of lead and its alloys, particularly the more dilute alloys, are extremely sensitive to variations in composition, grain size, metallurgical history and temperature and rate of testing. They are therefore rarely reproducible with any degree of accuracy, except on the same sample under identical test conditions and, even then, a delay of a few hours between tests may affect the results obtained.

The figures quoted in the following tables should therefore be considered only as *typical* and should not be used where accuracy is necessary. For these same reasons, the materials quoted in the tables are grouped according to their principal uses and the typical values quoted for various properties are merely intended as an indication of their suitability for those uses.

Lead alloys are also dealt with under 'Solders', Chapter 34.

Table 22.16   LEAD AND LEAD ALLOYS—TYPICAL MECHANICAL PROPERTIES

Common name	Nominal composition %	Hardness DPN	Tensile strength[1] MPa	Fatigue[2] strength MPa
A. Lead and lead alloys for chemical applications				
Type A lead	Pb > 99.99	4	16.8 (20°C)	±3.17 (20°C)
			12.1 (60°C)	±2.24 (60°C)
Copper lead	Cu 0.05–0.07	4.5	17.6 (20°C)	±4.96 (20°C)
			15.2 (60°C)	±4.69 (60°C)
Tellurium copper lead	Te 0.02–0.05 Cu 0.05–0.07	6	21.1 (20°C)	±7.24 (20°C)
			18.7 (60°C)	±6.55 (60°C)
Silver copper lead	Ag 0.003–0.005 Cu 0.003–0.005	5	16.4 (20°C)	±4.48 (20°C)
			13.4 (60°C)	±3.45 (60°C)
Antimonial lead	Sb 2.5–11.0			
	Sb 4.0	8–12	30.0 (20°C)	±10.62 (20°C)
			25.2 (60°C)	±10.04 (60°C)
	Sb 8.0	9–16	37.7 (20°C)	±14.82 (20°C)
			35.9 (60°C)	±12.06 (60°C)
Dispersion strengthened lead	PbO 1.5 dispersed phase	14	29.4	±13.4
	PbO 4.0 dispersed phase	—	35.5	±13.7
B. Lead alloys for cable sheathing				
	Sb 0.85	6–15 (depending on heat treatment)	31[3]	±8.3[4]
	Cd 0.075 Sn 0.2			±3.8[4]
	Sb 0.4 Sn 0.2	6	18.5[3]	±6.6[4]

Notes:
(1) Rate of testing: 0.4 mm mm^{-1} min^{-1}.
(2) 20×10^6 cycles.
(3) Testing rate: 0.1–0.25 mm mm^{-1} min^{-1}.
(4) 10^7 cycles.

Table 22.17   IMPORTANT LEAD ALLOYS WITH UNSPECIFIED MECHANICAL PROPERTIES[1]

Main application	Nominal composition %	Specific use
Soldering	Sn 64 or 60	Electrical and electronics
	Sn 40, 45, 50, 60	Can soldering, general engineering
	Sn 30, 35	Cable sheaths
	Sn 15, 20	Lamps, low service temperatures
	Sn 40 Sb 2.2	Heat exchangers, general dip soldering
	Sn 30, 32 Sb 1.6, 1.8	Plumbing, wiped joints
	Sn 28, 30 Sb 1.5, 1.6	General body soldering
	Sn 25 Sb 1.4	Radiator core dipping
	Sn 16, 18, 22 Sb 2.5, 1.0, 1.2	Body soldering, radiator dipping
	Sn 5.0 Sb 4.0	Hot dip coating, tubular radiator manufacture
	Sn 2.6, 10.2 Sb 5.1, 4.0 As 0.5	Body solders for shallow areas

(*continued*)

Table 22.17   IMPORTANT LEAD ALLOYS WITH UNSPECIFIED MECHANICAL
PROPERTIES[1]—*continued*

Main application	Nominal composition %	Specific use
Printing		
	Sn 2–4	Electrobacking metal
	Sb 2–5	
	Sn 2–5	Slug casting metal
	Sb 10–13	
	Sn 5–10	Stereotype metal
	Sb 15	
	Sn 6–13	Monotype casting metal
	Sb 15–19	
	Sn 13–22	Cast type casting metal
	Sb 20–28	

Notes:
(1) In many uses of lead alloys, the strength, hardness, etc. of the alloy are not of prime importance.
In general soldering, for example, the geometry of the joint and the materials being joined, are
of greater importance than the strength of the bulk solder. In most applications of type metals,
fluidity of the liquid alloy, contraction properties, and wear resistance of the solid alloy, are the
most important characteristics in formulating an alloy. See also Chapter 34.

* It is usual to add 0.2–0.4% Mn to alloys containing aluminium to improve corrosion resistance.
** Solution heat treated in an atmosphere of hydrogen.
† Wohler rotating beam tests at 2 960 c.p.m.
‡ U = Unnotched.
N = Notched. Semi-circular notch of 0.12 cm (0.047 in) radius. Stress concentration factor 1.8.

§ Hounsfield balanced impact test, notched bar values are equivalent to Izod values.
RE(D) = Neodymium enriched mischmetal.
*** Thorium-containing alloys are being replaced by alternative Mg alloys.
RE(Δ) = Neodymium plus Heavy Rare Earths.

Table 22.25   HEAT TREATMENT OF MAGNESIUM ALLOY CASTINGS

Heat treatment conditions for magnesium sand castings can be varied depending on the particular components and specific properties required. The following are examples of the conditions typically used for each alloy.

Material		Nominal* composition %		Condition	Time h	Temperature °C
Mg–Al–Zn	(AZ80)	Al	8.0	TB	12–24	400–420
		Zn	0.4			
	(AZ91)	Al	9.5	TB	16–24	400–420

		RE(Δ)	3.0		Water/Oil Quench/Air Cool	
		Zr	0.6		12–20	245–255
Mg–Zn–Cu–Mn	(ZC63)	Zn	6.0	TF	4–12	435–445
		Cu	2.7		Water Quench	
		Mr	0.5		16–24	180–200

* It is usual to add 0.2–0.4% Mn to alloys containing aluminium to improve corrosion resistance.

    RE = Cerium mischmetal containing approximately 50% cerium.   TB = Solution heat treated.

    RE(D) = Neodymium-enriched mischmetal.   TE = Precipitation heat treated.

    RE(Δ) = Neodymium plus Heavy Rare Earth metals.   TF = Fully heat treated.

† Thorium-containing alloys are being replaced by alternative Mg alloys.

Note: Above 350°C, furnace atmospheres must be inhibited to prevent oxidation of magnesium alloys. This can be achieved either by:
    (i) adding $\frac{1}{2}$–1% SO_1 gas to the furnace atmosphere; or
    (ii) carrying out the heat treatment in an atmosphere of 100% dry CO_2.

Mechanical properties at subnormal temperatures

At temperatures down to −200°C tensile properties have approximately linear temperature coefficients: proof stress and UTS increase by 0.1–0.2% of the RT value per °C fall in temperature, and elongation falls at the same rate: modulus of elasticity rises approximately 19 MPa (2 800 lbf in⁻²) per °C over the range 0° to −100°C. No brittle-ductile transitions have been found.

    Tests at −70°C have suggested that the magnesium-zinc-zirconium alloys show the best retention of ductility and notched impact resistance at this temperature.

22.5   Mechanical properties of nickel and nickel alloys

Table 22.26   WROUGHT NICKEL AND HIGH NICKEL ALLOYS, STANDARD SPECIFICATIONS AND DESIGNATIONS

Note for 8th edition: In the case of the UK, France, and Germany, this table refers to designations and standards that may have been superceded by European (EN) and international (ISO) standards. Consult Chapter 1 for references to current standards.

(1) Registered Trade Mark.
(2) All values in the tables in this section are representative and not to be considered as minima or maxima not to be used for specification purposes. Conversion figures have all been rounded off and are not to be taken as precise equivalents.
(3) Where trade marks apply to the name of an alloy there may be materials of similar composition available from other producers who may or may not use the same suffix along with their own trade names. The suffix alone, e.g. Alloy 800 is sometimes used as a descriptive term for the type of alloy but trade marks can be used only by the registered user of the mark.
(4) Other copper–nickel alloys, cupro-nickels, will be found listed under copper base alloys.
(5) Fully heat-treated usually implies a solution treatment followed by some form of precipitation hardening cycle. The precise heat-treatment and the associated properties may be varied to suit particular applications or according to the form of the alloy as forging, bar, sheet or welded fabrication.
(6) There are many nickel chromium alloys with and without iron used for electrical resistance heating and for general high-temperature applications in furnaces and heat-treatment plant. This alloy is typical.

22.5.1   Directionally solidified and single crystal cast superalloys

Directionally solidified (DS) and single crystal (SC or SX) nickel-base superalloys were developed to increase the creep and thermal fatigue strength of first stage turbine blades in aero-engine gas turbines, and are now increasingly used in land-based gas turbines. Property improvements over those of polycrystalline superalloys result from the elimination of grain boundaries transverse to the principal stress axis and the alignment of the low-modulus <100> crystal direction with the stress axis. In the case of the SC alloys, further improvements were realised by optimising alloy chemistry in the absence of grain-boundary strengtheners such as C, B, and Zr.

Table 22.34 lists nominal compositions for common DS alloys; the so-called 'first-generation' alloys represent slight modifications from polycrystalline cast superalloy compositions (generally addition of Hf). The second-generation alloys were specifically designed for directional solidification and several incorporate Re to achieve creep strengths equivalent to first-generation single crystal alloys. Table 22.35 lists nominal compositions for common SC alloys. As mentioned above, the first-generation alloys eliminated the grain boundary strengtheners C, B, and Zr. Increasing levels of Re in the second and third generation alloys have led to even higher creep resistance, due to the potent solid-solution strengthening effect of Re at high temperatures.

Property data for the various alloys are not listed due to the proprietary and specialised nature of these alloys. Users should consult the developer or supplier for property data for their specific needs.

22.9   Tin and its alloys

The applications of tin are governed very largely by its low melting point, excellent fluidity when molten, relative softness, formability and readiness to form alloys with other metals.

The low melting point of tin means that at normal ambient temperature the metal is nearly 60% of its melting point on the absolute Temperature Scale. This results in rather low mechanical strength at room temperature, as would be expected from any metal tested at a temperature corresponding to such a high proportion of its Absolute melting point, i.e. 505 K. Because of this, pure tin recrystallises readily at room temperature. Consequently, unlike the majority of industrial metals, only slight work hardening occurs initially in tin, followed by work-softening with further deformation due to grain growth. A similar behaviour is found in tin-rich alloys. The mechanical properties recorded for tin-rich alloys are strongly dependent on impurity levels and the strain rate.

Within reasonable limits any tin-base alloy can be die cast successfully. The choice of alloy, therefore, rests on such matters as mechanical properties, wear resistance or cost rather than on any consideration of the casting behaviour.

PURE TIN—MECHANICAL PROPERTIES

Tensile strength (at 0.4 mm/mm min) at	20°C	14.5 MPa
	100°C	11.0 N mm^{-2}
	200°C	4.5 N mm^{-2}
Shear strength at 20°C		12.3 MPa
Hardness at 20°C		3.9 HB
100°C		2.3 HB
200°C		0.9 HB
Young's modulus at 20°C		49.9 GPa
Rigidity modulus at 20°C		18.4 GPa
Poisson's ratio		0.357
Creep strength at 15°C		
(approx. life at 2.3 N mm^{-2})		170 days
(approx. life at 1.4 N mm^{-2})		550 days
Fatigue strength for 10^8 reversals at 15°C		± 2.5 MPa
Elastic modulus (tension)		
As cast		41.6 GPa
Self annealed		44.3 GPa
Impact strength		
0°C		44.1 J
150°C		22.7 J

Note: Mechanical properties are very dependent on the rate of loading.

22.10   Steels

Note for 8th edition: the tables in this section refer to standards that have been recently superceded by European (EN) and international (ISO) standards. The older British standards have been retained for information. Chapter 1 list equivalent designations in other systems for some alloys. For full information the relevant specifications must be consulted.

Table 22.56 TOOL STEEL HEAT TREATMENTS AND HARDNESS

Equivalent designations for some tool steels are presented in Chapter 1.

Material	British or other standards*	Annealing °C	Hardening °C	Quenching medium	Tempering °C	Hardness Annealed Max HB	Heat treated Min HV	Remarks
1. Carbon tool steels								
0.8C Steel	DIN C80W1	680/710	780/810	Water or brine	150/350	207	790	The wear resistance increases but the toughness decreases with increasing carbon content
0.9C Steel	BS BW1A*	740/770	770/790	Water or brine	150/350	207	790	
1C Steel	BS BW1B*	740/770	770/790	Water or brine	150/350	207	790	
1.2C Steel	BS BW1C*	740/770	760/780	Water or brine	150/350	207	790	
1CV Steel	BS BW2	740/7	780/800	Water or brine	180/350	207	790	The V addition reduces the case depth, and raises the resistance to cracking
2. Hot work tool steel								
$1\frac{3}{4}$NiCr-MoV Steel	DIN 55NiCr MoV6 Similar to Bs No. 5 Die Steel	650/700	830/870	Oil	500/600	—	—	Tough and wear resistant
3CrMoV Steel	BS BH10	850/870	1 000/1 060$^\phi$	Oil or air	530/650	229	—	Wear resistance and fairly tough. Resistant to softening on tempering
3CrMoV Co Steel	BS BH10A	850/870	1 000/1 060$^\phi$	Air or oil	530/650	241	—	Wear resistant

22. 12   Bearing alloys

Bearing alloys have to satisfy a number of criteria, depending on their application, of which the following are the more important.

WEAR RESISTANCE

The bearing must resist wear and more importantly must not cause wear of the mating surface. The stronger, harder bearing materials must therefore be operated against a hardened mating surface.

EMBEDDABILITY

When dirt or detritus from associated parts is present in the lubricant supply the bearing must minimise damage to the mating surface. Soft bearing materials can absorb more dirt than hard materials.

CONFORMABILITY

The misalignments inherent in mechanisms under load require an ability in the bearing to conform to the geometry of the mating surface. Softness and conformability in a bearing material also facilitate the creation of a hydrodynamic film of lubricant over the bearing surface under sparse lubrication conditions.

STRENGTH

Under static loads the bearing must have a yield strength greater than the applied load. Under dynamic fatigue or shock loads, a combination of high yield strength and ductility is required. The relative fatigue strengths of various bearing alloys can be seen from Figure 22.1 and mechanical properties from Table 22.58

CORROSION RESISTANCE

The bearing material must resist corrosion by the atmosphere or by the lubricant.

THERMAL EXPANSION

The expansion coefficient of the bearing material must be sufficiently close to that of the housing for there to be no significant loss of interference fit at bearing operating temperatures.

It will be apparent that a bearing material is a compromise between the conflicting requirements for softness and strength, and the optimum compromise depends on the application. High effective strength from a relatively weak bearing material may be achieved if the material is present as a thin lining on a steel backing, and the majority of bearings have this construction. The copper-based engine bearing linings and the stronger aluminium alloys are overlay plated with a thin layer of lead–indium. This soft, partly sacrifical layer provides surface embeddability and conformability, and is thin enough (0.01–0.03 mm) to have good load carrying capacity.

Table 22.58 MECHANICAL PROPERTIES OF BEARING ALLOYS

	Nominal composition and manufacturing process						Mechanical properties

23   Sintered materials

A wide range of useful metallic materials is made from powder by the process known as sintering. Such materials are commonly referred to as sintered materials, and individual engineering components made by the process are known as sintered parts, sintered components, or PM parts—PM or P/M being the acronym for powder metallurgy.

23.1   The PM process

This process consists of shaping the powder by means of pressure in a die or mould of prescribed shape; the compact thus formed must have sufficient green strength to allow it to be removed from the die and handled without fracture. This is an important property. After removal from the die, the compact is heated, normally in a protective atmosphere or vacuum, to a temperature usually below the melting point, such that the particles weld together and in some cases densify markedly to increase the strength. This is the step known as sintering. In some cases, especially when the sintered compact is to be subsequently rolled or extruded, isostatic compaction in a flexible mould is used. An exception to the compaction process is the production of filter elements from spherical powders, often of bronze, by what is known as loose powder sintering, in which powder is poured into a mould of the appropriate shape and sintered in the mould. Most recently shaping has embraced injection moulding and the use of polymers to lubricate the powder flow into a mould cavity. After moulding, the polymer is extracted and the powder is sintered to near full density.

Increasingly, sintered billets are being made for subsequent mechanical working such as hot extrusion or rolling. These processes yield wrought material to which the name sintered parts does not apply, but the bulk of PM products are items made individually to the final shape and size.

23.2   The products

The main classes of PM products are:

1. Engineering components, i.e. parts for machinery made by directly pressing or moulding in rigid dies of the required shape, and sintering with either no or only minor further shaping. This is the largest and most familiar class of PM product.
2. Refractory metals. These often have melting points that are inconveniently high and/or are difficult or impossible to work in the cast state because they are brittle. This group includes tungsten, molybdenum, tantalum, and related metals.
3. Intentionally porous materials for use as filters or as oil-retaining (self-lubricating) bearings.
4. Composites. These may consist of two or more metals that are insoluble in each other in the solid state, but the name is generally used to signify a metal in which is dispersed one or more non-metallic ingredients such as refractory oxide, carbide, or other compound that is insoluble in the metal. These are referred to as metal matrix composites. A very important member of this group, the hardmetals, is the subject of a later section.
5. High-duty alloys in wrought form having mechanical properties superior to those of the corresponding material made from ingot. In this category must be included certain composite materials having fine dispersions of oxide or the like designed to improve the strength, especially at elevated temperatures. In some other cases the principal reason for making wrought products from powder is that higher yields of usable material are possible. This applies to metals such as titanium alloys the scrap from which cannot readily be re-used.
6. Magnetic materials. This very important class of sintered material is dealt with in Chapter 20.

23.3   Manufacture and properties of powders

23.3.1   Powder manufacture

There is a large number of possible ways of making metal powders, the principal ones used on a commercial scale for powders for PM being:

— Solid state reduction of a compound of the metal, commonly the oxide. This often results in a loosely caked sponge which is converted into powder by milling.
— Thermal decomposition of a compound of the metal. This also may yield a sponge.
— Electrolysis. By suitable choice of the various parameters certain metals can be deposited in a spongey or powder form. Such powders are often dendritic. In the case of iron, a dense deposit is formed which is reduced to powder by comminution.
— Atomisation, in which molten metal is disintegrated into small drops which are caused or allowed to solidify out of contact with each other and with any solid surface. There are many ways in which the molten droplets may be produced, the most common being to allow a stream of molten metal to fall vertically from a tundish into a chamber where it is broken up by jets of high-pressure liquid or gas. Another process now gaining in importance is centrifugal atomisation, in which droplets are flung from a rapidly rotating pool of molten metal or from a disk on to which a thin stream of metal impinges. In another process the end of a rotating bar is progressively melted and if the heating is by laser beam or plasma arc the process can be carried out in near vacuum, thus substantially eliminating the risk of contamination. This is called REP (Rotating Electrode Process) and if a plasma arc is used PREP (Plasma REP). An important feature of atomisation is that it can produce homogeneous fully pre-alloyed powders.

   Table 23.1 lists the powder production processes used for many of the metals used in PM.

— Rapid solidification. This means cooling molten metal at a very high rate such that on solidification an amorphous or other non-equilibrium structure results. In the case of certain aluminium alloys, for example, it is possible to hold in solution significantly higher percentages of alloying elements (see Table 23.2). If a rapidly solidified alloy is consolidated by a powder metallurgical process that does not involve heating to a temperature high enough to induced recrystallisation, wrought material with substantially improved mechanical properties may result. The processes

Table 23.1   PRODUCTION PROCESSES FOR METAL POWDERS

The most widely used method is put first.

Aluminium	Gas atomisation (usually air), Comminution
Beryllium	Comminution, electrolysis
Brass	Atomisation—water or gas
Bronze	Water atomisation for irregular powder, Air atomisation for spherical powder
Cobalt	Oxide reduction
Copper	Water atomisation, electrolysis (Both are in general use)
Iron: unalloyed	Oxide reduction, water atomisation, electrolysis, carbonyl decomposition
Iron: cast	Comminution
Molybdenum	Oxide reduction—by hydrogen
Nickel	Thermal decomposition of the carbonyl, reduction of a salt in solution
Nickel alloys inc. superalloys	Atomisation—inert gas, centrifugal
Platinum	Thermal decomposition of a salt
Silver	Precipitation from solution of a salt, usually by an organic reducing agent, electrolytic
Silver alloys	Atomisation
Steels	Atomisation—usually with water or nitrogen
Tin	Air atomisation
Titanium	Reduction of the chloride by magnesium, Thermal decomposition of the hydride
Tungsten	Reduction of the oxide—by hydrogen

Note: Powders of practically all metals can be produced by atomisation—the table lists the processes common in present day commercial practice.

Table 23.2   EXTENDED SOLUBILITY IN ALUMINIUM VIA RAPID SOLIDIFICATION

Additive	Maximum equilibrium solubility, at. %	Observed maximum by rapid quenching
Cu	2.5 (at 821 K)	18
Mn	0.7 (at 923 K)	9
Si	1.6 (at 850 K)	16

used mostly involve projecting molten metal to form a very thin film on a rotating water cooled cylinder to produce flake or ribbon which is crushed to powder.
— Mechanical alloying. Another way of achieving higher strength and especially retention of that strength at elevated temperatures is to include in the metal matrix a finely dispersed insoluble phase, commonly a stable oxide. Oxide Dispersion Strengthened (ODS) materials are increasingly of interest in aerospace technology, and they are of necessity made by PM. In general the performance improvement is greater the finer the particles of the dispersed phase, the mechanism being dislocation locking as in precipitation hardening. An approach near to ideal is mechanical alloying, in which a metal powder is mixed with a fine oxide powder and the mixture milled for several hours or even days usually in an attritor, during which process the oxide is beaten into the metal, the particles of which are repeatedly flattened, broken up, and reflattened while at the same time the oxide particles are broken down into progressively smaller fragments, typically less than 100 nm. Mechanically alloyed powders are generally consolidated and converted into wrought shapes.

23.3.2   Properties of metal powders and how they are measured

Chemical composition

Chemical composition is the main factor that determines the properties of the finished material. One feature that is specific to powders is the oxide layer on the surface of the particles. This has an important influence of the green strength of compacts but more especially on the sintering process which depends on the formation of true metallurgical bonds between adjacent particles. In the case of metals with easily reducible oxides the level of surface oxide is determined by heating a weighed sample in hydrogen under specified conditions, cooling in hydrogen, and weighing. The reduction in weight is commonly called the loss in hydrogen or hydrogen loss. The procedure gives a misleading figure if volatile material is present, such as organic additions (pressing lubricants), moisture, or volatile metals such as zinc. The process is not applicable to metals with very stable oxides that are not reducible in this way, nor to alloys containing a high percentage of metals such as aluminium, titanium, chromium, and stainless steels. Table 23.3 gives the specified reduction conditions for some common metals.

Table 23.3   CONDITIONS FOR DETERMINATION OF LOSS IN HYDROGEN

Metal powder	Reduction temperature °C	Reduction time min
Tin bronze	775 ± 15	30
Cobalt	1 050 ± 20	60
Copper	875 ± 15	30
Copper lead[1] and leaded bronze[1]	600 ± 10	10
Iron	1 150 ± 20	60
Alloyed steel	1 150 ± 20	60
Lead[1]	550 ± 10	30
Molybdenum	1 110 ± 20	60
Nickel	1 050 ± 20	60
Tin	550 ± 10	30
Tungsten	1 150 ± 20	60

[1] Results should be interpreted with caution.

Particle size and size distribution

The meaning of size is complicated by the enormous variety of shape of particles which makes quantitative assessment difficult. Volume, maximum linear dimension, average dimension, cross sectional area are different measurements which can be made. A considerable range of techniques is or has been used, including among others microscopical examination, elutriation, sedimentation, light obscuring, and light scattering, but for most PM powders the process normally used is laser light scattering. Historical size analysis was based on sieving. The screen size is designated by the number of strends of wire per unit length and has been superseded by specifying the aperture size in terms of the largest sphere that will pass through it. However the older designation is still used and Table 23.4 shows the relationship between the various standards. The less equiaxed the particles the less meaningful will be the result of a sieve test. For example in the extreme case of an acicular powder, the length rather than the diameter is likely to be the controlling dimension. Nevertheless, meaningful and useful results are obtained, especially when different batches of nominally similar powder are being compared. For very small subsieve size powders other methods have to be employed. This is the primary domain of laser light scattering. These data are supplemented by the BET method which is based on gas absorption. This measures in effect the total surface area.

Apparent density (*AD*)   This most important property is in a general sense the same as bulk density, i.e. it is the mass of a unit volume of powder, but the method and apparatus used to determine it need to be carefully specified if consistent results are to be obtained. The test normally specified—ISO 3923/1—is to allow the powder to emerge from a funnel through a specified orifice into a cylindrical cup of specified dimensions which overflows. The surplus is carefully removed by drawing a straight edge across the top of the cup, the powder in the cup then being weighed. The apparatus used is specified in ISO 3923/1 and illustrated in Figure 23.1. (The same apparatus is also used to determine the flow properties of powders.) AD is of importance in several ways but especially in that it determines the amount, i.e. mass, of powder in the die before compaction.

Tap density (*TD*)   This density is based on vibration of the powder to its highest packing density. The TD is an excellent measure of the maximum suspension density that can be expected in various polymer-assisted shaping technologies.

Flow factor   In the commercial production of compacts, powder is fed automatically into the die cavity and must, therefore, flow readily. The flowability is measured by timing the flow of 50 g of powder from a funnel of specified geometry and the result expressed in seconds. The procedure is laid down in ISO 4490, the apparatus being generally referred to as the Hall flowmeter after its designer (Figure 23.1). The properties of some widely used PM grade powders are given in Table 23.5.

23.4   Properties of powder compacts

Apart from dimensions which are, of course, of major importance in the manufacture of individual PM parts, the relevant properties of compacts are density and strength. Green density as it is called has a marked influence on green strength and can impact the final, i.e. sintered, density. It is determined by Archimedes principle. Green strength is the term used to indicate the strength of a compact and two standard methods are in general use for measuring it.

1. A three point bend test on a standard compact of rectangular cross section gives the Transverse Rupture Strength—ISO 3995.
2. A compression test on the diameter of a ring shaped compact gives the Radial Crushing Strength (*K* factor)—ISO 2739. This test applies especially to cylindrical bearings. The *K* factor is given by the formula: $(K = F(D - e)/Le^2 \text{ N/mm}^2$, where $F =$ breaking load in Newtons, $L =$ the length in mm, $D =$ the external diameter in mm, $E =$ the wall thickness in mm.

Compressibility (*compactibility*)   For economic as well as technical reasons it is desirable to use as low a pressure as possible to achieve the required compact density, therefore the compressibility of the powder is of considerable importance. This factor is usually expressed either as the density obtained with a given compacting pressure (see Table 23.5) or is shown as a curve relating density to pressure. Compressibility as defined in this way is influenced by the AD of the powder and by the actual strength of the particles. Thus an alloy powder will have a lower compressibility than that of a pure metal. For this reason it is often preferred to use mixtures of elemental powders (for low alloys) rather than pre-alloyed powders of the composition ultimately required. However, today pre-alloyed powder is needed to satisfy most of the high performance applications.

Temperature

Figure 23.2

23.5   Sintering

Most PM components (other than hardmetals) are sintered in continuous furnaces normally having three major zones:

1. A pre-heating or de-waxing zone in which the lubricant is driven off.
2. The sintering zone proper, the temperature of which is called the sintering temperature.
3. A cooling zone normally surrounded by a water jacket. Figure 23.2 shows a typical temperature profile for the work load.

Compacts of pure metals and of fully pre-alloyed alloys shrink during sintering, the amount of shrinkage being dependent on the green density and the sintering regime, i.e. temperature and time. With mixtures of elemental powders or of alloys of different compositions, the situation is different. Diffusion effects can cause an expansion to occur initially and this feature can be used to provide mixes that neither shrink nor grow on sintering. The green density homogeneity is the major factor that determines the consistency of dimensions of the sintered component. It is in most cases the ability to produce components directly, i.e. without any subsequent machining, that provides the economic justification for making them from powder.

In the case of large compacts that are intended to be subsequently wrought into sheet, rod, or wire, these factors are of little or no importance.

23.6   Ferrous components

Iron-based materials account for the bulk of PM parts and they range in composition from nearly pure iron through low alloy steels to stainless steels and high-speed steels for cutting tools, etc. It should be noted, however, that as regards low-alloy steels the compositions used differ from those of ingot-based metal. The reason for this is that alloying elements that give rise to oxide films that are stable in normal sintering atmospheres and which therefore inhibit sintering are used in low concentrations. Such elements include manganese, chromium, and silicon. Favoured compositions for sintered steels contain, in addition to carbon, one or more of the elements copper, nickel and molybdenum, the oxides of which are readily reducible by hydrogen. In addition there are compositions containing up to 0.6% of phosphorus.

Sintered steels differ from wrought in strength in that the hardness, strength, and ductility depend not only on composition and state of heat-treatment, but also markedly on density (see Figure 23.3). Considerable effort has been put into ways of increasing the density of sintered parts in order to extend their use to more heavily stressed applications. Ways of doing this are:

1. Re-press and re-sinter.
2. Re-press at elevated temperature.
3. Hot forge.
4. Sinter density.
Figure 23.3 *Effect of density on strength of as-sintered 4% nickel steel*

In the third process, called sinter forging or powder forging, a sintered blank of appropriate geometry is hot forged in a closed die to the required shape and dimensions. In this way it is possible to achieve properties as good as those of wrought steels and in some respects better because of the complete homogeneity and isotropy of the material (see Table 23.6). Accuracy too may be superior because it is possible to maintain closer tolerances on the mass of the blank than is normal with blanks cut from bar. Flash should be completely absent. Another way of increasing the density is to fill the voids with copper or a dilute copper alloy which is melted on the surface and absorbed into the pores. This process, known as liquid infiltration, is liable to affect adversely the dimensional accuracy.

23.7 Copper-based components

There is a relatively limited market for structural components made of bronze, brass, or copper itself, copper usually being used for electrical applications. There is, however, a considerable market for oil-retaining bronze bearings, (porous) filter elements, art objects, and decorative hardware sintered from bronze. As regards bearings there is a conflict between the oil capacity which increases as the density decreases, and strength which increases as the density increases. The oil content normally lies between 15 and 30% by volume. Table 23.7 lists specified compositions and properties of several standard types of bearing including those made of iron or its alloys. Figure 23.4 shows the relationship between strength and sintering temperature for bronze bearings, and Figure 23.5 shows how the diameter varies with temperature.

23.8 Aluminium components

The sintering of pure aluminium is difficult by reason of the tenacious oxide film present on the surfaces of the particles which cannot be reduced by any feasible sintering atmosphere. However, if certain alloying elements are present the alloy may have a significant gap between the solidus and liquidus temperatures so that sintering may be carried out near the solidus and a liquid phase might be present; this breaks down the surface oxide films and allows interparticle welding to take place. This is a typical example of what is called liquid phase sintering. As with copper based materials, the quantity of sintered aluminium components is relatively small, but they find application where lightness, corrosion resistance, or electrical or thermal conductivity are controlling requirements. The properties of some sintered aluminium alloys are given in Table 23.8.

23.9 Determination of the mechanical properties of sintered components

The properties of interest to users are the same as those of cast or wrought metal, but the measurement of hardness especially requires some elaboration because of the porous nature of some sintered metals.

1. Hardness. A traditional indentor will make a larger impression and therefore record a lower hardness than that of dense metal of the same composition because the pore offer no resistance to deformation. A distinction is, therefore, made between apparent hardness as measured in a standard test, and true hardness, i.e. that of the same metal in the pore-free state. True hardness may be measured using a micro indentor and a carefully specified technique which minimises the risk of the result being falsified by the porosity. Apparent hardness is related to strength in the same way as with dense materials; true hardness is relevant to wear resistance.
2. Strength. Strength is determined by tensile test, but because sintered parts are normally used without machining, it is rarely desirable to cut test pieces from the parts themselves. It is standard practice, therefore, to produce separate test pieces compacted to the same density as a batch of parts and to sinter them along with the batch. Figure 23.6 shows the standard test piece.
3. Impact. The presence of porosity has a very deleterious effect on impact properties and it is not common practice to measure this property when porosity is over about 5%. For components sintered to full density, standard notched Charpy tests are employed, but for porous samples the convention is to use an unnotched Charpy bar to obtain higher apparent toughness.
4. Fatigue. In recent years there has been considerable concern over the fatigue properties of sintered ferrous alloys, since many of the applications involve components used in cyclic loading. Table 23.9 contains example fatigue endurance strengths as measured using rotating beam fatigue tests for several sintered compositions. These correspond to 50% survival at 10 million cycles. Residual pores act as cracks and greatly accelerate fatigue failure. Accordingly,

attention on improved fatigue life demands densification improvements via techniques such as hot forging, high temperature sintering, and hot isostatic pressing.

The compositions and mechanical properties of the standard PM materials are shown in Tables 23.10–23.15.

23.10   Heat treatment and hardenability of sintered steels

Sintered steels can be hardened and tempered in the same way as wrought steels (see Figure 23.7), but for materials over approximately 5% porosity the use of salt baths is not recommended because of the difficulty of removing the salt from the pores. The porosity has a marked effect on hardenability as shown in Figure 23.8. This is a consequence of the lowering of the thermal conductivity.

23.11   Case hardening of sintered steels

Here also the porosity has a significant effect. In carburising, nitriding, and carbo-nitriding, the gas enters the pores so that for a given regime the depth of hardening is greater and the transition between case and core is much more gradual. As would be expected, these effects are more marked the greater the amount of porosity (*see* Figure 23.8). If the parts are first infiltrated (*see* Section 23.6) this effect largely disappears and a more nearly normal case is produced.

23.12   Steam treatment

A process peculiar to sintered ferrous components is to heat them in superheated steam which produces a layer of magnetite, Fe_3O_4, on the surface including those of the surface-connected pores. This significantly increases the surface hardness and wear resistance, and to some extent the density, as can be seen in Table 23.16.

23.13   Wrought PM materials

Substantial tonnages of wrought metals are made by PM. The products can be divided into three classes.

1. Metals that are difficult or impossible to produce in wrought form from ingot because of their inherent brittleness. Those of most commercial importance are tungsten, molybdenum, and the

other refractory metals tantalum, niobium, and rhenium, as well as beryllium, chromium, and magnesium.

2. Metals containing a finely dispersed insoluble second phase. ODS materials and aluminium with a dispersion of silicon carbide have been referred to in Section 23.3 under 'Mechanical alloying'. In such cases the purpose is to produce materials with better properties than are available in standard wrought products of the same nominal composition but without the dispersed phase. The metals aluminium, copper, nickel alloys especially superalloys, molybdenum, and other refractory metals strengthened in this way are in commercial production. Additionally copper and silver containing dispersed oxide(s) are used for make and break electrical contacts combining the excellent conductivity of these metals with marked resistance to welding.

3. Metals and alloys that present no great production difficulty starting from ingot, but which can be produced more economically from powder, generally because of the higher yield of finished material and/or reduction in the number of annealing and pickling steps. Superior properties can sometimes be claimed and result from the greater homogeneity and freedom from pipe defects. Of importance commercially are austenitic stainless steels and superalloys.

Figure 23.9   *Stress dependence of rupture life in hours of 0.007″ (178 μm) tungsten wire at 3 000 K. W is pure tungsten wire, 218 is doped tungsten wire*

23.13.1   Refractory metals

Tungsten wire was one of the first PM products to be made on a large scale, the use being filaments for incandescent electric light bulbs, for which purpose it is still made. In order to induce in the wire a particular elongated microstructure which increases remarkably the life of the filament, a small percentage of thorium oxide was included. It is to tungsten doped in this way that the properties shown in Figure 23.9 refer.

Molybdenum is used extensively in high-temperature furnaces as heating elements, radiation shields, and structural components. The high-temperature strength can be increased by ODS. ODS platinum/rhodium used for handling molten glass has much improved creep strength as is shown in Figure 23.10.
Figure 23.10 *Creep strength of ODS Pr/10% Rh*

23.13.2 Superalloys

This family of alloys is used for load-bearing applications at elevated temperatures, and is especially relevant to turbine discs and blades for aircraft engines. For manufacture by PM, spherical powders produced either by gas (usually argon) atomisation or centrifugal atomisation are used. The attractions of the PM route are that it is possible to achieve a fine homogeneous structure free from pipe-related defects and segregation, and also a better yield of usable material. Table 23.17 lists some relevant properties of one well known alloy. Most all of the current production of PM superalloys relies on hot isostatic pressing to obtain full density. Often the HIP consolidation is followed by hot forging.

Superalloys owe their good strength properties to precipitation hardening by a titanium–aluminium compound, but as the temperature rises, this compound begins to go into solution and loses its effect. This puts a ceiling on the working temperature. The mechanical alloying process to produce a fine dispersion of a ceramic material—yttria is favoured—that is virtually insoluble in the metal matrix, significantly increasing the temperature at which useful strength is retained. A list of ODS superalloy compositions is given in Table 23.18, and Figure 23.11 shows the improved performance of one of these alloys compared with that of a similar composition made conventionally.

23.13.3 Copper

One of the main users of copper is the electrical industry where conductivity is the primary consideration. Increasingly, power plant is required to operate at temperatures well above ambient where pure copper recrystallises and becomes very soft. Increasing the strength and recrystallisation temperature by alloying drastically reduces the conductivity. The inclusion in pure copper of a small percentage of finely dispersed aluminium oxide provides significantly better elevated temperature strength with only a small reduction in conductivity. An atomised powder of a dilute aluminium copper alloy is internally oxidised to give a very fine Al_2O_3 particles, the powder being then processed by compaction, sintering, and working. The improved strength at room temperatures enables smaller sections to be used in, for example, miniaturised systems. Figure 23.12 gives some results for a range of alumina contents.

23.13.4 Lead

This is another soft metal whose strength can be increased by a dispersed oxide phase. In this case lead oxide is used. The chief application is to chemical plant especially for handling sulphuric acid.

Iron–chromium alloys: INCOLOY alloy MA 956 sheet, plate, bar, spinnings, rings and forgings have applications in the hot sections of gas turbines and diesel engines where the resistance of the alloy to creep, oxidation and sulphidation allow higher metal temperatures and longer component life. The alloy is being used to replace molybdenum in high-temperature vacuum furnaces for fixtures and heat-treatment trays. INCOLOY alloy MA 957 is intended for nuclear power applications, especially fuel cladding in liquid metal cooled reactors. Compared with 316 type stainless steel it has higher strength at 700°C and considerable resistance to irradiation damage.

Nickel–chromium alloys: INCONEL alloy MA 754 is used for brazed nozzle guide vane and band assemblies in advanced military aero engines. The principal advantages of the alloy for these applications are thermal fatigue resistance, long term creep strength and a high melting point. INCONEL alloy MA 758 is highly resistant to attack by molten glass and is used in spinnerettes for the production of fibre glass. The parts are formed by hot spinning plate.

Gamma prime ODS alloys: The immediate applications for INCONEL alloy MA 6000 are for first- and second-stage turbine vanes and blades machined from solid bar. Forced airfoil components have also been developed. The characteristics of INCONEL alloy MA 6000 allow blade cooling to be reduced or eliminated as the metal temperature can be increased by 100 K or more in engines where the stresses are medium or low. INCONEL alloy MA 760 is an industrial gas turbine derivative of INCONEL alloy MA 6000 having greater resistance to corrosion and oxidation. Initial applications are for machined vanes and blades but forged components are under development.

23.13.5   Aluminium

Section 23.3.1 referred to the mechanical alloying of Al with graphite to produce powder containing a carbide dispersion. This powder compacted into billets and extruded gives a product with much improved strength at elevated temperatures (see Figure 23.13).

23.13.6   Ferrous alloys

Powder metallurgy has found success at full density with ferrous alloys because of the improved microstructural homogeneity, especially important with high alloy systems. Table 23.19 provides mechanical property data for a few example full density ferrous alloys fabricated by hot isostatic pressing. Most of the applications for these materials are in demanding situations, such as military hardware, oil well drilling, and high performance automobiles. However, a few products have found their way into microelectronics processing, printers, and other applications demanding high performance.

23.13.7   Aluminium matrix composites

Mixed powders are used to form particulate or whisker reinforced composites. A common technique is to mix the two constituents and to hot consolidate the mixture, since sintering proves difficult with the

reinforcing phase. Up to approximately 50 vol.% of the inert phase can be fabricated by a combination of mixing and hot pressing. Two types of hot pressing are common based on uniaxial or isostatic pressures in a heated chamber. Table 23.20 gives the properties of Al–SiC composites fabricated by vacuum hot pressing using an aluminium alloy for the matrix. The tabulation shows how thermal and mechanical properties change with composition. The harder, stiffer carbide phase increases the elastic modulus, while lowering the thermal expansion coefficient and thermal conductivity. Note ductility falls rapidly with the addition of the silicon carbide.

23.14   Spray forming

This process is not powder metallurgy in the strict sense of the term in so far as the metal is at no stage in the form of powder. However, for reasons that will be apparent the PM world has adopted it. The process involves gas atomisation of a liquid metal, but instead of allowing the droplets to solidify as powder, the spray is caused to impinge on a solid surface where the droplets are collected as a semi-solid layer which solidifies as a dense metal. This layer may be built up to any desired thickness, and by suitable choice of design of the original target, the angle of the spray, and other parameters, near-net shapes can be produced. For example if the target is a cylinder rotating horizontally and capable of being moved in a controlled manner in the axial direction, a tube of dense deposited metal is formed. The deposit has all the advantages of dense metal produced from powder, i.e. complete absence of macro-segregation and pipe-related defects. A further merit of the process is that by injecting fine refractory powder particles, i.e. by entraining them in the atomising gas stream, ODS material can be deposited.
Figure 23.12   *Properties of dispersion-strengthened copper (C15715 and C15760 are compositions made by SCM Metal Products)*

23.15   Injection moulding

Commonly referred to as PIM (powder injection moulding), this process consists of mixing small ≤20 μm metal powder with a thermosetting polymer material to form a plastic mass that can be injected under pressure into a mould to form the equivalent of a compact. The compact is then carefully treated by solvents and/or heat to remove the polymer and then at a higher temperature to sinter the powder. Shrinkage of the order of 15% linear occurs but this can be predicted accurately and parts with very close dimensional tolerances and of quite complex shape can be made. It is widely used process because the advantages in eliminating expensive machining operations make it viable for a number of applications.

Unlike traditional powder metallurgy, the metal powder injection moulding route is followed by high temperature sintering. As a result, the sintered alloys are essentially full density, giving superior

23.16   Hardmetals and related hard metals

This family of PM materials consists of fine, hard, and usually brittle carbide particles bonded with a relatively tough binder phase which is normally metallic. The hard particles are generally between 1 and 5 µm, but even finer grades with particles below 1 µm are now being made. The original hard phase was tungsten monocarbide (WC) and the preferred binder phase was cobalt. The name *cemented carbide* was, and to a large extent still is, used to describe these materials. Carbides other than that of tungsten were later added, e.g. those of tantalum, niobium, and titanium, and binder metals other than cobalt have been used, but the WC/Co-based compositions still have the lion's share of the market. More recently, products have been developed in which the hard phase is not carbide, but nitride, boride, carbo-nitride, oxide, or combinations of these.

Uses

Hardmetals were originally developed as a substitute for diamond as wire drawing dies for tungsten, and they are still used for that purpose, but the largest single use today is as cutting tools and oil drilling or mining tools. It is for this application that the non-carbide alloys have been developed, but no cost effective substitute has been found for the WC/Co hardmetal where straightforward wear resistance is the primary requirement, and this includes cutting tools for non-ferrous metals and non-metallic materials. Other such cases are wire drawing dies, dies for the compaction of metal powders for the manufacture of PM parts, rolls for metal rolling mills, and other large abrasion-resistant parts.

Manufacture

The process for the production of hardmetal is a classic example of liquid phase sintering: a mixture of WC and cobalt powders is pressed and sintered at a temperature above the eutectic temperature. Good results require special procedures in the preparation of the powder mix. The ingredients are wet milled together to coat each carbide particle with cobalt, and to facilitate this, the cobalt powder must be extremely small. It is well known that very small powders do not flow readily, if at all, and to overcome this problem the WC/Co mixture is 'granulated', by which is meant the production of agglomerates. A favoured method of granulation is the spray drying of a slurry of the powder with a liquid containing also a pressing lubricant. Injection moulding is now being used to replace die compaction, because of the greater shape complexity and higher final tolerances. During sintering, the compact shrinks by as much as 50 vol% to become nearly 100% dense. The sintering temperature used in practice varies with the composition, being lowest (1400°C) when the cobalt content is high, and rising to 1600°C or higher with compositions having high proportions of the carbides of Ti, Ta, and/or Nb and low cobalt contents. In cases where it is not possible to get close to the required shape by direct pressing and sintering, the compact may be pre-sintered at a lower temperature so as

to remove the lubricant and provide sufficient strength for handling. In this state, the object can be machined using tools of bonded diamond or other hard material.

Although it is usual to refer to the binder phase as being cobalt there is some mutual solubility between it and the carbide, and great care is needed to ensure that the carbon balance is maintained such that neither the brittle W/Co (eta) phase nor free graphite is formed. The toughness is affected also by the size of the carbide particles; the finer they are the harder but less shock-resistant is the final product. However, grades with carbide particle size well below 1 μm are reported to combine high hardness with toughness.

Hot isostatic pressing

Although the porosity of conventionally produced hardmetal is normally low, porosity can be completely eliminated by hot isostatic pressing (HIP). Toughness is, thereby considerably increased and the possibility of the rejection of large and expensive components at a late stage of grinding or polishing no longer presents a problem. HIP is now routinely applied to a large number of hardmetal parts including indexable cutting tool tips that are a major product. Recently it has been found possible to combine HIP with the sintering stage. The parts are sintered in vacuum to a density such that the porosity is sealed, and then high pressure gas, usually argon, is introduced into the furnace. The pressure required for full densification is lower than that needed for the HIP of already sintered parts, and the new process, referred to as Sinter-HIP or Pressure-Assisted Sintering is rapidly replacing the original two-stage process of vacuum sintering followed by HIP in a separate furnace, at least for cutting tool tips.

Compositions

Straightforward WC/Co hardmetal appears to be the most cost-effective material for many applications where wear resistance is the primary requirement, including the machining of non-ferrous metals. Additions of e.g. TaC improve the already good wear resistance by acting as grain growth inhibitors, and are especially valuable in applications involving high temperatures. When the use is the machining of ferrous materials at high speeds, the situation is different. In addition to abrasive wear, reaction between the carbide particles and the steel results in what is known as crater wear. The substitution of more stable carbides such as those of Ta, Nb, Ti, and Hf for some or all of the WC considerably improves the cratering resistance. Wear resistance is, as would be expected, markedly influenced by the amount of binder phase as shown in Figure 23.14, but reduction in the cobalt content also makes the alloy more brittle, so a compromise between toughness and wear resistance is necessary.

Table 23.22 gives compositions and properties of one manufacturer's range. Table 23.23 lists the ISI classification of carbides according to use.

Alternative binders

Because of the high price of cobalt and the perceived instability of the countries that produce the bulk of it, continuing efforts have been made to find alternatives. Ni, Fe, and Ni/Mo have been used successfully in certain applications, and a recent entry into the field is Ni/Cr which now appears in some commercial grades. One grade is based on TiC with MoC and a Ni/Mo binder. Good results have been reported also with intermetallic and superalloy binders, which combine conspicuous high-temperature strength with toughness. Useful results have been reported also with a nickel binder containing ruthenium, but this member of the platinum group is costly.

Coatings

For tools for the machining of steels the most dramatic improvement has been the development of surface coatings. An ideal tool material from the cutting point of view would be a pure, very hard, and stable compound such as one of the more stable carbides, nitrides, or oxides, were it not for the fact that they are far too brittle. However, if they are applied as a very thin layer to a sufficiently strong and tough substrate, an approximation to the best of both worlds is possible. Such coatings can be applied successfully by chemical vapour deposition (CVD) or physical vapour deposition (PVD). Titanium nitride, TiN, is widely used and gives the tool a striking gold colour. An essential requirement, of course, is that the coating adheres firmly to the substrate and this is facilitated by using multiple coatings only a few micrometres thick. Another factor in the equation is the possibility of reaction between the coating and the substrate and between the coating and the steel workpiece. In addition to nitrides, carbides, carbo-nitrides, borides, and oxides—especially alumina—are used, and as many as ten layers are applied, so the permutations are manifold. Recent additions to the range of coatings are cubic boron nitride (CBN) and diamond, but the latter is not suitable for the high-speed cutting of steel because it reacts with the steel at the high temperatures that are reached. The importance of matching the tool to the application should be emphasised.

Tool life

In cutting applications much is made of the improved tool life of modern throw-away inserts achieved by careful design of substrate and coating, but a more important factor from the economic point of view is the improved cutting speed that is made possible. The cost of the tool insert is a small part only of the total machining cost, and if the cutting rate can be doubled and the tool life halved in consequence, the overall efficiency may well be much greater than that of prolonging the life of the tool.

23.17 Novel and emerging PM materials

Besides the traditional PM materials, largely dominated by WC-Co, iron and steel, and refractory metals, several useful and exotic materials are emerging with unique properties only available via sintering techniques. Many of these are targeted at applications such as sporting equipment, computer or electronic components, sensors and instruments, and military components. Sintering is performed at high temperatures for most of these applications to improve the density and properties. High sintering temperatures induce more rapid atomic motion, resulting in properties that rival wrought materials. Further, new compositions are possible via sintering that cannot be fabricated via alternative techniques such as casting. A good example of the latter is seen with the tungsten heavy alloys. The properties of several liquid phase sintered heavy alloys are given in Table 23.24. These are formed

by mixing tungsten, molybdenum, nickel, iron, or copper powders. The mixed powders are shaped by die compaction, cold isostatic pressing, or injection moulding, and then sintered at temperatures near 1500°C to give over 99% of theoretical density. The composite sintered microstructure consists of hard tungsten grains in a matrix of solidified liquid that provides toughness. These alloys find uses in projectiles, heat sinks, weights, and computer disk drives.

A related application are for liquid phase sintered composites relates to the need for high thermal conductivity and low thermal expansion in microelectronic packaging applications. These are for heat dissipation around semiconductors where computing performance is degraded by heat. For these applications, the nickel-iron matrix phase in the heavy alloys is replaced by copper to improve thermal conductivity. If weight is not an issue, then the W–Cu composites are the best combinations of properties, but as weight becomes more of a concern then Mo–Cu and Al-based compositions are more popular. However, as illustrated in Table 23.25, these latter alloys suffer with respect to thermal conductivity when compared to the W–Cu alloys.

Finally, another emerging area for sintered metals is in magnetic applications. Several alloys are available, ranging from pure iron for soft magnetic uses to iron-neodymium-boron rapidly solidified materials for hard magnetic applications. Table 23.26 gives a tabulation of the magnetic properties available from some of the most popular alloys.

24   Lubricants

24.1   Introduction

Lubricants minimise friction and wear in rubbing contacts by reducing metal–metal contact, removing wear debris, and carrying away frictional heat. They may also prevent rusting and with liquid lubricants remove heat. Lubricants may be solid, such as graphite, molybdenum disulphide, polytetrafluoroethylene and talc; or gaseous, commonly air; but the principal lubricants are liquids such as mineral oil, or the semi-solid greases formed from liquids by the use of thickening agents.

24.1.1   Main regimes of lubrication

HYDRODYNAMIC LUBRICATION (HL)

A viscous fluid film between two solid surfaces moving in very close proximity to one another becomes pressurised and holds those surfaces apart, often against considerable loads. During the process, the surface may be deformed elastically (EHL – elastohydrodynamic lubrication) or plastically.

HYDROSTATIC LUBRICATION

In this case, two solid surfaces are separated by a thick fluid film supplied from an external pressure source, e.g. by an oil pump system.

BOUNDARY LUBRICATION

When the contact of asperities on sliding couples increases as the load increases, the sliding speed decreases or the fluid viscosity decreases, the friction significantly increases and the load is mainly supported by the asperity contact. Such lubrication condition is known as boundary lubrication.

MIXED LUBRICATION

This is the situation when several lubrication modes, such as HL and boundary lubrication, coexist.

24.2   Lubrication condition, friction and wear

In hydrodynamic lubrication friction is purely viscous and is directly dependent on the area of the film, the rate of shear and the viscosity of the lubricant. Coefficients of friction are as low as 0.001–0.003 and wear is negligible. When the speed of sliding and the oil viscosity are insufficient for the viscous film to carry the load, contact occurs between asperities on the opposing surfaces. Friction then rises and wear ensues. Where viscous effects are absent or negligible, lubrication is independent of the nominal area of contact and is said to be of boundary type. Where boundary and viscous effects occur together, the conditions are said to be those of 'mixed' lubrication.

When sliding speeds are very low a 'stick-slip' or jerky motion arises due in part to the elastic response of the drive and in part to the coefficient of static friction exceeding the coefficient of

dynamic friction. This undesirable effect can be suppressed by the use of special lubricants containing fatty acids, acid phosphates, or similar materials able to react with the metal surfaces to produce soft, easily-sheared layers of soap which considerably reduce the coefficient of static friction.

For moderate sliding speed and load, boundary lubrication can exist with only the oxide film being worn away and replaced at a tolerable rate of wear. Under these conditions lubricants which produce low friction do not necessarily produce low wear. For most machine bearings, boundary lubrication is inadequate, since the oxide film wears away very rapidly and direct metal to metal contact occurs. The surface asperities weld together momentarily and are broken apart again to produce wear debris largely composed of metallic particles. This is called adhesive wear, or scuffing.

Boundary lubrication is the most important mode in the chipless-forming type of metal working operation since the local pressures have to be high enough to exceed the yield strength of the metal. In such operations the surface area of the workpiece is being enlarged and new, easily-weldable areas are being created. For severe operations, therefore, solid lubricants are used which can resist high pressures and are capable of extension to cover the new areas. Examples of such lubricants are waxes, graphite, molybdenum disulphide, talc, whiting and pastes of dry soap and fats. For more severe operations such as tube and bar drawing thick layers of lubricants may be built up before the operation by, for example, phosphating, baking on a coating lime, treating with special inorganic salts, or by coating with soft metals such as lead.

24.3   Characteristics of lubricating oils

24.3.1   Viscosity

Viscosity is probably the most important property of a lubricating oil or grease. For most fluids in laminar flow there is a linear relationship between the shear stress and the rate of shear. The constant of proportionality is the viscosity or, more specifically, the dynamic viscosity to distinguish it from the kinematic viscosity which is given by the ratio of viscosity to density.

Dynamic viscosity may be defined as the shear stress necessary to move a flat surface at unit speed over a parallel surface unit distance apart when the intervening space is filled with the fluid. In SI units, dynamic viscosity is expressed in $N\,s\,m^{-2}$, but the centipoises or $nN\,s\,m^{-2}$ is at present commonly used. Direct measurements are relatively few. Usually dynamic viscosities are derived from measurement of density and kinematic viscosity, which is easily measured in calibrated glass capillary tubes using gravity flow. The units of kinematic viscosity are $m^2\,s^{-1}$ but centistokes ($1 \times 10^{-6}\,m^2\,s^{-1}$) are most commonly used. Obsolescent units such as Redwood and Saybolt seconds and Engler degrees derived originally from short efflux tube instruments are still to be found, but nowadays they are derived from measurement of kinematic viscosity with which they have almost linear relationships.

With increase of temperature, the viscosity of gases rises while that of liquids falls. A moderately viscous mineral oil falls from $1\,N\,s\,m^{-2}$ at 5°C to $0.01\,N\,s\,m^{-2}$ at 100°C. This property is commonly expressed as the Kinematic Viscosity Index (KVI) measured over the range 37.8–98.9°C (100–210°F) and expressed in values usually ranging between 0 and 100. However, a more rational Dynamic Viscosity Index, which may be measured over any convenient range, has been proposed. Oils with a KVI of 35 and below are known as Low Viscosity Index (LVI) oils, those between 35 and 80 are Medium Viscosity Index (MVI) oils, those between 80 and 110 are High Viscosity Index (HVI) oils and those over about 110 are Very High Viscosity Index (VHVI) oils.

With minerals oils and oils of similar molecular weight, viscosity is independent of the rate of shear, except possibly under very high pressures. Shear rates in elastohydrodynamic lubrication (or EHL) are said to be 'Newtonian'. Oils of very high molecular weight, such as silicones, exhibit a reduction in viscosity at quite moderate rates of shear and are said to be 'non-Newtonian'. While such loss in viscosity may be only temporary, there may also be permanent loss due to mechanical breakdown of very high molecular weight polymer molecules.

The lubricant viscosity usable in practice depends on the type of machine involved. Low viscosity oils are used for high speeds and high viscosities for low speeds. Very approximately $3\,N\,s\,m^{-2}$ is the maximum viscosity at which machines can be started up, while 0.002 is the minimum for maintaining hydrodynamic lubrication under running conditions.

24.3.2   Boundary lubrication properties

This property of a lubricant is essentially its ability to produce on one or both of the rubbing surfaces a layer of adequate thickness of coherent and adherent, low shear strength material which will minimise

metal-to-metal contact and reduce friction. Lubricants exemplifying this property under very mild, slow speed conditions are the fatty acids which produce soap layers on metals with active oxide surfaces, such as copper.

Under such mild conditions the property is often known as 'lubricity'. Under more severe conditions of load, speed and temperature, the property is known as 'Extreme Pressure' or 'EP'. As an example, free sulphur is added to cutting oils to prevent excessive tool wear with tough steels.

24.3.3   Chemical stability

Lubricants are usually required to have an effective life of some hundreds or thousands of hours during which its necessary properties are sensibly unaltered. They may, however, change in whole or part by thermal decomposition, oxidation or by hydrolysis. Thermal decomposition followed by polymerisation results in the formation of materials of very high molecular weight, especially insoluble coke-like substances, as well as low molecular weight materials including gases. The viscosity and flash point of the lubricant therefore generally drops. Similar materials are also formed during oxidation, but in addition highly oxygenated species including lacquers and organic acids are formed and the viscosity generally increases. This viscosity increase, the amount of insoluble material and the increase in organic acidity, are conveniently used as expressions of the degree of oxidation. Lubricants based on esters and lubricants containing esters or salts as components, e.g. as additives, are subject to hydrolysis and here again acidity, perhaps with a corrosion test for a sensitive metal such as lead, are used as criteria of stability.

Water-containing lubricants require particularly clean working conditions as contamination may lead to bacterial attack and thus to unpleasant odour, corrosion, and reduced effectiveness. Systems should be prepared and regularly cleaned by flushing with 5% solutions of caustic soda, detergent solutions or both. Biostats or biocides may also be helpful.

24.3.4   Physical properties

The thermal capacity of an oil is particularly important as in many cases the flow of oil is used to remove heat. Thermal capacity varies from around $2\,000\,\mathrm{J\,kg^{-1}\,K}$ for mineral oils to around $1\,500$ for silicones and triaryl phosphate esters, which compare with $4\,200\,\mathrm{Jkg^{-1}\,K}$ for water.

In general, lubricants must not evaporate rapidly at the highest temperatures of usage. At well above their maximum usable temperatures, mineral oils and similar flammable oils reach their flash points at which, in particular apparatus, the evaporation is sufficient to reach the lower explosive limit with air. High volatility is, however, occasionally desirable. In some metalworking operations, working is followed by an annealing operation and any lubricant remaining must evaporate away cleanly.

At low temperatures paraffinic mineral oils reach a lower limit of usage at the pour point. At about $-7°C$ a separate wax phase comes out of solution from the rest of the oil and at about $-10°C$ sufficient needle-like crystals form to block the flow.

24.4   Mineral oils

The most important type of oil, the mineral oils, are made from petroleum. They are abundant, are comparatively low in cost and are available in a wide range of viscosities. The fatty oils are inferior in all respects except boundary friction properties which, where required, can easily be provided by the incorporation of a low concentration of fatty material. The various synthetic oils are of growing importance and find effective use in extreme applications where some particular property or properties justifies their high price but, in general, their scale of use is very limited.

There are, broadly speaking, two types of mineral oil: paraffinic, having comparatively long alkyl side chains in the molecule and consequently high KVI, together with a 'wax' pour point; and naphthenic, having comparatively short side chains, low to medium VI and a 'viscosity' pour point. With both types a wide range of viscosity grades can be made. Low viscosity mineral oils are frequently known as 'spindle oils' from their early use in textile machinery while the more viscous oils are known as 'cylinder oils' from their use in steam engines. Grades between these two extremes are called 'light machine' and 'heavy machine' oils. These basic grades are produced by refining and intermediate grades are produced by blending.

The wide range of viscosities available is indicated in Figure 24.1 for paraffinic oils of 95 KVI to BS 4231, in which each grade is designated by its mid-point viscosity at 37.8°C (100°F) expressed in
Figure 24.1   *BS 4231 ranges for 95 KVI oils with SAE limits*
NB: Such oils normally have a pour point of approximately −10°F, but the lines have been extrapolated to
permit comparison with the SAE grades

centistokes (mm² s⁻¹). Figure 24.1 also indicates in its margins the important classification system
of the Society of Automotive Engineers (SAE), the 'W' or winter grades of which are classified in
dynamic units, the remainder in Saybolt seconds.

Oxidation stability may be significantly increased by the use of antioxidants as shown in
Figure 24.2, which indicates the life obtainable for a moderate degree of deterioration of a well
refined paraffinic oil.

Oxidised oils tend to be corrosive to active metals such as cadmium, zinc and, especially, lead
but there is no difficulty in selecting suitable materials of construction since resistant paints and
elastomers have been developed over many years.

Typical physical properties for mineral oils are given in Table 24.1 and Table 24.2. Additives are
often added to the lubricating oil to improve their performance (more information on oil additives
has been given in section 24.9).

24.5   Emulsions

For many applications, particularly in metalworking and for the provision of fire-resistant lubricants, emulsions of water and lubricating oils are used. Because their thermal capacities are close to that of water, emulsions of 1–10% oil in water are used where heat dissipation is more important than lubrication, as for instance in high speed metal cutting, in grinding and in rolling. Emulsions are also used for fire-resistant hydraulic fluids where a low cost fluid is required. The water should be clean and free from acids with hardness preferably between 15 and 50 p.p.m. $CaCO_3$ equivalent. Very soft water may cause foaming while very hard water may reduce stability and corrosion protection. Oil/water emulsions, however, cannot be used as a direct replacement for oil in conventional hydraulic systems.

Water in oil emulsions with about 40% deionised water are used as cylinder lubricants for reciprocating compressors handling oil-soluble gases and as fire-resistant lubricants to replace oil, however, the presence of water accelerates the fatigue failure of heavily loaded rolling bearings.

Emulsions are non-Newtonian. At high rates of shear their viscosities are close to that of the base oil, which is usually a spindle oil. They are not broken down by shear. Their useful life is largely limited by emulsion stability. To limit loss of water and loss of emulsion stability the maximum continuous operating temperature is about 65°C.

24.6 Water-based lubricants

Aqueous solutions, either true or colloidal, of various substances are widely used as coolants and lubricants. The water-glycol type of fire-resistant lubricants are solutions of 50–65% polyglycols, sometimes including ethylene glycol. Two or three grades between 0.03 and 0.07 N s m^{-2} at 38°C (100°F) are usually available. Their VIs are very high and pour points very low, e.g. −40°C. They are completely shear stable but operating temperatures are usually limited to 65°C in order to avoid excessive loss of water.

Solutions of corrosion inhibitors and load carrying additives are used for high speed cutting and grinding operations.

24.7 Synthetic oils

Many synthetic lubricants have been developed which have found increased use, particularly for those applications requiring their unique properties, such as for extreme temperature and fire resistance. However, high cost limits their use. In addition, environmental problems in handling and disposing of some synthetic lubricants are also an issue.

24.7.1 Diesters

These were developed principally for aviation gas turbines because of their very high VI, and low pour point gives them a wide range of usage while the susceptibility to antioxidants allows them to work continuously at 120–150°C with bearing temperatures up to 250°C.

The load carrying capacity of the diesters in spur gear rigs is about twice as high as that of equiviscous mineral oil; under boundary conditions they appear to be equal to mineral oil while in heavily loaded ball and roller bearings the diesters appear to provide somewhat superior protection against surface fatigue.

24.7.2 Neopentyl polyol esters

This group, based on neopentyl alcohols and mixed aliphatic acids, has significantly better thermal stability and the possibility of rather higher viscosity (0.002–0.008 N s m^{-2}) than the diesters. These esters are suitable for continuous operation at 200°C with hot spots of 275°C but at these high operating temperatures it is necessary to avoid the use of cadmium, magnesium and silver because of corrosion and to use silicone and fluorinated types of elastomers.

The load-carrying properties of the neopentyl esters are better than those of the diesters, because of their higher viscosity. They apparently do not promote surface fatigue pitting in heavily loaded ball and roller bearings.

24.7.3 Triaryl phosphate esters

These esters find their greatest use as fire-resistant hydraulic fluids in diecasting machines, and like machines, as well as in the governor systems of large steam turbines. Viscosities range from 0.0036 to 0.008 N s m^{-2} at 100°C. Their oxidation stability is good, but thermal degradation is catalysed by steel. This limits their maximum operating temperature to about 120°C. The fire-resistance is on a par with that of the water-in-oil emulsions, and is generally adequate for industrial purposes.

The hydrolytic stability of these esters is rather poor and appears to be catalysed by acid impurities or similar substances developed by initial hydrolysis. If the acidity can be kept low by filtration through fullers earth the degradation can be very greatly retarded. Hydrolysis may result in some corrosion of aluminium and steel but the phosphate esters are not corrosive to cadmium, zinc or other common metals.

Triaryl phosphate esters tend to damage conventional rubber elastomers and therefore butyl, silicone or fluorinated types are preferred. Ordinary paints are also affected and those based on epoxy resins should be used.

These esters are good lubricants under both boundary and hydrodynamic (including elasto-hydrodynamic) conditions but they promote fatigue pitting of rolling element bearings and, for a life equivalent to that when using mineral oils, a 20% reduction in load may be required.

Toxicity is largely related to the amount of ortho-tolyl isomer in the oil which is accordingly kept to a low value. Particular attention should be paid to personal cleanliness and good ventilation wherever people come into contact with these oils.

24.7.4   Fluorocarbons

Usually these are polymers of trifluorovinyl chloride, the terminal groups being fluorine. The range of oils with pour points below 20°C is only 0.002–0.004 N s m^{-2}. Densities and volatilities are unusually high. They are exceptionally stable to strong oxidising agents such as fuming nitric acid, hydrogen peroxide, etc. Thermally, they are completely stable below 300°C and the degradation at high temperatures is depolymerisation so that carbonaceous deposits are not formed.

Fluorocarbons are non-corrosive to metals. Load carrying capacity under boundary conditions is rather better than that of equiviscous mineral oil, but they may have a lower protection against fatigue failure of heavily loaded rolling bearings.

24.7.5   Polyglycols

These oils are also known as polyalkylene glycols, polyoxyalkylenes, glycols and polyethers. The water soluble types are mainly polyethylene oxides and have high pour points and very high viscosity indices, while the mainly polypropylene oxides are water insoluble with low pour points and somewhat lower viscosity indices. A wide viscosity range is covered: from 0.008 to 19.5 N s m^{-2} at 38°C.

Polyglycols are very responsive to oxidation inhibitors and when inhibited are much more stable to oxidation than mineral oils. At about 250°C polyglycols exhibit rapid thermal decomposition, but as the products of decomposition are volatile they do not form deposits. Polyglycols are not corrosive to the usual metals, but since even the water-insoluble grades are slightly hygroscopic rust inhibited grades are preferred wherever moisture may enter the oil.

The water-soluble types have important uses as components of water-glycol type fire-resistant lubricants and automotive brake fluids and are very good lubricants under hydrodynamic and elasto-hydrodynamic conditions. Under boundary conditions they are not very good but may be provided with suitable properties by the addition of small amounts of long-chain fatty acids.

Typical physical properties of these synthetic lubricating oils are given in Table 24.3.

In summary, synthetic oils are used in place of mineral oils for the liquid phase where their special advantages outweigh their greater cost. Diesters are particularly useful where low volatility and good performance at low temperature are needed, e.g. in aircraft bearings. Polyglycols are used where good oxidation stability and good lubrication between steel and bronze are required, also for special cases where the liquid phase is required to evaporate at high temperature without passing through deposit-forming decomposition stages. Silicones are used where good stability is required at high temperatures without the conditions of load and speed being at all severe. Fluorocarbons are, however, preferred in spite of their very high cost where maximum resistance to oxidation is required, e.g. from contact with liquid oxygen or ozone.

24.8   Greases

24.8.1   Composition

The standard definition of a lubricating grease is 'A solid to semi-fluid product of dispersion of a thickening agent in a liquid lubricant. Other ingredients imparting special properties may be included.' The most common types of thickener are calcium and lithium metal soaps. Bentonite is used for high temperatures, above about 140°C. Esterified silica, vat dyestuffs and urea compounds are used for the most specialised applications.

The fatty acids of the metal soaps also influence the properties of the grease. Mixed acids from tallow, stearic acid and hydroxy stearic acid are probably the most widely used. Complex soaps formed by the co-crystallisation of two compounds permit operation at high temperatures.

A grease is usually 80–90% liquid lubricant, commonly low and medium viscosity mineral oil but high viscosity residual oils are used for high temperatures and low speeds. For special purposes, synthetic oils are used.

Additives are commonly used in greases for particular purposes as follows:

Solid lubricants	e.g. graphite, molybdenum disulphide for heavily loaded low speed applications where lubrication will be mainly of the boundary type.
Antioxidants	To prevent rapid oxidation during storage and in use.
Metal passivators	To reduce catalytic oxidation of the grease by cuprous-metals, e.g. in the cages of rolling element bearings. To prevent rusting, particularly of rolling element bearings, during storage and use.
Extreme pressure	To prevent scuffing and wear under boundary lubrication conditions, particularly those arising temporarily from shock loads.

24.8.2 Properties

The essential property of a grease is that it possesses a yield stress up to which it only deforms elastically and above which it flow plastically. When flow commences the ratio shear stress/rate of shear decreases smoothly until at shear rates in the region of 10^6 s^{-1} it closely approaches that ratio for the liquid phase of the grease, i.e. its viscosity. Above the yield stress greases are non-Newtonian liquids, and at any point the ratio shear stress/rate of shear is called its 'apparent viscosity', which is, in effect, the viscosity a Newtonian fluid would have if it exhibited the same shear stress at the same shear rate.

The significance of these properties, in relation to plain bearings is that under stationary conditions grease tends to remain in place in clearance spaces and at the ends of bearings. Thus lubricant is available immediately the machine starts up again, and grease clinging to the ends of bearings acts as a seal to exclude dirt.

Semi-fluid greases of negligible yield stress reduce leakage from gearboxes by virtue of their very high apparent viscosity at low rates of shear. They also permit feeding through long narrow bore piping, particularly at sub-zero temperatures.

The yield stress of a grease is not easily measured and for production quality control and other ordinary purposes the worked Penetration (IP 50/69, ASTM D217-C8) i.e. the depth in mm of the penetration in the grease of a special metal cone under its own weight, is used. The National Lubricating Grease Institute has classified greases according to their consistency after a specified amount of mechanical working as shown in Table 24.4.

No. 2 grade is popular since it combines satisfactory yield properties with easy pumpability, but where there are extreme vibration and shock loads a No. 3 grade is preferred. Grades more fluid than No. 0 or stiffer than No. 3 are not normally used for roller bearings. Softer grades (down to grade 000) are used for better feeding characteristics in some roller bearings and gear mechanisms.

Important properties of the thickener structure are temperature stability, resistance to water and mechanical stability. Table 24.5 lists the various types of thickeners and indicates the extent to which they have these properties.

Table 24.4 NLGI GREASE CLASSIFICATION

NLGI grade	Worked penetration range (0.1 mm)	Description	Approximate yield value, Pa
000	445–475	Very fluid	0
00	400–430	Fluid	90
0	355–385	Semi-fluid	130
1	310–340	Very soft	180
2	265–295	Soft	300
3	220–250	Semi-firm	560
4	175–205	Firm	1 300
5	130–160	Very firm	—
6	85–115	Hard	—

Table 24.6 TYPES OF ADDITIVES

Main types	Function and sub-types
Acid neutralisers	Neutralise contaminating strong acids formed for example by combustion of high sulphur fuels or, less often, by decomposition of active EP additives
Anti-foam	Reduce surface foam. Silicon polymers are often used to enhance separation of air bubbles from oil
Antioxidants	Reduce oxidation. Various types are: oxidation inhibitors, retarders; anti-catalyst metal deactivators, metal passivators
Antiwear agents	Reduce wear and prevent scuffing of rubbing surfaces under steady load operating conditions by the formation of low shear strength films on metallic surfaces to diminish friction and wear, usually including sulphur, phosphorous, zinc compounds or inorganic substances
Corrosion inhibitors	Type (1) Reduces corrosion of lead. Type (2) Reduces corrosion of cuprous metals
Detergents	Reduce or prevent deposits formed at high temperatures, e.g. in internal combustion engines
Dispersants	Prevents deposition of sludge by dispersing a finely divided suspension of insoluble material formed at low temperatures
Emulsifiers	Form emulsions either water in oil or oil in water according to type
Extreme pressure	Prevent scuffing of rubbing surfaces under shock load operating conditions mainly by formation of inorganic surface films
Lubricity	Reduce friction under boundary lubrication condition, increase load carrying capability especially where limited by frictional temperature rise, by formation of organic film. Examples are fatty acids and their esters
Pour point depressant	Reduces the temperature at which a mineral oil is immobilised by wax
Tackiness	Reduces loss of oil by gravity, e.g. from vertical sliding surfaces, or centrifugal forces
Viscosity index improvers	Reduce the decrease in viscosity due to increase of temperature Long-chain polymers are usually used in multi-grade oils

24.9 Oil additives

Plain mineral oils are used in many units and systems for the lubrication of bearings, gears and other mechanisms where their oxidation stability, operating temperature range, ability to prevent wear, etc. are adequate. The addition of fatty oils improves boundary lubrication properties at the expense of oxidation stability and demulsibility, but over the last 30 years oil-soluble chemical compounds called 'additives' have been developed which improve or confer a wide range of properties. The functions required of these 'additives' gives them their common names as indicated in Table 24.6.

24.9.1 Machinery lubricants

As shown in Tables 24.7 and 24.8 below, additives and oils are combined in various ways to provide the performance required. It must be emphasised, however, that indiscriminate mixing can produce undesirable interactions. Indeed some additives may be included in a blend simply to overcome problems caused by other additives.

Table 24.7   TYPES OF OIL REQUIRED FOR VARIOUS TYPES OF MACHINERY

Type of machinery	Usual base oil type	Usual additives	Special requirements
Food processing	Medicinal white oil	None	Safety in case of ingestion
Plain roll-neck bearings of rolling mills	HVI	None	Best demulsibility
Oil hydraulic	HVI down to −20°C MVIN below	Antioxidant Anti-rust Anti-wear Pour point depressant VI Improver Anti-foam	Minimum viscosity change with temperature Minimum wear of steel/steel
Steam and gas turbines	HVI or MVIN distillates	Antioxidant Anti-rust	Ready separation from water, good oxidation stability
Steam engine cylinders	Unrefined or refined residual or high viscosity distillates	None or fatty oil	Maintenance of oil film on hot surfaces, resistance to washing away by wet steam
Air compressor cylinders	HVI or MVIN distillates	Antioxidant, anti-rust	Low deposit formation tendency
Gears (steel/steel)	HVI or MVIN	Anti-wear EP antioxidant Anti-foam Pour point depressant	Protection against wear and scuffing
Gears (steel/bronze)	HVI	Oiliness, tackiness	Maintains smooth sliding at very low speeds. Keeps film on vertical surfaces
Hermetically sealed refrigerators	MVIN	None	Good thermal stability, miscibility with refrigerant, low floc point
Diesel engines	HVI or MVIN	Detergent Dispersant Antioxidant Acid-neutraliser Anti-foam Anti-wear Corrosion inhibitor	Vary with type of engine thus affecting additive combination

Table 24.8   CHIP-FORMING METAL WORKING LUBRICANTS

Type of lubricant	Base lubricant	Additive	Remarks
Soluble oil (oil-in-water emulsion)	LVI oil	Emulsifiers Rust inhibitors	With 20–50 parts water For grinding and light cutting operation where cooling and absence of fuming important
Aqueous cutting solution	Water	Rust inhibitors	As for soluble oil
Inactive EP cutting oil	HVI	Mild EP but no free sulphur	For cutting yellow metal and other non-ferrous alloys where good lubrication without staining required
Active EP cutting oil	HVI	Mild EP and free sulphur	For heavy cuts on tough steel

24.9.2   Cutting oils

Factors entering into the selection of cutting oils are: the material of the workpiece; the speed and nature of the operation; whether cooling is more important than lubrication; and the compatibility of the cutting oil with the machine tool.

Table 24.8 gives a very general system of lubricant selection.

Table 24.9 TYPES OF LUBRICANTS FOR DRAWING, STAMPING AND PRESSING

Metal	Lubricant in order of severity of operation
Steel	Mineral oils of medium to heavy viscosities Fatty oil/mineral oil blends Soap solutions Soap/fat pastes Baked-on-lime coatings Soft metals, e.g. lead
Brass and copper	Dilute soap solutions Light mineral oil Soap/fat pastes with solid lubricants Dried on soap
Magnesium	Colloidal graphite in low volatile mineral oils Graphite in volatile solvents
Aluminium	Oil-in-water emulsions Mineral oils, viscosity increasing with severity Mineral oil with 10–15% fatty oil

Table 24.10 ROLLING OILS

Metal	Lubricant in order of severity of operation
Steel	Oil-in-water emulsions Mineral oil/fatty oil blends and with lubricity and EP additives Palm oil
Brass and copper	Oil-in-water emulsion Mineral oil Mineral oil with lubricity additive
Aluminium	Mineral oils of viscosity from $40\,\text{mN s m}^{-2}$ at 20°C to $50\,\text{mN s m}^{-2}$ at 40°C with lubricity additives

24.9.3 Lubricants for chipless-forming

Lubricants for chipless-forming probably present a greater range of diversity than any other branch of lubrication. Table 24.9 gives the types of lubricants used in drawing, stamping and pressing.

24.9.4 Rolling oils

Lubrication is often required in metal rolling but excessive lubricity causes 'lack of bite' or roll slippage. Lubrication affects surface finish, ease of application, removal, and uniformity of adherence to the surface. Table 24.10 gives selected lubricants used in rolling.

24.10 Solid lubricants

Many mechanical components are required to work under extreme conditions, such as high or ultra-low temperatures, high loads, high vacuum, nuclear radiation, oxidative environment, etc. Fluid lubricants may not be used under such conditions. Solid lubricants therefore play an important role in lubricant engineering.

Solid lubricants provide thin films of solid between two rubbing surfaces. In order to reduce friction and wear, the solid lubricants are required to have low shear strength. Table 24.11 lists several common solid lubricants.

Table 24.11   COMMON SOLID LUBRICANTS

| Material | Usage temperatures (°C) | | | | Average friction coefficient (f) | | Remarks |
| | Minimum | | Maximum | | | | |
	In air	In vacuum or N_2	In air	In vacuum or N_2	In air	In vacuum or N_2	
MoS_2	−240	−240	370	820	0.10–0.25	0.05–0.10	Low f with high-load carrying capability; may promote metal corrosion
Graphite	−240	unstable	540	unstable	0.10–0.30	0.02–0.45	Low f with high-load carrying capability in air; corrosion resistant, stable up to 450°C, low thermal expansion; electrically and thermally conductive
PTFE	−70	−70	290	290	0.02–0.15	0.02–0.15	Lowest f with moderate load carrying capability that decreases at elevated temperatures
Calcium fluoride-barium fluoride eutectic, Ca_2–BaF_2	430	430	820	820	0.10–0.25 above 540°C 0.25–0.40 below 540°C	0.10–0.25 above 540°C 0.25–0.40 below 540°C	Can be used at higher temperatures than other solid lubricants, high f below 540°C

Soft metals are also used as solid lubricants due to their low shear strength, high thermal conductivity, good adherence to metal substrates, ability to imbed abrasive debris and to act as sacrificial components in critical or expensive machinery. Table 24.12 and Table 24.13 respectively lists some soft metals and alloys often used for lubrication purpose.

The solid lubricants can be applied in different ways, such as:

a) Add solid lubricants in the form of powder to sintered work pieces and polymeric composite components;
b) Paint or spray mixtures of solid lubricants and adhesives onto the surface of work pieces;
c) Coat work pieces with solid lubricants using electroplating (e.g. soft metals and self-lubricated composites), vapour deposition, PVD, and CVD techniques;
d) Use solid lubricants as oil additives.

25 Friction and wear

The friction and wear characteristics of materials are not intrinsic properties but, rather, depend on a large number of variables including the physical, chemical and mechanical properties of the material and surfaces and the environment.

25.1 Friction

25.1.1 Friction of unlubricated surfaces

DEFINITION

Friction is the resistance to motion when two bodies in contact slide on one another. The frictional force F is the force required to initiate or maintain motion. If W is the normal reaction of one body on the other, the coefficient of friction μ is defined as $\mu = F/W$.

STATIC AND KINETIC FRICTION

If the force to initiate motion of one of the bodies is F_s and the force to maintain its motion at a given speed is F_k, there is a corresponding coefficient of static friction $\mu_s = F_s/W$ and a coefficient of kinetic friction $\mu_k = F_k/W$. In some cases these coefficients are approximately equal; in most cases $\mu_s > \mu_k$ and there is a tendency for intermittent or 'stick-slip' motion to occur.

BASIC LAWS OF FRICTION

The two classic laws of friction, which are valid over a wide range of experimental conditions, state that:

1. The frictional force F between solid bodies is proportional to the normal force between the surfaces, i.e. μ is independent of W.
2. The frictional force F is independent of the apparent area of contact.

Friction generally comes from two main sources: adhesion and deformation including ploughing and asperity deformation.[1] The coefficient of friction may be expressed as

$$\mu = \mu_a + \mu_d$$

where μ_a and μ_d are components corresponding to the adhesion and deformation effects, respectively. Higher adhesion between the two surfaces in contact would result in larger friction. Rough surfaces could favour asperity interlocking, thus resulting in increased friction. However, if surfaces are sufficiently smooth, the adhesive force could be large due to lack of air between the surfaces in contact, leading to consequently large friction.

25.1.2 Friction of unlubricated materials

When clean metal surfaces are placed in contact they do not touch over the whole of their apparent area of contact. The load is supported by surface irregularities (asperities) which deform plastically

as the load is applied. The area of real contact is approximately proportional to the load and inversely proportional to the hardness of the surfaces.[1]

For very clean surfaces strong adhesion occurs at regions of real contact, a part of which may be due to cold-welding, and these junctions must be sheared if sliding is to take place. Thus, it is almost impossible to slide such surfaces in a vacuum and complete seizure often occurs as shown in Table 25.1. However, if the surfaces are contaminated the adhesion is much weaker because the formation of strong junctions is inhibited. For example, hydrogen or nitrogen atmospheres have little effect on in-vacuo coefficients of friction, but the smallest trace of oxygen or water vapour produces a profound reduction in friction (Table 25.1). A further reduction in the coefficient of friction often occurs at high sliding speeds, particularly at speeds sufficient to produce local hot-spots and surface melting,[4] e.g. ice at $0.1 \, \text{m s}^{-1}$ for which μ may be less than 0.1.

Friction values for metal couples in air are influenced by a number of factors. Principal ones are the tendency for formation of oxide films, the degree of deformation in sliding, the ability of oxide films to survive sliding contact and the tendency for transfer of material from one surface to the other. Table 25.2 shows the relative hardnesses of some common metals and their oxides and the load (for a spherical slider on polished surfaces) at which appreciable metallic contact occurs. For instance, the oxide on copper is not easily penetrated, whereas the very hard aluminium oxide on the soft aluminium substrate is readily shattered during sliding. Thick oxide films, such as produced by anodising aluminium, may be more protective because sliding deformation can be restricted entirely to the oxide. Similarly, with very hard metal substrates, such as chromium, the surface deformation may be so small that the oxide is never ruptured.

Coefficients of friction of a number of metals and alloys are shown in Table 25.3. It should be indicated that pick-up may occur on the surfaces in contact such that the sliding couple becomes the metal on itself. Harder materials generally have lower friction coefficients due to less mechanical interlocking, greater support of the surface oxide, and the effect of second phase such as carbides and graphite in reducing adhesion of junctions.

Very hard solids often have low coefficients when sliding on themselves or other materials because of the reduced asperity interlocking and limited surface deformation that occurs during sliding (Table 25.4).

Very low coefficients of friction may be obtained by plating hard metal substrates with thin soft metal films (Table 25.5). The substrate supports the load while sliding occurs within the soft film which has low shear strength. Typical film thicknesses are 1 to $10 \, \mu\text{m}$. The friction of materials

changes with temperature largely due to changes in adhesion, mechanical behaviour, phase transformations, and the formation of oxide film. If there are not considerable changes in these factors with temperature, change in the friction of materials may not be significant (Table 25.6).

It needs to be pointed out that large fluctuations in μ may exist, due to the fact that friction is influenced by many factors such as roughness, temperature and surface deformation, which may significantly vary during sliding. However, μ values given in the tables reflect general friction behaviour of the sliding couples and can therefore be used as references.

Compared to that of metals, the friction of ceramic materials is relatively low. Ceramic materials generally have very limited slip systems and low adhesion due to the nature of their ionic or covalent bonds. These factors make ceramic materials never have very high coefficients of friction (Table 25.7). The friction coefficient of ceramic materials may be similar to the values of metallic materials with oxide films sliding in air. It should be indicated that the surfaces of many ceramics are susceptible to tribochemical reaction. Atmospheric composition and temperature may lead to variations in the friction coefficient of ceramics (Table 25.8).

The friction of many materials is little affected by high or low temperatures (see Table 25.7). Exceptions are when the plastic flow pressure changes significantly or when oxide films become very much thicker.

The friction behaviour of polymers differs from that of metals in three respects. First, the coefficient of friction tends to decrease with increasing load; it also tends to decrease if the geometric contact area is decreased. Second, if the surfaces are left in contact under load the area of true contact may increase with time because of creep and the starting friction may be correspondingly larger. Thirdly, the friction may show changes with speed which reflect the visco-elastic properties of the polymer but the most marked changes occur as a result of frictional heating. Even at speeds of only a few m s^{-1} the friction of unlubricated polymers can rise to very high values. On the other hand at extremely high speeds the friction may fall again because of the formation of a molten lubricating film. Table 25.9 lists friction coefficients of some polymeric sliding on various materials.

The main effect of speed of sliding is an increase in local temperature caused by frictional heating at the regions of real contact. Local hot-spots may produce phase changes or alloy formation at or near the sliding interface, they may greatly change the rate of surface oxidation and even produce local melting. At speeds of a few m/s these effects are not as marked as those at very high speeds (see Table 25.10) but may still be significant. At very high sliding speeds the friction generally falls off because of the formation of a very thin molten surface layer, which acts as a lubricant film.[2] Although this is, broadly speaking, the main trend, other factors may considerably change the behaviour. For example, with steel sliding on diamond the friction first diminishes and then increases, because at higher speeds the steel is transferred to the diamond so that the sliding resembles that of steel on steel. In some cases the metals may fragment at very high speeds, particularly if they are of limited ductility. Again, if appreciable melting occurs the friction may rise at high speeds because of the viscous resistance of the liquid interface: this occurs with bismuth.

25.1.3 Friction of lubricated surfaces

DEFINITIONS

When moving surfaces are separated by a relatively thick film of lubricant the resistance to motion is entirely due to the viscosity of the interposed layer. The friction is extremely low ($\mu = 0.001 \sim .0001$) and there is no wear of the solid surfaces. These are the conditions of hydrodynamic lubrication under which bearings operate in the ideal case. If the pressures are sufficiently high or the sliding speeds sufficiently low the hydrodynamic film becomes so thin that it may be less than the height of the surface irregularities. The asperities then rub on one another and are separated by films only one or two molecular layers thick. The friction under these conditions ($\mu \approx 0.05$ to 0.15) is much higher than for ideal hydrodynamic lubrication and some wear of the surfaces occurs. This type of lubricated sliding is called 'boundary' lubrication.[24] Under boundary conditions as for unlubricated surfaces the frictional resistance is proportional to the load and independent of the size of the surfaces.

In certain circumstances a further type of lubrication, known as elastohydrodynamic lubrication, may obtain. It arises in the following way.[25–28] Under conditions of severe loading the moving surfaces may undergo appreciable elastic deformation: this not only changes the geometry of the surfaces, it also implies that very high pressures are exerted on the oil film. The main effect of this is to produce a prodigious increase in the viscosity of the oil. For example at contact pressures of 30, 60, 100 kg mm^{-2} (such as may occur between gear teeth of hardened steel) the viscosity of a simple mineral oil is increased by 200, 40 000 and 1 000 000 fold respectively. Thus the harder the surfaces are pressed together the more difficult it is to extrude the lubricant. Consequently effective lubrication may obtain under conditions where it would normally be expected to break down.

In general, elastohydrodynamic lubrication becomes effective when the oil film thickness is of the order of 10^{-1}–1 μm. This is very much thicker than the boundary film (1–10 nm) but it is very small in engineering terms. Consequently for practical exploitation of elastohydrodynamic lubrication the surfaces must be very smooth and carefully aligned.

25.1.4 Boundary lubrication

Boundary lubricants function by interposing between the sliding surfaces a thin film which can reduce metallic interaction and which is, in itself, easily sheared. The latter criterion restricts boundary lubricants almost exclusively to long chain organic compounds, e.g. paraffins, alcohols, esters, fatty acids and waxes. Radioactive tracer experiments show that while a good boundary lubricant may reduce the friction by a factor of about 20 (from $\mu \approx 1$ to $\mu \approx 0.05$) it may reduce the metallic transfer by a factor of 20 000 or more. Under these conditions the metallic junctions contribute very little to the frictional resistance: the friction is due almost entirely to the force required to shear the lubricant film itself. For this reason two good boundary lubricants may give indistinguishable coefficients of friction, but one may easily give 20 times as much metallic transfer (i.e. wear) as the other. Thus with good boundary lubricants the friction may be an inadequate indication of the effectiveness of the lubricant.

Most boundary lubricants are used as additives, dissolved as a few per cent in a mineral oil: they provide lubrication by adsorbing from solution on to the surfaces. As the temperature is raised the film may dissolve into the superincumbent fluid and lubrication may become ineffective at temperatures appreciably below the melting point of the film itself. The breakdown temperature depends on solubility and concentration, as well as on speed, load, and surface roughness.[29]

With more protracted heating, oxidation of the lubricant occurs and the behaviour is now determined by the properties of the oxidation products themselves. In the early stages these may be beneficial but later they lead to polymerisation, gumming and the formation of other deleterious products. The effect of lubrication on friction of some metallic materials is demonstrated in Tables 25.11–25.14.

25.1.5 Extreme pressure (EP) lubricants

Even the best boundary lubricants (e.g. long-chain acids or soaps) cease to provide any lubrication above about 200°C. Since localised hot-spots of very much higher temperature are often reached in running mechanisms it is necessary to use surface films that have a high melting point and which, as far as possible, possess a low shear strength. One obvious method is to coat the metal with a thin film of a softer metal. These films are effective up to their melting point but are gradually worn away with repeated sliding. Other materials which are very effective are listed in Table 25.15.

Another approach is to form a protective film *in situ* by chemical attack, a small quantity of a suitable reactive compound being added to the lubricating oil. The most common materials are additives containing sulphur or chlorine or both. Phosphates are also used. The additive must not be too reactive, otherwise excessive corrosion will occur. The results in Table 25.16 are based on

laboratory experiments in which metal surfaces were exposed to H_2S or HCl vapour and the frictional properties of the surface examined. The results show that the films formed by H_2S give a higher friction than those formed by HCl: however in the latter case the films decompose in the presence of water to liberate HCl and for this reason chlorine additives are less commonly used than sulphur additives.

The detailed behaviours of commercial additives depend not only on the reactivity of the metal and the chemical nature of the additive but also on the type of carrier fluid used (e.g. aromatic, naphthenic, paraffinic). Further, the chemical reactions which occur are far more complicated than originally supposed.

The differences in friction are not very marked showing that the friction is a very poor criterion of the effectiveness of an EP lubricant. Marked differences in seizure-preventing properties are often accompanied by almost indistinguishable coefficients of friction. The last four lines of the table also show that EP effectiveness depends to some extent on the nature of the base oil.

25.2   Wear

DEFINITIONS

Wear is the progressive loss of substance from the operating surface of a body occurring as a result of relative motion at the surface. Wear is usually detrimental, but in mild form may be beneficial, e.g. during the running-in of engineering surfaces. The major types of wear are abrasive wear, adhesive wear, erosive wear, fretting and corrosive wear. Abrasive wear is wear by displacement of material caused by hard protuberances or particles. Adhesive wear is, strictly, wear by transference of material from one surface to another due to the process of solid-phase welding. Erosive wear is loss of material from a solid surface due to relative motion in contact with a fluid which contains solid particles impingement by a flow of sand, or collapsing vapour bubbles. Fretting is a wear phenomenon occurring between two surfaces having oscillatory motion of small amplitude and is used, frequently, to include fretting corrosion, in which a chemical reaction predominates. Corrosive wear results from synergistic attack of wear and corrosion. The wear rate could be much higher than that caused by either wear or corrosion only.

25.2.1   Abrasive wear

Abrasive wear is caused by asperities of surfaces in contact that move in opposite directions (two-body abrasion) or by particles existing between two surfaces moving in opposite directions (3-body abrasion). Abrasion rates vary considerably for abrasives of different hardness, size, and shape. Wear rates increase approximately linearly with increase in applied load per unit area, up to loads at which extensive failure of the abrasive occurs. Figure 25.1 shows the major effect of relative hardness of the worn surface and abrasive on volume wear rate. Relative wear rates in practice may vary over a wide range, as shown in Tables 25.18–25.22. The wear resistance generally increases as the material hardness increases, except when materials are hardened by prior plastic deformation that decreases the strain at fracture. Archard's wear equation is often used to estimate the wear rate of engineering materials,[1] which states that the volume loss (V) of a material due to wear is inversely proportional to its hardness (H) while proportional to the normal load (L) and the distance slid (S), that is:

$$V = K \frac{L \cdot S}{H}$$

where K is a dimensionless constant known as the wear coefficient.

It should be indicated that for highly elastic materials the hardness only plays a partial role in resisting wear. The wear resistance of the materials also benefits from their elastic behaviour. Examples include pseudoelastic TiNi alloy and tool steels,[30] whose wear behaviour deviates from Archard's wear equation.

Since the hardness plays a predominant role in resisting wear for most engineering materials, surface modification through diffusion processes, surface alloying, and coating is often used to harden surfaces for enhanced wear resistance. Table 25.23 lists various processes of surface treatment.
Figure 25.1   *Effect of abrasive hardness on wear rate of metallic materials and ceramics worn on* 80–400 μm *commercial bonded abrasives under an applied stress of* 1 MN m^{-2} (*Reproduced from the Fulmer Materials Optimiser by permission of Fulmer Research Institute Ltd.). Refs* [31–33]

25.2.2   Adhesive wear

Adhesive wear involves the contact and interaction of asperities on two surfaces with strong adhesive force. Adhesive wear is promoted by two major factors:

1. The tendency for different materials to form solid solutions or intermetallic compounds with one another. Thus, material combinations of different crystal structure and chemical properties tend to have lower adhesion. Low adhesion may result in low wear rate and friction, provided that other properties and surface geometries are the same. Figure 25.2 illustrates the tendency of metal couples to adhere together.
2. The cleanliness of the surface. Cleaner surfaces are more likely to bond together. Surfaces having a thick and adherent oxide film have low wear. Stainless steels and nickel alloys that do not form thick oxides have poor adhesive wear resistance.

  Reproduced by courtesy of Fulmer Research Institute Ltd.

In metal-to-metal wear, two forms of wear debris are often observed; at very high loads the debris is mainly oxide, but at intermediate loads it is metallic. The transition from oxidative to metallic wear is accompanied by a rapid increase in wear rate. The transition load varies for different materials, microstructures, sliding speed and environment. Thus, wear rates of materials vary by several orders of magnitude (Table 25.24).

25.2.3   Erosive wear

Erosive wear due to the impact of a stream of solid particles is largely dependent on the size, hardness, velocity and angle of impact of the particles. Wear rate generally increases with increasing particle size, angularity, hardness and impact velocity. For strong and tough materials the maximum wear rate occurs at an impact angle of about 30°, but for hard and brittle materials it occurs at an impact angle of about 90° and for tough and elastic materials such as rubber, the maximum wear rate occurs at an impact angle close to 0° (Figure 25.3). The performance of selected materials in erosion are given in Tables 25.25 and 25.26.

Cavitation erosion is wear resulting from localised high impact stresses when bubbles within liquid collapse at or close to a solid surface. During cavitation erosion, corrosion could be involved. The cavitation erosion resistance of a range of materials is given in Table 25.27.

Ease and convenience of replacement	*Typical fields of application*	*Remarks*
Usually convenient with good design to facilitate replacement.	Cast irons are very suitable materials to resist medium to high stress abrasive wear due to their good wear resistance and reasonable cost. At very severe levels of impact abrasion, however, inadequate toughness can be a problem and only materials of the work-hardening type should be used. Also cheaper materials may be preferred due to the excessively high wear rates involved.	These materials have the merit that a combination of strength i.e. toughness and hardness, may be readily obtained by varying the alloying method of manufacture, and treatment; thus giving suitable combinations of these properties to suit a particular application and wear situation. Various techniques of surface hardening can also be employed to improve resistance to abrasive types of wear. Other products are sintered metals and metal coatings, e.g. Cr plate and sprayed coatings.
Usually convenient with good design to facilitate replacement.	Due to the very large quantity production involved, steels tend to be comparatively cheap. Thus steels with low wear rates become a competitive materials choice. Their main application lies in hardened steels to resist medium stress abrasion as very low wear rates can be obtained. Austenitic manganese steels can be used in more severe situations due to their work-hardening capability.	
Replacement can be difficult if applied *in situ*. These materials are often chosen because hard weld may be built up and worn away several times to its total depth under severe wear situations.	For medium and high stress abrasion hard-facings give low wear rates generally, and so are used in many situations to resist abrasive wear, e.g. excavator teeth and other earth moving applications.	

25.2.4 Fretting wear

Fretting wear occurs when two contacting surfaces are subject to very small oscillatory slip (of no more than 150 μm). Damage occurs when oxide films are disrupted locally, and may proceed by continuous formation and removal of the oxide, by the abrasive action of the oxide or by localised formation and failure of metal-to-metal adhesive bonds. The rate of fretting wear is normally very low—about 0.1 mg per 10^6 cycles, per MN m^{-2} normal load, per μm amplitude of slip for mild steel. However, localised cyclic stresses may enhance fatigue crack initiation, causing up to 80% reduction in fatigue strength.

Fretting damage is reduced by eliminating slip (by increasing the contact pressure or separating the surfaces) by lubrication (to separate surfaces and wash away debris) and by surface treatments such as electrodeposits of soft metals or chemical conversion coatings of phosphate and sulphidised coatings on steels and anodised coatings on aluminium alloys.

25.2.5 Corrosive wear

Corrosive wear is encountered in various industries. The synergistic attack of wear and corrosion may result in a significantly high wear rate. In such a wear mode, highly wear resistant materials, such as metal-matrix composites, may perform poorly. The microstructural inhomogeneity accelerates

Table 25.18b COMMONLY USED MATERIALS FOR ABRASIVE WEAR RESISTANCE

Type of material	Typical commercially available materials	Wear rates relative to 0.4% C low alloy steel quenched and tempered to about 500 Vickers hardness				Ease and convenience of replacement	Typical fields of application	Remarks
		Sliding wear by coke	Sliding wear by blast furnace sinter	Impact wear by blast furnace sinter	Wear on commercial bonded 384 μm flint abrasive			
Ceramics	Fusion cast 50% Al_2O_3, 32% ZrO_2, 16% SiO_2	0.1—0.2	~0.2	0.6	—	Convenient if ceramic is bolted in place. Less convenient if ceramic is fixed by adhesive or cement as long curing times may lead to unacceptably long down-times.	Possible to achieve very high hardness but brittleness tends to be a problem. Most suitable to resist low stress abrasion by low density materials and powders.	—
	Sintered 95–99% Al_2O_3	—	~0.2	~0.7	0.04–0.3			
	Reaction Bonded SiC	—	6.9	—	~0.02			
	Cast basalt	0.9	0.9	—	~3			
	Tungsten carbide/6% Co	0.07	—	—	0.007			
Glass	Plate glass	4.5	—	—	22	Used in sheet form where transparency is required.	Glass is brittle and so it is only used at the lowest levels of abrasive wear.	—
Concretes	Aluminous cement-based concrete with proprietary aggregates	3.5	15	—	—	Long curing times can lead to unacceptably long down-times. Can be messy and difficult under dirty conditions.	Useful to resist wear of irregularly shaped components and when abrasion is of low to medium stress.	Also useful in large flat areas, especially when curing time is no real problem, e.g. aircraft hanger flooring, etc.
	As above with 2% by volume 25 × 0.4 mm diam. wire fibres	—	—	2	—			
	Concrete tile—6 mm wear resistant surface	—	6.7	—	—			
Elastomers	Wear resistant rubbers, 55°–70° shore hardness	7.8	—	—	—	Bonded and bolted. Sticking with adhesive can be difficult under dirty conditions.	Very useful to resist impact abrasion—most wear resistant at 90° impact angles. Softer types of rubber are used for low stress impact abrasion. Resilient rubber for more severe impact.	Bonding of rubber to component is a very large problem in high stress abrasive wear. Good anti-sticking properties and low density.
	65° shore hardness rubber with saw tooth surface profile	15.1	—	—	—			
Plastics	Polyurethane	18.5	2.7	—	—	Usually used in sheet form. Difficult to bond plastic to component. Solid moulded components are superior but are limited to small sizes.	Low coefficient of friction, good anti-sticking properties. Best for low stress abrasion by fine particles. Resin bonded aggregates are trowellable and so are useful to resist wear or irregulary shaped components.	Composite plastics are only as tough as their bonding matrix and therefore find more applications where low stress abrasion by powders or small particles takes place.
	High density polyethylene	15.5–31	—	—	—			
	Epoxy resin based PTFE	40	—	—	—			
	Calcined bauxite filled epoxy resin	11	—	—	—

Hardfacing overlays: WC/Ni alloy WC/Co	Steel	1 000–50 000	600–1 800

the material dissolution, particularly at interphase boundaries, thus resulting in break-away of the reinforcing hard particles from the matrix and consequent high wear rate. Under corrosive wear attack, corrosion-resistant materials such as stainless steel may be as ineffective as carbon steel. Since the protective passive film is continuously damaged by wear during such a process, passive materials may lose their resistance to corrosion attack and thus perform poorly during corrosive wear. However, if the mechanical properties of the passive film and its bond to the substrate are improved, corrosive wear of the materials can be decreased.[51,52]. Table 25.28 lists wear rates of selected materials in a H_2SO_4 slurry.

Although the synergism of wear and corrosion has not yet been completely understood, general guidelines are available for selecting suitable materials against wear in corrosive environments:

a) Severe wear and minor corrosion:
In this case, one may choose hard materials, such as composites and precipitation-hardened alloys that have high resistance to mechanical wear.

b) Severe corrosion and minor wear:
Since corrosion is the major factor responsible for the material loss, corrosion-resistant materials such as stainless steel may therefore be an adequate choice. Although they may not perform

as well as they do under pure corrosion attack, rapid re-passivation capability or high intrinsic
resistance to electrochemical attack is beneficial to their resistance to surface failure under
such a condition.

c) Severe wear and severe corrosion:
   Under such a wear condition, one may select materials that have high strength with less
   microstructural inhomogeneity. Solution-strengthened materials having high electrochemical
   potential (i.e. intrinsically resistant to corrosion) could be suitable candidates.

d) Minor wear and minor corrosion:
   In this case, there are no particular requirements for selecting materials.

	Ti CP with medium interstitial content	DTD 5273	0.7	Low density. High cost
Cast irons and cast steels	Martensitic stainless	Hardened	1.8	Stainless steels are reasonably
	Austenitic stainless	Annealed	0.8	corrosion resistant.
	Ferritic stainless	Annealed	0.77	Martensitic stainless
	SG cast iron	Tempered	0.7	steels are less corrosion resistant

Table 25.27 RESISTANCE OF VARIOUS MATERIALS TO CAVITATION EROSION—*continued*

Range of materials	Typically used materials		High intensity relative cavitation erosion resistance (Aluminium bronze = 1)	Remarks
	Material type	Specification		
	Martensitic stainless	Tempered	0.5	than austenitic
	Alloy cast iron (D2 Ni-resist)		0.2	stainless steels
Wrought steels	HT low alloy	Hardened En24	2.5	
	Martensitic stainless	Tempered En57	0.67	
	Martensitic stainless	Tempered En56	0.62	
	Austenitic stainless	Annealed En58J	0.5	
	Mild steel	En1A	0.2	
Stellites (cobalt alloys)	Stellite 12 (cast)—29% Cr 9% W 1% C		19.3	Most resistant to high cavitation erosion
	Stellite 4 (cast)—31% Cr 14% W 1% C		15.0	
	Stellite 6 (cast)—26% Cr 5% W 1% C		5.3	
	Stellite 6 (wrought)		3.4	
	Stellite 7 (cast)—26% Cr 6%W 0.4%C		2.5	
Plastics	Nylons, acetals, high impact polyethylenes		1.7–3.0	Values of cavitation erosion resistance fall at sharply elevated temperatures. Generally, plastics with high impact strengths have good cavitation erosion resistance. Very suitable for mass manufacture of small components, e.g. boat propellers. Corrosion resistant.
	Polyethylenes Polypropylenes		0.9–1.6	
	PVC PTFE		0.15–3.5	
	Chlorinated polyether		0.04–0.1	
	Perspex		0.01–0.035	
Rubbers	Bonded rubber coatings		—	Rubber requires careful preparation and application. Rubber gives satisfactory resistance to mild cavitation erosion, and where relative fluid velocities are low. Failure usually occurs at bond to components at higher fluid velocities.
	Neoprene

Table 25.28 WEAR RATES OF SEVERAL MATERIALS IN 2 wt pct SILICA SAND SLURRY IN 1 N H_2SO_4 WITH SPEED = 16 m/s[53]

Material	Wear rate (mm^3/h)	Relative wear, %	Hardness, RA
Iron	5.08	230	27.5
Fe–5Al	17.62	345	43.5
Fe–10Al	9.68	438	55.5
Fe–15Al	14.3	647	68.5
Fe–20Al	12.3	556	65.0
Fe–25Al	7.19	325	68.0
316 Stainless steel	2.38	108	41.1
A514 steel	2.21	100	62.0
20 Cr WCI	29.1	1 320	81.0
UHMWPE	0.84	38.1	67.02

20 Cr WCI: 20 Cr white cast iron
UHMWPE: ultrahigh molecular weight polyethylene

26 Casting alloys and foundry data[†]

26.1 Casting techniques*

Table 26.1   TECHNIQUES USING AN EXPENDABLE MOULD AND PATTERN

	Investment casting	*Full mould*
Equivalent terminology	Lost wax casting Precision casting	Cavity-less casting Lost foam
Pattern material	Metal Rubber } die Plastic Wax, thermoplastics, frozen mercury	Foamed polystyrene or polyurethane Foamed poly
Mould material	Silica base ceramic Slurry + stucco	Silica sand Full mould—
Binder	Ethyl silicate Magnesium or aluminium phosphate	Usually Na_2SiO_3 or resin (Furane) Lost foam—unbonded
Size range (kg)	Up to 4.5 except frozen Hg for which up to 45	Up to 5 000 in iron
Scope	Complex shapes and fine detail	One-off castings, e.g. jigs and press tools, complex shapes
Alloys cast	High temp Steel Cu base Al base alloys	iron and aluminium castings
Surface finish (CLA)	25 25–125 50–85 50–125	60–250
Minimum section for length		
25 mm	1.5 1.0 1.5 12	
150 mm	1.5 1.5 1.5 12	
Dimensional tolerance[†] ± mm		
25 mm	0.13 0.13 0.13 0.6	0.20
150 mm	0.38 0.25 0.18 2.5	0.61
Labour cost per kg	High	Low
Equipment cost per kg	High	Low
Mould material cost	High	Polystyrene pattern approximate cost one third that of wood. Low for unbonded. For other *see* Table 26.2.

* Report No. 187 *PERA*, March 1969.
R.A. Flinn, 'Fundamentals of Metal Casting', Addison–Wesley, New York, 1963.
[†] The following additional tolerances should be added if dimension chosen crosses parting line:
Sand ±0.38   Permanent ±0.38   Centrifugal ±0.25
Shell ±0.25   Plaster   ±0.25   Shaw   ±0.10 to 0.15   for a 25 mm casting.

[†] For additional alloy data, *see* Chapters 1 and 22. Fuels and furnace design are discussed respectively in Chapters 28 and 40.

Table 26.2   TECHNIQUES USING AN EXPENDABLE MOULD

	Ceramic mould casting	*Plaster mould casting*	*Shell mould casting*	*Sand casting*	*Vacuum moulding*
Equivalent terminology	Shaw process Ceramic shell process	'Antioch' process Gypsum moulding	'C' process Cronig process	—	'V' Process
Pattern material	Wood, plastic, metal	Wood, plastic, metal	Metal	Wood, plastic metal	Wood, plastic, metal
Mould material	Molochite, sillimanite, mullite	Calcium sulphate	Silica or zircon sand	Silica, zircon, chromite, olivine, sand	Silica, zircon, chromite, olivine, sand
Binder	Ethyl silicate plus gelling agent, e.g. 50/50 NH_4OH/H_2O	Water (autoclave in saturated steam atmosphere at 0.1 $N\,mm^{-2}$ (15 psi) for 6–8 h-stand at amb. temp 14 h)	Phenol-formaldehyde resin (Novolac) + hexamethylenetetramine + heat (from pattern at c. 260°C)	Many variants, e.g. clay, CO_2-silicate, cement, resin self set, silicate self set, etc.	None
Size range (kg)	Usually up to 180	All sizes	Up to 136	Green sand up to 500, dry sand 500 and above, others to 500 and above	All sizes
Scope	Complex shapes and fine detail	Limited by pattern withdrawal. Intricate shapes, e.g. wave guides	Better surface finish and accuracy than conventional sand castings	Limited only by pattern work	Excellent surface Finish—No draft
Alloys cast	Most types: Mg base, Al base, Cu base, steels	Mainly aluminium alloys and some Mg and Cu base	Carbon and alloy steels. Manganese steel. Some stainless and HR steels | Grey, SG and malleable irons | Al, Cu and Mg base alloys	All common foundry alloys | Steel Cast-irons Cu base Al base	All common foundry alloys
Surface finish (CLA)	120 to 180, with fine zircon facing 80 or better	30–40	100–300 100–250 100	300–1 000	125–200
Minimum section for length 25 mm	2.5 2.5 3.0	Al 1.4 Cu 1.1	4.6 3.2 Al 1.6 Cu 2.3	6.3 3.2 2.3 3.2	—
150 mm	3.2–4.0 3.2 3.2–4.0	1.4 1.4	6.4 3.5 3.1 3.1	6.3 5.1 3.6 3.6	
Dimensional tolerance ±mm 25 mm	0.18 0.18 0.18	0.13 0.13	0.25 0.25 0.13 0.13	1.52 0.76 0.38 0.38	0.25
150 mm	0.30 0.25 0.25	0.18 0.25	0.76 0.76 0.33 0.33	2.54 1.27 0.38 0.38	0.51
Labour cost per kg	High	Medium	Low	Low	Medium
Equipment cost per kg	Moderately high	Moderately high	Medium to high	Low	Low
Mould material cost	Moderately high	Medium	Medium	Low	Low

Table 26.3 TECHNIQUES USING A NON-EXPENDABLE MOULD (DIE)

	Permanent mould casting (*Gravity-die casting*)	*Low-pressure die casting*	High-Pressure die casting (*including 'Acurad'*)	*Centrifugal casting*	*Continuous casting*	*Semi-solid casting*
Equivalent terminology	Gravity-die casting chill casting	—	Pressure-die casting Cold-chamber (Al-base) Hot-chamber (Zn base)	'Spun-cast'	'Semi'-continuous (in non-ferrous)	Rheocasting Thixocasting Squeeze casting
Pattern material	—	—	—	Conventional wood	—	—
Mould material	Heat-resisting cast iron (expendable cores sometimes used)	Heat-resisting cast-iron (expendable cores sometimes used)	Heat resistant steel die	Metal die Conventional sand mould	Water-cooled metal die	Heat-resistant steel die
Binder	—	—	—	—	—	
Size range (kg)	Usually 0.45–25 in aluminium but can be up to 250	Up to 11.5 in Al-alloy	Up to 2.25 in brass, 20 in Mg. 34 in Zn, 45 in Al	Pipes up to 1.2 m dia. × 11 m long. Rings up to 15.2 m dia.	Casting speeds vary between 0.04 and 0.11 m s^{-1}	Up to about 10 in Al-alloy
Scope	Casting design must allow for removal from die	Complex shapes and pressure tight castings	Restricted internal shapes. Die withdrawal	Mainly grey iron pipes and cylinder liners and SG iron pipes and other symmetrical annular shapes	Semi-finished simple shapes (strip, rod, bar) in non-ferrous and grey iron and steel	Restricted internal shapes. Die withdrawal
Alloys cast	All common non-ferrous foundry alloys + some grey iron Zn base Cu base Mg base Cast-iron Al base	Almost exclusive to Al-alloys but steel, cast in USA using graphite mould Aluminium	Mainly Zn and Al base but some brass and Mg base, Sn and Pb Zn base Al base Mg base Cu base	Highly alloyed steels, grey and SG irons. Most Cu base	Alloy and plain carbon steels, Al and Cu base	All common non-ferrous foundry alloys
Surface finish (CLA)	100–250	40–100	40–100	Varies widely according to die used and metal cast. Typical range 100–500	100–200	40–100
Minimum section for length 25 mm 150 mm	2.5 2.5 6.4 4.1 5.0 10.2	1.3–6.4	1.3 0.8 2.0 1.5	Varies widely according to die and metal cast. Typical range 1.8–7.6	Down to 7.6	—
Dimensional tolerance* ± mm 25 mm 150 mm	0.18 0.38 0.76 0.25 0.53 0.76	0.10 0.36	0.10 0.10 0.60 0.51	Dependent on type of die. Usually in region of ±0.64	Usually within 0.13–25 mm	0.10 0.60
Labour cost per kg	Low	Low	Low	Moderately low	Moderate	Low
Equipment cost per kg	High	High	High	High	High	High

* The following additional tolerances should be added if dimension chosen crosses parting line:
Sand ±0.38   Permanent ±0.38   Centrifugal ±0.25
Shell ±0.25   Plaster   ±0.25   Shaw   ±0.10 to 0.15   for a 25 mm casting.

Table 26.6   TYPES OF MATERIAL USED IN GREEN AND DRY SAND MOULDING*

Class	Material	Approximate AFS/GFN
A	Naturally bonded sands of medium grain size (Dullatur 40 and other 'rotten rocks')	40
B	Naturally bonded sands of fine grain size (Bramcote)	80
C	Naturally bonded sands of very fine grain size (Mansfield Red)	Over 130
D	Silica sand of medium grain size (Arnold No. 19, Garside No. 21)	30–40
E	Silica sand of fine grain size (Redhill 65, Windsor Rose)	60–70
F	Silica sand of very fine grain size (Ryarsh, Redhill H)	> 100
G	Old sand renovated for further use. Grain fineness depends on original sand	
H	Added clay bond—bentonite	
I	Fuller's earth or other intermediate bonds with proprietory trade names	
J	Fire clay	
K	Organic binders—molasses, sulphite lye solution	
L	Dextrine and other cereal binders	
M	Special additions—coal dust (increasing fines and decreasing quantities for thinner castings), blacklead (graphite), blacking	
N	Sulphur	
P	Boric acid	
Q	Fluoride salts, e.g. ammonium bifluoride NH_4HF_2, ammonium silicofluoride $(NH_4)_2SiF_6$, ammonium borofluoride NH_4BF_4, ammonium fluoride NH_4F	
R	Crushed materials such as 'grog' firebrick or ganister	

* W. H. Salmon and E. N. Simons, 'Foundry Practice', Pitman, London, 1996.

Table 26.7   TYPICAL MIXTURES USED IN GREEN AND DRY SAND MOULDING*

The figures refer to weight percentages and the letters to the materials shown in Table 26.6

Nature of material	Sand	Clay	Additions	Added moisture %	Remarks
Cast-iron					
Green sand:					
Thin castings	60G 37C		3M	6	NB: Coal dust not used on castings for vitreous enamelling
Medium castings	76G 20B		4M	6	
Thick castings	66G 28B		6M	7	
Synthetic green sand:	91G				
Thin castings	54G 36E	3H	6M	$3\frac{1}{2}$	
Thick castings		4I	6M	$3\frac{1}{2}$	
Non-ferrous					
Copper alloys	70C 30F			7	
Phosphor bronze–dry sand	65G 25C		10M	7	
Aluminium alloys	90G 10C			$6\frac{1}{2}$	+5% P for high Mg alloys
Magnesium alloys	88E	4H	6N, 1P	4	
Steel[†]					
Synthetic green sand	73E 25D	$1\frac{1}{2}$H	$\frac{1}{2}$L	$3\frac{1}{2}$	
Synthetic dry sand	85G 14D	$\frac{1}{2}$H	$\frac{1}{2}$L	5	
Naturally bonded dry sand	75A 25D			7	NB: For 'Compo' stove to dull red-heat. Highly permeable refractory mixture for very large castings
Compo-dried mould	84R	15J	1M	8	
Loam	40B 40R	10J	10M	15–20	

* W. H. Salmon and E. N. Simons, 'Foundry Practice', Pitman, London, 1966.
[†] Refractory sand essential for steel casting.

Table 26.8   TYPICAL STANDARD AFS TESTS ON CLAY-BONDED MOULDING SAND MIXTURES*

Casting	Moisture %	AFS green permeability number	Compressive strength 10^4 Pa	
			Green	Dry
Cast iron				
Stove plate	9.0	10	4.1	13.8
Radiators	7.0	35	3.4	34.5
Cylinder blocks	6.5	80	4.8	31.0
Average castings	7.0	35	4.1	41.4
Synthetic–thin	3.5	70	5.5	41.4
Non-ferrous copper base				
Small	6.0	25	4.8	28.0
Large	5.5	60	6.9	41.4
Aluminium				
Small castings	7.0	20	3.4	13.8
Large castings	7.0	35	3.4	20.7
Magnesium	4.0	80–150	5.5	69.0
Steel				
Green sand	3.5	180	5.5	48.3
Dry sand	7.5	120	6.2	103
Compo	7.5	40	8.3	172

* W. H. Salmon and E. N. Simons, 'Foundry Practice', Pitman, London, 1960.
Note: The tensile strength of sands is less than half the compressive strength.

Table 26.9   TYPICAL MIXTURES FOR THE CO_2-PROCESS AND TYPICAL PROPERTIES OF STANDARD AFS COMPACTS*

Sand	Silicate			Gassing time s	Compression strength (kPa)	
	Weight ratio $SiO_2 : Na_2O$	°TW	% Added		As gassed	After 24 h storage
Chelford 50	2:1	112	4	60	1 050	2 680
Redhill 65	2:1	112	4	60	860	2 140
Erith (56)	2:1	112	4	60	550	2 300
King's Lynn (95)	2:1	112	4	60	1 700	—
					Gassing time s	After 24 h storage
Windsor	2.0:1	112	4	40	1 340	30	5 600
Rose	2.4:1	112	4	40	2 040	24	1 790
(68)	2.9:1	100	6	40	1 620	18	1 035

*K. E. L. Nicholas, 'The CO_2-Silicate Process in Foundries', BCIRA, 1963.
CO_2 flow-rate in all cases 2.5/1 min^{-1}.

Table 26.10   SUMMARY OF CORE BINDING PROCESSES

Method	Binder	Equipment
Natural sand	Clay	Wood, metal, or resin core boxes
Synthetic sand core	Clay, usually bentonite	Metal, wood, or resin core boxes
Loam	Clay	Generally strickled on spindle or barrel
Cereals	Starch and corn products Dextrose	Wood, metal, or resin core boxes
Oil	Wide variety including linseed, cotton-seed and fish oils	Wood, metal, or resin core boxes
Cellulose	Water-soluble cellulose ethers and melamine resins	Wood, metal, or resin core boxes
CO_2	Carbon dioxide and sodium silicate plus breakdown agent, e.g. dextrose monohydrate or molasses	Wood, metal, or resin core boxes
Self-setting silicate	Sodium silicate plus one of: (a) Dicalcium silicate (b) Ferro-silicon (c) Organic esters (acetins or glycol diacetates)	Wood, metal, or resin core boxes. Special box paints preferred for (a) and (b)
Air set (no bake)	Oils, usually heat-treated Tung linseed and alkyd resin modified. Catalysts—sodium perborate, 'metal driers', e.g. cobalt naphthenate, and isocyanates	Wood, metal, or resin core boxes
Cold box	Resin (Novolak) isocyanate MDI plus trimethylamine/ air vapour	Gas dispensers Fume extraction Wood, metal, or resin core boxes
Air set (no bake)	(a) Urea-formaldehyde/furfuryl alcohol plus phosphoric acid (b) Phenol–formaldehyde/furfuryl alcohol or (c) Furfuryl alcohol polymer both plus paratoluene sulphonic acid (b) and (c) are nitrogen free	Wood, metal, or resin core boxes
Fascold	Resin (polyurethane) + catalyst (isocyanate) Chemical polymerisation at room temperature	Need special core-blowing machine (sand + resin to mix with sand + catalyst) Wood Metal } core boxes Resin
Hot box	Phenolic furfuryl or other resin and catalyst (NH_4^+ salts or p.t.s.a.)	Metal core boxes on machine with heating and cooling cycle
Shell	Phenol formaldehyde resin Novalac type plus hexamine catalyst originally. Now usually 'precoated' or 'resin-coated' sands used	Metal core boxes on machine with heating and cooling cycle
Shaw	Ethyl silicate	Accurate and highly finished metal core boxes
Plaster	Gypsum	Accurate and highly finished metal core boxes
SO_2 process	UFFA or Furane polymer resin with peroxide mix	Gas dispensers. Fume extraction Wood, metal, or resin core boxes

(*continued*)

Process	Applications and limitations
Cores usually baked to develop the clay bond	Suitable for medium and large simple cores for jobbing foundries
Strength developed by baking clay bond	General use for jobbing foundry for all sizes of core. High green strength, good breakdown
Hand-made cores shaped by strickling on straw rope base, clay bond developed by baking	Suitable only for jobbing foundries for simple round and cylindrical cores
Bond developed by baking	Suitable for small and medium cores in jobbing repetition foundries
Oil oxidised by baking to develop bond	For general applications in all foundries but mostly on small and medium work. Poor green strength, and accuracy therefore difficult to maintain
Cores stoved to develop bond	Suitable for jobbing or repetition work. Good breakdown, finish and low gas content
No baking. Core gassed with CO_2 in core box	Suitable for jobbing or repetition work. Fast—accurate—stoving cores, low gas evolution. Main difficulties on breakdown, improved using breakdown agent, but storage life reduced
Silicate cures by either dehydration or for chemical gelling in 0.5–4 h	Suitable for jobbing foundry. Medium to large cores. Good finish. No fume. Breakdown little better than CO_2
Air drying process of 0.5–4 h duration plus 1–2 h baking	Suitable for jobbing foundry and large cores. Good finish, easy breakdown, good green strength, high accuracy
Almost instantaneous hardening in box. Gas passage, e.g. 3 s Air purge, e.g. 5 s	Sand air must be dry. Good dimensional accuracy. Knockout excellent. Efficient ventilation required. Cores of intermediate size in batches too small to warrant use of shell process
Resin cures after addition of acid in 10–4 min. No baking	Suitable for jobbing foundry and large cores. Good finish, easy breakdown. Good green strength. High accuracy
Both resin and catalyst liquid. Cured in 30–45 s Usable 30–60 min after strip	Machine operations are automatic Mass production of small cores—similar sizes to hot-box (Usually for iron-foundry)
Resin cures after addition of catalyst in 10–40 s baking at 180–300°C	Suitable only for large quantity repetition work and generally small cores.
Resin cured by heating cycle of 30–120 s at 200–400°C	Suitable for large quantity repetition work. Good finish, accuracy and breakdown. High permeability due to shell construction
Conversion of ethyl silicate to silica bond by hydrolysis	For accurate high-temperature metal application where surface finish and accuracy are of prime importance
Hydration of gypsum subsequently dried	For accurate low-temperature applications where surface finish and accuracy are of prime importance
Almost instantaneous hardening by SO_2 gas	Good dimensional accuracy. Knockout excellent. Not sensitive to water

(*continued*)

Table 26.10   SUMMARY OF CORE BINDING PROCESSES—*continued*

Method	Binder	Equipment
FRC (free radical cure)	Acrylic/epoxy resin + organic peroxide/sulphur dioxide gas	Gas dispensers. Fume extraction. Wood, metal, or resin core boxes
Alphaset	Alkalic phenolic resin self setting	Wood, metal, or resin core boxes
Betaset	Alkalic phenolic resin hardened by methyl formate gas	Gas dispenser. Fume extraction (although methyl formate itself is odourless and non-toxic) Wood, metal or resin core boxes

26.2   Patterns—crucibles—fluxing

Table 26.11   CONTRACTION ALLOWANCES OF COMMON ALLOYS (SAND CAST)*

Alloy	Pattern size m (in)		Type of construction	Contraction allowance Traditional	%
Grey cast iron (*see* Note 2)	Up to 0.61	(2.4)	Open	1 in 96	1.04
	0.64–1.22	(25–48)	Open	1 in 120	0.83
	Over 1.22	(Over 48)	Open	1 in 144	0.69
	Up to 0.61	(24)	Cored	1 in 96	1.04
	0.64–1.22	(25–48)	Cored	1 in 120	0.83
	Over 1.22	(Over 48)	Cored	1 in 144	0.69
Cast steel	Up to 0.61	(24)	Open	1 in 48	2.08
	0.64–1.83	(25–72)	Open	1 in 64	1.56
	Over 1.83	(Over 72)	Open	1 in 77	1.30
	Up to 0.46	(18)	Cored	1 in 48	2.08
	0.48–1.22	(19–48)	Cored	1 in 64	1.56
	1.24–1.68	(49–66)	Cored	1 in 77	1.30
	Over 1.68	(Over 66)	Cored	1 in 96	1.04
Manganese steel	—	—	—	1 in 38 decreasing to	2.63
				1 in 64 for long castings	1.56
Malleable cast iron	—		Section thickness		
(*see* Note 3)			mm (in)		
			1.6 ($\frac{1}{16}$)	1 in 70	1.43
			3.2 ($\frac{1}{8}$)	1 in 77	1.30
			4.8 ($\frac{3}{16}$)	1 in 80	1.25
			6.4 ($\frac{1}{4}$)	1 in 85	1.18
			9.5 ($\frac{3}{8}$)	1 in 96	1.04
			12.7 ($\frac{1}{2}$)	1 in 110	0.91
			15.9 ($\frac{5}{8}$)	1 in 128	0.78
			19.1 ($\frac{3}{4}$)	1 in 152	0.66
			22.2 ($\frac{7}{8}$)	1 in 256	0.39
			25.4 (1)	1 in 384	0.26
Pearlitic nodular iron, as cast	—		—	1 in 120 to 1 in 180	0.83 to 0.56
Pearlitic nodular iron, heat-treated to ferritic	—		—	1 in 120	0.83

Process	Applications and limitations
Almost instantaneous hardening by SO_2 gas	Good dimensional accuracy. Knockout excellent. Not sensitive to water + long bench life of mixed sand; to resistant to distortion on casting
The resin is cured with a liquid ester	Environmentally pleasant. Resistant to finning and veining defects. Good surface finish for steel castings
The resin is cured with a gaseous ester: methyl formate	Environmentally pleasant. Resistant to finning and veining defects. Good surface finish for steel castings

Table 26.11 CONTRACTION ALLOWANCES OF COMMON ALLOYS (SAND CAST)*—*continued*

Alloy	Pattern size m (in)		Type of construction	Contraction allowance Traditional	%
Nodular iron (thin section) containing carbide as cast and annealed	—		—	1 in 120 contraction to 1 in 240 expansion	0.83 0.42
Aluminium alloys	Up to 1.22	(48)	Open	1 in 77	1.30
	1.24–1.83	(49–72)	Open	1 in 85	1.18
	Over 1.83	(Over 72)	Open	1 in 96	1.04
	Up to 0.61	(24)	Cored	1 in 77	1.30
	0.64–1.22	(25–48)	Cored	1 in 85 to 1 in 96	1.20 to 1.04
	Over 1.22	(Over 48)	Cored	1 in 96 to 1 in 192	1.04 to 0.52
Magnesium alloys (*see* Note 4)	Up to 1.22	(48)	Open	1 in 70	1.43
	Over 1.22	(Over 48)	Open	1 in 77	1.30
	Up to 0.61	(24)	Cored	1 in 77	1.30
	Over 0.61	(Over 24)	Cored	1 in 77 to 1 in 96	1.30 to 1.04
Brass	—		—	1 in 64	1.56
Bronze	—		—	1 in 96 to 1 in 48	1.04 to 2.08
Nickel alloys	—		—	1 in 48	2.08
Everdur (silicon bronze)	—		—	1 in 64	1.56
PMG (silicon bronze)	—		—	1 in 96 to 1 in 64	1.04 to 1.56
High tensile brass	—		—	1 in 120 to 1 in 64	0.83 to 1.56
Aluminium bronze	—		—	1 in 43	2.32
Zinc alloys	—		—	1 in 85	1.18

* From 'Cast Metals Handbook', American Foundrymen's Society.

Notes:
(1) Contraction varies with the casting design, type of metal, pouring temperature, and mould or core resistance. It may be necessary to use several different contraction allowances for the various dimensions of a single pattern.
(2) Standard pattern maker's allowance for common grey iron is 1 in 96. For higher strength alloys and white cast irons, the contraction allowance averages 1 in 77.
(3) Contractions shown for malleable irons are net values, e.g. white iron castings which shrink 1 in 48 when cast, expand 1 in 96 during the anneal, giving a net contraction of 1 in 96.
(4) Contraction varies with the alloy. Average values are:

A8, AZ91, C	1 in 85.
Z5Z, RZ5, TZ6, MSR–A, MSR–B	1 in 77.
ZREI, ZT1	1 in 64.

Table 26.12   WEIGHTS OF CASTINGS FROM PATTERN WEIGHTS

Multiply pattern weight by the factor shown for the type of wood/metal and the alloys. For wooden patterns, allowance must be made for any metal reinforcement in the pattern.

Pattern material	Metal cast							
	Cast steel	Cast iron	Brass	Gun metal or bronze	Zinc	Copper	Aluminium	Magnesium
Mahogany	9.5	8.5	9.5	10.0	8.2	10.1	3.1	2.05
White pine	16.3	14.7	16.5	17.3	14.3	17.5	5.3	3.5
Yellow pine	14.4	13.1	14.7	15.4	12.7	15.6	4.7	3.1
Oak	10.4	9.4	10.5	10.8	9.1	11.2	3.4	2.24
Aluminium alloys	2.87	2.56	2.87	2.98	2.45	3.08	0.93	0.61
Brass	0.98	0.84	0.95	0.99	0.81	1.04	0.31	0.21
Iron	1.09	0.97	1.09	1.13	0.93	1.17	0.35	0.23
White metal	1.08	0.96	1.08	1.11	0.92	1.15	0.34	0.23

Note:
Allowance must also be made for cores and coreprints. For round cores and prints multiply the square of the diameter by the length of the core and prints in inches, and the product by 0.014. This will give the weight of the white pine core in pounds to be deducted from the weight of the pattern.

26.2.1   Pattern materials

(1) Wood: Yellow pine (for limited production) and mahogany (for production patterns) represent the most usual practice.
(2) Metal:
   (a) Cast iron.
   (b) Brass.
   (c) Aluminium alloy
   (d) White metal (only to a limited extent because of softness and easily worn away by moulding sand. Used, for example, for lining stripping plates).

Notes:

(1) For small patterns, an alloy of 40% Sn, 18% Sb, 40% Pb, 2% Bi, is used, shrinkage being negligible. Similarly, use is made of a modified 'Wood's metal' (50% Bi, 26.7% Pb, 10% Cd, 13.3% Sn) for making master patterns. It is completely molten at about 70°C and can readily be poured at the temperature of boiling water into wood or plaster moulds.
(2) Contraction allowance for 'master' patterns for casting metal patterns is contraction allowance for casting material, plus contraction allowance for metal pattern material.
(3) Plaster of Paris and proprietory cements: mainly for odd-side impressions.
(4) Plastics: epoxy resins, often reinforced with fibreglass.

Table 26.13   RECOMMENDED STANDARD COLOURS FOR PATTERNS

Part of pattern		Colour
As-cast surfaces which are to be left unmachined		Red or orange
Surfaces which are to be machined		Yellow
Core prints for unmachined openings and end prints	Periphery	Black
	Ends	Black
Core prints for machined openings	'A' periphery	Yellow stripes on black
	'B' ends	Black
Pattern joint (split patterns)	'A' cored section	Black
	'B' metal section	Clear varnish
Touch core	Cored shape	Black
	Legend	'Touch'
Seats of and for loose pieces and loose core prints		Green
Stop offs		Diagonal black stripes with clear varnish
Chilled surfaces	Outlined in	Black
	Legend	'Chill'

Table 26.14   GUIDE TO MACHINING ALLOWANCE ADDITIONS TO PATTERN CONTRACTION ALLOWANCES*

Casting alloy	Pattern size m (in)	Bore mm (in)	Finish mm (in)
Cast iron	Up to 0.3 (12)	3.12 (0.125)	2.38 (0.09)
	0.3–0.6 (13–24)	4.76 (0.187 5)	3.18 (0.125)
	0.6–1.1 (25–42)	6.35 (0.25)	4.76 (0.187 5)

Table 26.15   MATERIALS FOR PARTING POWDERS AND LIQUIDS

Powder	Moisture proofer
Pulverised limestone*	
Precipitated calcium carbonate*	Paraffin wax
Fireclay grog	
Sillimanite	Calcium stearate
Phosphate rock	
Bone ash	Aluminium stearate
Walnut shells	
Ptfe (from aerosol spray)	
Lycopodium powder (very expensive, for art casting only)	
Aluminium powder (as in aluminium paint)	
Liquid—paraffin plus small addition Colza oil	

* React unsatisfactory with chemical binders such as acid-catalyzed resin binders.

MOULD DRESSING, POWDERS, PAINTS

Table 26.16   SURFACE POWDERS FOR GREEN SAND MOULDS

Non-ferrous	Flour, soapstone, talc (French chalk)
Cast iron	Plumbago, black lead, bituminous coal dust

Material dusted on to mould surface, rubbed in by hand or sleeked with a smooth tool.

Table 26.17   MATERIALS FOR MOULD DRESSINGS

Filler material	Suspending agent	Binder	Carrier
Silica flour	(*a*) *For water base*	Core oil	Water
Zircon flour	Western bentonite	Dextrine	Iso-propyl alcohol
Graphite	China clay	Fire clay	(<5% H_2O)
Olivine	Carboxy-methyl-cellulose	Linseed oil	Carbon tetrachloride
Mica	Sodium alginates	Phenolic resin	Toluene
Molochite	(*b*) *For spirit base*	Vinsol resin	Petroleum-ether
Magnesite	Sodium bentonite	Polyvinyl acetate	Methylated spirits
Chamotte	Bentone	Molasses	
Tale			
Plumbago			
Carbon black			

Table 26.18   MIXES FOR WATER-BASED MOULD DRESSINGS*

Alloy type		Mixture components (wt. % & component)			Added water wt. %

Table 26.20   MOULD COATINGS FOR SPECIAL APPLICATIONS

Cast metal	Coating constituent(s)	Purpose	For further information consult
Aluminium base alloys	Acetylene soot	Increased fluidity,	—
	Hexachlorethane-containing wash	Increased fluidity + refined grain	—
Copper base alloys	325 mesh molochite Powdered vinsol resin 99% Iso-propyl alcohol	Prevention of 'steam' reaction at metal–mould interface resulting in globular sub-surface porosity	BNFMTC, AFS
Phosphor-bronzes and gunmetals	Finely divided Al–MG alloy suspended in a solvent (e.g. toluene)	Prevention of pinhole porosity	BNFMTC, AFS
Grey iron	Finely divided bismuth	Suppresses micro-shrinkage porosity in 'hot spots'	BCIRA, AFS
Grey iron	Finely divided tellurium	Local chilling for additional hardness	BCIRA, AFS
Malleable irons	Zinc/ground coke or cobalt, cobalt/iron oxide	Prevents hot-checking on white-iron castings and modifies dendrite structure	BCIRA, AFS

BNFMTC—British Non-Ferrous Metals Technology Centre.
BCIRA—British Cast Iron Research Association.
AFS—American Foundry Society.

26.2.2   Crucibles and melting vessels

Refractory crucibles were originally produced from clay alone, but since the beginning of the century most melting crucibles have incorporated up to 30% graphite, bonded with clay, to improve thermal shock resistance, erosion from fluxes and conductivity. Additions of silicon carbide are also made where higher duty is required. The life of crucibles has been improved over recent years by development of glazes which protect the crucible against oxidation or 'perishing'.

   Carbon-bonded silicon carbide crucibles made from silicon carbide and graphite bonded with tar, which on firing produces a carbon bond, have superior thermal shock resistance and improved performance against flux attack and oxidation under certain conditions. 80% of crucibles manufactured in recent years are produced from carbon-bonded silicon carbide. They are generally more expensive than clay-graphite crucibles.

TYPES OF CRUCIBLES

Three types of crucibles are in general use for non-ferrous work. These are:

1. *Crucibles used in pit or 'pull-out' furnaces*
   A and C shape which have to be removed from the furnace for metal to be poured.
      These vary in size from a few kilograms to greater than 1 000 kg brass capacity, though the latter sizes are not generally used on account of the difficulty of handling them. In oil- and gas-fired furnaces the crucible rests on a small stand or stool—of similar material to the crucible, and a ring or cylinder to accommodate and protect protruding solid metal is sometimes placed on the top of the crucible. The chief value of the pit furnace lies in its flexibility and low capital cost and it is ideal for small or medium-sized foundries where relatively small quantities of a variety of metals or alloys are required.
2. *Crucibles used in tilting furnaces*
   For convenience in pouring or where the size of crucible is such it cannot be readily handled, it is mounted permanently in the furnace, which is tilted to discharge its molten contents.
      Crucibles varying from 70 kg to greater than 760 kg brass capacity are in general use, though larger crucibles and furnaces are now available with capacities of up to 1 520 kg brass (590 kg aluminium).
3. *Maintaining crucibles*
   Crucibles or basins for holding molten metal for periodic casting or for process work are extensively used for purposes such as die casting.
      Those used for die casting are usually of basin shape and are wide in proportion to their height. They are made in sizes up to 600 kg aluminium capacity for aluminium die casting, or 135 to 180 kg brass capacity for aluminium bronze or brass die casting.
      Silicon carbide basins are particularly suited to maintaining molten aluminium alloys for die casting, as neither aluminium nor aluminium oxide attack the crucible material.

26.2.3   Iron and steel crucibles—fluxing

Steel crucibles are normally used for the melting of magnesium alloys. Low carbon steels are used and nickel and cobalt should be absent from the steel because of the adverse effect of even small traces of these elements on the corrosion resistance of magnesium alloys.

   The crucibles may be of a pressed construction or made up of welded boiler plate.

   For very large melts, cast-steel (∼0.4% carbon) crucibles are used.

   Although cast-iron crucibles were often used in holding furnaces for aluminium alloy die casting, they appear to have fallen out of favour and are now rarely found in use.

   Where they are still used a refractory wash of similar nature and composition to the following:

Finely ground whitening	9 wt.%
Water	90 wt.%
Waterglass (hot conc. soln)	1 wt.%

applied daily will minimise iron contamination.

   Silicon carbide or plumbago basins are used in preference to cast-iron pots nowadays, for aluminium melting.

Table 26.21   COMMON FLUXING AND INOCULATION PRACTICES FOR VARIOUS ALLOYS

Alloy group	Cover fluxes	Degassing and/or cleansing fluxes and treatments
		(a) Inert gases N_2, He, Ar ⎡Response time⎤ ⎣slowest⎦
Most aluminium alloys (except Al–Mg, *see* below)	(a) NaCl + NaF (or cryolite) + KCl + small amounts of $SO_4^{2-} + NO_3^-$ (b) $Na_2SiF_6 + NaCl^-$ ↓ also used for metal recovery from drosses	⎡Use N_2 at <700°C or −⎤ AlN formation Use N_2 at ≤670°C with Al-Mg alloys or ⎣→Mg_3N_2 formation⎦ (b) Inert active gas mixtures ⎡Response time⎤ e.g. 90N_2/10Cl_2 ⎣reasonably fast⎦ (c) Active gases Cl_2, F_2 or compounds containing them, ⎡Response time⎤ e.g. hexachlorethane ⎣fast⎦ C_2Cl_6 and Freon 12 CCl_2F_2
	(c) Reverberatory furnaces (typical) CaCl₂ 50% NaCl 30% KCl 20% (d) Rotary furances (typical) NaCl 45% ⎫ KCl 45% ⎬ m. pt 607°C Cryolite 10% ⎭	(d) Metal chlorides $ZnCl_2$ ⎫ BCl_3 ⎪ Careful selection to prevent $CuCl_2$ ⎬ contamination $MnCl_2$ ⎪ All hygroscopic $TiCl_2$ ⎭
Aluminium–magnesium alloys (3–10% Mg)	Similar to magnesium alloys. Mixtures of chlorides and fluorides, e.g. $MgCl_2 + KCl + MgF_2$ or CaF_2 *NB:* No sodium compounds of any description if present → embrittlement, hot-shortness	Groups (b) and (c) above (20% Mg loss at 690°C 90% Mg loss at 710°C, 50% Mg loss with C_2Cl_6 regardless of temperature) Also used—K_2ZrF_6, Ti sponge
Magnesium alloys		Degas with (a) C_2Cl_6 (b) Cl_2 ⎡$MgCl_2$ rich flux⎤ (c) N_2 'Flux bubbled' on crucible bottom ⎣650–680°C⎦
(a) Mg Mg–Al Mg–Mn	CaCl₂ 40% ⎫ NaCl 30% ⎪ KCl 20% ⎬ 'Melrasal Z' MgCl₂ 10% ⎭	$MgCl_2$ 35% ⎫ CaCl₂ 15% ⎪ NcCl 10% ⎪ Inspissating KCl 10% ⎬ flux CaF₂ 20% ⎪ 'Melrasal E' MgO 10% ⎭
		CaCl₂ 19% ⎫ NaCl 11% ⎪ For holding furnaces KCl 7.5% ⎬ BaCl₂ addition to increase BaCl₂ 37.5% ⎪ density MgF₂ 25% ⎭
	'Melrasal UE' all-purpose flux (melting, refining, covering) made up of 1 part 'Z' flux to 6 parts 'E' flux	
(b) Mg–Zr	BaCl₂ 39% BaCl₂ 28% ⎫ MgCl₂ 30% CaCl₂ 26% ⎪ for alloys KCl 10% KCl 10% ⎬ containing BaF₂ 21% NaCl 16% ⎪ rare earths MgF₂ 20% ⎭	Zr acts as its own degasser $Zr + 2[H]Mg → ZrH_2 ↓$
	BaCl₂ 40% ⎫ MgCl₂ 35% ⎪ KCl 10% ⎬ for alloys containing thorium MgF₂ 15% ⎭	
Copper-base alloys HC Copper	Charcoal	Degas N_2 only if necessary Deoxidation: 15% phosphor-copper (equiv. to 0.005% P) followed by CaB₂, Li (0.003–0.01%) or 10% Be–Cu (0.005–0.02% Be)

Special purpose fluxes and inoculants

(1) Grain refinement
 (a) Combined additions of K_2TiF_6
     +
    KBF_4
     +
   (sometimes) C_2Cl_6 for better efficiency
  KBF_4 used alone if alloy contains Ti near maximum specified
 (b) Using a 'hardener', e.g.: Al–5% Ti–1% B

(2) 'Modification' of Al–Si alloys

 (a) Eutectic or near-eutectic (11–14% Si)
  Salt mixtures containing NaF,
  e.g. 88% NaCl–KCl (1:1) + 12% NaF (fuses at 607°C)
  Vacuum-melted sodium sealed in air-tight Al containers
     ⎡ Sr modification lasts for several hours
  or Sr ⎨ Sr modified alloys can be remelted without loss
     ⎣ or fine structure

 (b) Hypereutectic (17–25% Si)
  Red phosphorus introduced as particles ($<60\,\mu m$) in a mixture of KCl and K_2TiF_6. Effect strengthened
  if subsequent Cl_2 treatment

Grain refinement with salt mixtures as in 1(a) above

Grain refinement:

Alloy type	Treatment	Degree of grain refinement achieved
Mg–Al(–Zn–Mn)	Carbon inoculation (C_2Cl_6)	Marked
	Superheat to $\geq850°C$	Marked
Mg–Al–Mn(–Zn)	$FeCl_3$	Marked
Mg–Zn(–RE–Mn)	$FeCl_3$, Zn–T% Fe alloy, or NH_3	Very marked
Mg–Mn	$Ca+N_2$	Mild
	Zr	Increases with falling Mn content
Mg–Zr	Use master alloy (proprietory) 'ZIRMAX' Max gr. ref. at max solubility of Zr (0.6%) Zr will not grain refine in presence of: Al, Si, Sn, Ni, Fe, Co, Mn, Sb	Zr will grain refine in presnce of: Zn, Cd, Ce, Ag, Th, Tl, Cu, Bi, Pb, Ca

Protection:
(1) 'Dusting' fluxes
 S, NH_4BF_4,
 NH_4HF_2, NH_4F,
 H_3BO_4
 e.g. S + 5 to 30% H_3BO_4
(2) SO_2 atmosphere
 'Purge' mould prior
 to cast

(*continued*)

Table 26.21   COMMON FLUXING AND INOCULATION PRACTICES FOR VARIOUS ALLOYS—*continued*

Alloy group	Cover fluxes		Degassing and/or cleansing fluxes and treatments	
Gunmetals	Charcoal	C($\geq$25 mm thick)	Degas with dry N_2	
	Borocalcite	$4CaO \cdot 5B_2O_3 \cdot 9H_2O$	(e.g. 45 kg melts at 5–10 l min^{-1} for about 5 min)	
	Boric oxide	B_2O_3 (crucible attack)	or use 'oxidation-reduction' technique	
	Borax	$Na_2B_4O_710H_2O$		
	Soda ash	Na_2CO_3 (desulphuriser)	*Oxidising agents*	*Deoxidants*
	Common salt	NaCl	Cupric oxide CuO	15% P–Cu
	Calcium fluoride	CaF_2	Cuprous oxide Cu_2O*	Lithium
	Silica sand	SiO_2	Manganese dioxide $\Big\}$ $MnO_2^\dagger$	10% Li–Cu
	Glass (green bottle)	—	Manganese ore	98% Zn–2% Na
	Barium carbonate	$BaCO_3$ (desulphuriser)	Barium peroxide BaO_2	
	Calcium oxide (lime)	CaO	$\Big[$ * Reduced by H_2 to Cu, does not evolve oxygen$\Big]$ $\Big[$ $\dagger$ Also removes As, Fe, Si and S $\Big]$	
Tin bronzes	Typical: Fused borax 30, dry silica sand 50, cupric oxide 20:2.75 kg charge Electric furnace melting: 3 parts lime +1 part fluorspar			
Brasses and high tensile brasses	Charcoal, borax, greenbottle glass $\downarrow$ $\quad\quad\quad$ $\downarrow$ Virgin $\quad\quad$ All scrap melts melts		None usually practised (Zn, Al, Mn are all deoxidants)	
Aluminium bronzes	Manganese chloride (MnCl$_2$) $\Big\}$ Both reduce Cryolite (AlF$_3$–3NaF) $\Big\}$ crucible life (Do not use compounds containing boron)		Degas with dry N_2 or CO_2	
Silicon bronzes	Bottle glass + small % of fluoride salts (Pb free) Can be thickened before skim with silica sand. *NB:* Not charcoal		Degas with dry N_2 or CO_2 Deoxidation not required	
Nickel silvers	Broken glass, 80:20 borax–boracic acid, Borocalcite, all Pb free. *NB:* not charcoal. Thicken for removal with powdered CaO		Deoxidation 0.1% Mn + 0.06% max. Mg (Mg also desulphurises)	
Copper-nickels and Monels	As for Ni-Silvers + MnO$_2$ (1% charge wt), NiO or Cu$_2$O *NB:* Not charcoal		Deoxidation Si 0.5–2.0% dependent on % Ni $\quad\quad\quad\quad\quad\quad$ Mg 0.03–0.06% dependent on % Ni e.g. for 30% Ni alloy 1.2% Mn followed by $\quad\quad\quad\quad\quad\quad\quad\quad$ 0.6% Si followed by $\quad\quad\quad\quad\quad\quad\quad\quad$ 0.03% Mg Can degas with N_2 or dry air	
Cast-irons			Acid cupola: Limestone 28–32 kg tonne^{-1} providing (a) Standard cupola practice (b) Coke ash content–10% (c) $CaCO_3$ is 96% of limestone 'Energised' flux for increased efficiency 21 kg tonne^{-1} (14 kg limestone + 7 kg CaF$_2$) Basic cupola: 80 to 90 kg tonne^{-1} of flux made up as Limestone 30–40% coke wt Dolomite 10% coke wt *Fluorspar 25% of limestone	

* Can replace fluorspar by 50 : 50 fluorspar/soda ash.

Special purpose fluxes and inoculants

Grain refinement not usually beneficial with these alloys—encourages 'layer porosity'—although has been achieved with 0.03% Zr + 0.02% B, Ti, Co

Grain refinement of manganese bronzes by iron

Fe in alloy acts as a grain-refiner

—

Some grain refinement with Mn

—

Anhydrous soda ash or calcium carbide for desulphurisation of acid cupola metal
Calcium silicide: 'Meehanite iron'

Ferro–silicon (+1–2% Al and up to 1% Ca), zirconium etc., $\begin{cases} \text{for grain size control (eutectic cells)} \\ \text{and reduction of 'chill depth'} \end{cases}$

75% FeSi (Al and Ca free) and 1–4% Sr
          ↓
     elimination of 'pinholing' in green sand moulds

Nodularisation (spheroidisation): sulphur ≤0.02%
Magnesium for hypo- and hypereutectic irons introduced as: Mg impregnated coke
                                                            Mg–Ni(Si) alloys
                                                            Mg–FeSi alloys
                                                            Mg–Si alloys

Cerium for hypereutectic irons introduced as mischmetal

ⓐ The alloys listed are those which have been included in US Federal Specifications QQ-A-596d, ALUMINUM ALLOYS PERMANENT AND SEMI-PERMANENT MOULD CASTINGS, QQ-A-601E, ALUMINUM ALLOY SAND CASTINGS, and Military Specification MIL-A-21180c, ALUMINUM ALLOY CASTINGS, HIGH STRENGTH. Other alloys are registered with The Aluminum Association and are available. Information on these should be requested from individual foundries or ingot suppliers.

ⓑ Except for 'Aluminium' and 'Others,' analysis normally is made for elements for which specific limits are shown. For purposes of determining conformance to these limits, an observed value or calculated value obtained from analysis is rounded off to the nearest unit in the last right hand place of figures used in expressing the specified limit, in accordance with the following:
When the figure next beyond the last figure or place to be retained is less than 5, the figure in the last place retained should be kept unchanged.
When the figure next beyond the last figure or place to be retained is greater than 5, the figure in the last place retained should be increased by 1.
When the figure next beyond the last figure or place to be retained is 5 and
(1) there are no figures or only zeros, beyond this 5, if the figure in the last place to be retained is odd, it should be increased by 1; if even, it should be kept unchanged;
(2) if the 5 next beyond the figure in the last place to be retained is followed by any figures other than zero, the figure in the last place retained should be increased by 1; whether odd or even.

ⓒ S = Sand Cast; P = Permanent Mould Cast

ⓓ If iron exceeds 0.45 percent, manganese content shall not be less than one-half the iron content.

ⓔ Also contains 0.04–0.07 percent beryllium.

ⓕ Also contains 0.003–0.007 percent beryllium, boron 0.005 percent maximum.

ⓖ Also contains 5.5–7.0 percent tin.

ⓗ Also contains 0.40–1.0 percent silver.

ⓘ Also contains 0.05 max percent tin.

ⓚ The sum of those 'Others' metallic elements 0.010 percent or more each, expressed to the second decimal before determining the sum.

[1] Values represent properties obtained from separately cast test bars and are derived from ASTM B-26, Standard Specification for Aluminum-Alloy Sand Castings; Federal Specification QQ-A-601e, Aluminum Alloy Sand Castings; and Military Specification MIL-A-21180c, Aluminum Alloy Castings, High Strength. Unless otherwise specified, the tensile strength, yield strength and elongation values of specimens cut from castings shall be not less than 75 percent of the tensile and yield strength values and not less than 25 percent of the elongation values given above. The customer should keep in mind that (1) some foundries may offer additional tempers for the above alloys, and (2) foundries are constantly improving casting techniques and, as a result, some may offer minimum properties in excess of the above. If quality level 4 castings are specified as described in Table 1 of AA-CS-M5-85, no tensile tests shall be specified nor tensile requirements be met on specimens cut from castings.

[2] F indicates 'as cast' condition; refer to AA-CS-M11 for recommended times and temperatures of heat treatment for other tempers to achieve properties specified.

[3] Footnote no longer in use.

[4] Hardness values are given for information only; not required for acceptance.

[5] The T4 temper of Alloy 520.0 is unstable; significant room temperature ageing occurs within life expectancy of most castings. Elongation may decrease by as much as 80 percent.

[1] Values represent properties obtained from separately cast test bars and are derived from ASTM B-108, Standard Specification for Aluminum-Alloy Permanent Mould Castings; Federal Specification QQ-A-596d, Aluminum Alloy Permanent and Semi-Permanent Mould Castings; and Military Specification MIL-A-21180c, Aluminum Alloy Castings, High Strength. Unless otherwise specified, the average tensile strength, average yield strength and average elongation values of specimens cut from castings shall be not less than 75 percent of the tensile strength and yield values and not less than 25 percent of the elongation values given above. The customer should keep in mind that (1) some foundries may offer additional tempers for the above alloys, and (2) foundries are constantly improving casting techniques and, as a result, some may offer minimum properties in excess of the above.

[2] F indicates 'as cast' condition; refer to AA-CS-M11 for recommended times and temperatures of heat treatment for other tempers to achieve properties specified.

[3] Hardness values are given for information only; not required for acceptance.

Table 26.27d   TYPICAL PHYSICAL PROPERTIES OF COMMONLY USED SAND AND PERMANENT MOULD CASTING ALLOYS

These typical properties are not guaranteed, and should not be used for design purposes but only as a basis for general comparison of alloys and tempers with respect to any given characteristic.

ⓐ Assuming solid (void-free) metal. Since some porosity cannot be avoided in commercial castings, the actual values will be slightly less than those given.

ⓑ Cgs units equals calories per second per square centimeter per centimeter of thickness per degree centigrade.

© Chill cast samples; all other samples cast in green sand mould.

ⓓ Estimated value.

ⓔ Exceeds operating temperature.

Table 26.32   HIGH TENSILE BRASSES

Zinc equivalents

	Guillet method		American method	
Element	Coefficient		Element	Coefficient*
Silicon	10		Silicon	+10
Aluminium	6		Aluminium	+5.0
Tin	2		Tin	+1.0
Lead	1		Lead	—
Iron	0.9		Iron	−0.1
Manganese	0.5		Manganese	−0.5
Nickel	−1.2		Nickel	−2.3
Magnesium	2		Magnesium	+1.0

$$\text{Zinc equivalent} = \frac{[\%Zn + \Sigma(\%M \times \text{coeff})]100}{[\%Zn + \Sigma(\%M \times \text{coeff}) + \%Cu]}$$

$$\text{Zinc equivalent} = \left[100 - \frac{100 \times \%Cu}{100 + \Sigma(\%M \times \text{coeff})}\right]$$

Where
   M = alloying element
   % α-phase = 10 (46.6-zinc equivalent)

In practice, these factors operate with good accuracy, provided that the element considered is not present in amounts greater than 2%.

* These values are Guillet Coefficients minus 1.

These values are employed as a guide to whether a complex brass will have either alpha, beta, or mixed alpha/beta structure. For instance equivalent zinc values of 46.6% and above will produce a beta structure. To obtain 15% alpha the zinc equivalent must be below 45%. As further examples, 1%Si will be equivalent to 10%Zn, and 1%Ni is equivalent to taking 1.2%Zn out (i.e. putting 1.2%Cu in).

26.5   Nickel-base casting alloys

Table 26.36a   PHYSICAL PROPERTIES AND USE OF NICKEL CASTING ALLOYS

Alloy name	Casting characteristics	Melting range °C	Denisty kg dm^{-3}	Uses
Nickel	C 0.2/0.3 for better castability	1 360–1 430	8.4	Corrosion resistant to alkales
Ferry Metal (60% Cu)	Castability improves as Si increases	1 315–1 350	8.6	Good corrosion resistance
Monel Med Si	Tends to be hot short	1 290–1 320	8.6	Good corrosion and galling resistance
Monel High S	Tends to be hot short	1 260–1 290	8.5	Corrosion resistant with max hardness and galling resistance
Nichrome[†]	Susceptible to H absorption	1 375–1 425	8.2	Heat and oxidation resistance. Furnace windings
Hastealloy B[†]	Less liable to H absorption than Nichrome	1 320–1 350	9.2	Good corrosion resistance especially to HCl
Hastealloy C[†]	Castability—moderate	1 270–1 310	8.9	Good corrosion resistance over wide range
Hastealloy D[†]	Similar to Monels	1 110–1 120	7.8	Resistance to hot conc. H_2SO_4
Hastealloy X[†]	Moderate	1 380–1 400	8.2	High temp. service, gas turbines
Nimocast 80[†]	—	1 310–1 380	8.17	High temp. service, gas turbines, furnace equipment
Nimocast 90[†]	Moderate	1 310–1 320	8.18	High temp. service, gas turbines, furnace equipment
Nimocast 242[†]	—	1 370–1 400	8.4	High temp. thermal starch resistance
Nimocast PE10[†]	Good fluidity	1 235–1 340	8.84	Gas turbines, diesel engines
Nimocast 263[†]	—	1 268–1 385	7.75	Gas turbine blades
IN-100	Vacuum cast	1 265–1 335	7.75	Gas turbine blades
IN-162	Vacuum cast	1 275–1 330	8.1	Gas turbine blades
IN-591	Vacuum cast	—	9.13	Nozzle guide vanes
IN-643	Moderate	1 450–1 500	8.7	Reformer tubes
IN-657	Moderate	1 304–1 314	7.96	Reformer tubes and general high temp. service
IN-738LC	Vacuum cast	1 230–1 315	8.11	Industrial and marine texture and nozzle guide vances
IN-792	Vacuum cast	—	8.25	Industrial and marine texture and nozzle guide vanes
IN-939	Vacuum cast	1 235–1 315	8.16	Turbine blades and nozzle guide vanes—gen. service
IN-6201	Vacuum cast	1 185–1 290	—	Turbine blades and nozzle guide vanes—gen. service
IN-6203	Vacuum cast	—	—	Turbine blades and nozzle guide vanes—gen. service
IN-6203	Vacuum cast	—	—	Turbine blades and nozzle guide vanes—gen. service

IN-6312	Vacuum cast	1 320–1 410	—	Turbine blades and nozzle guide vanes—gen. service
C242	Vacuum cast	1 225–1 340	8.4	Turbine blades and nozzle guide vanes—gen. service
C263	Vacuum cast	1 300–1 355	8.36	Turbine blades and nozzle guide vanes—gen. service
713C	Vacuum cast	1 260–1 290	7.91	Turbine blades and nozzle guide vanes—gen. service Turbo charges
713LC	Vacuum cast	1 290–1 320	8.0	Turbine blades and nozzle guide vanes—gen. service Turbo charges
B-1900	Vacuum cast	1 275–1 300	8.22	Servo gas turbine rotor blades
MAR-M002[†]	Vacuum cast	—	8.53	Aero gas turbine rotor and nozzle guide vanes
MAR-M002 + Hf	Vacuum cast	—	8.53	Aero gas turbine rotor blades

Applications	For pressure tight applications Increased proof stress after full heat treatment			Principal alloy for commercial usage		

Elektron designation		AZ91(HP)		ZC63
ASTM designation	AZ91E		AZ91D	ZC63
Specifications BS 2970:1989		MAG11(GP)		—
BSS L series		—		—
Equivalent DTD		—		—
Heat treatment—continued				
Precipitation:				
Time, h	8 (min)		Not suitable	16 (min)
Temperature,°C	210 (max)			200 (max)
Stress relief:				
Time, h	—		—	—
Temperature, °C	—		—	—
Mechanical properties—sand cast—(SI units first, Imperial units following in brackets)				
Tensile strength (min), MPa (tonf in^{-2})	200		Typical high	210
0.2% proof stress (min), MPa (tonf in^{-2})	130		pressure die-cast	125
Elongation % min (5.65$\sqrt{S_0}$)	2		properties	3
Mechanical properties—chill cast—(SI units first, Imperial units following in brackets)				
Tensile strength (min), MPa (tonf in^{-2})	215		200	210
0.2% proof stress (min), MPa (tonf in^{-2})	130		150	125
Elongation % min (5.65$\sqrt{S_0}$)	2		1	3
Applications		High purity alloy—offers excellent corrosion resistance. Max. temp. 120°C		Better foundability than AZ91 with superior elevated temperature properties

* M—as cast.
   TS—Stress relieved only.
   TE—Precipitation treated only.
   TB—Solution treated only.
   TF—Solution and precipitation treated.
† GP General purpose alloy.
   SP Special purpose alloy.
‡ Permanent mould = gravity die casting.
§ Ability to fill mould easily, A, B, C, indicate decreasing castability.

¶ Damping capacity ratings.
   A = Outstanding; better than grey cast iron.
   B = Equivalent to cast-iron.
   C = Inferior to cast-iron but better Al-base cast alloys.
** A = Particularly recommended.
   B = Suitable but not especially recommended.
   C = Not recommended where strength at elev. temps is likely to be an important consideration.
†† 1 MPa = 1 H mm^{-2} = 0.064 75 tonf in^{-2}.
‡‡ SO_2 or CO_2 atmosphere.

Applications	High strength in thick and thin section castings. Good elevated temperature (up to 250°C) short time tensile and fatigue props.		Similar to MSRA-B.	Superior short time tensile and creep resistance at temperatures around 300°C.	Similar to MSR alloys but less	Excellent strength up to 300°C for short time applications. Excellent corrosion resistance.	Excellent strength up to 250°C for long time applications. Excellent corrosion resistance.

After 5 weeks	−0.32	−0.69	Shrinkage 0.03% after 100 days.	Shrinkage 0.005% after 30 days ambient, and 0.03% after 1 000 days. At 95°C, shrinkage followed by growth, i.e. zero change after 1 000 days.	Shrinkage 0.005% after 30 days ambient, and 0.015% after 1 000 days. At 95°C rapid shrinkage then growth to +0.1% after 1 000 days.	
After 6 months	−0.56	−1.03				
After 5 years	−0.73	−1.36				
After 8 years	−0.79	−1.41				
Dimensional changes after stabilising heat treatment $(\mathrm{mm\,m^{-1}})$ 16 h at 100°C ± 5°C—air cool						
After 5 weeks	−0.20	−0.22				
After 3 months	−0.30	−0.26				
After 2 years	−0.30	−0.37				
Ageing	At RT all the alloys show little decrease in strength. Exposure to elevated temperature (100°C) may result in decrease of up to 30%					
Applications and uses	Extensive use where a large number of strong dimensionally accurate metal components required, e.g. components of cars, domestic appliances, business machines, record players, hydraulic and pneumatic valves, toy models.		Used for pressure diecastings requiring creep resistance. Gravity castings requiring excellent fluidity or very high quality electroplating.	General purpose sand and gravity casting alloy and a higher strength diecasting alloy. Good wear and bearing properties.	Strongest of the alloys. Used in the sand, gravity or pressure diecast form for applications where its strength is required. Best wear and bearing properties (comparable to SAE660 bronze).	Pressure die, sand and gravity die cast. For applications where hardness is an advantage. Sheet metal forming dies, moulds for plastics[‡‡], zip fastener sliders.

UNS = Unified Numbering System.

26.8   Steel castings

26.8.1   Casting characteristics

Casting is usually carried out at 1500–1700°C, or even higher, according to the type of steel and section of the casting. Highly refractory sands with high resistance to the molten metal stream are essential. Liquid shrinkage is high, so that generous risers are needed and the metal is hot short. Manganese steels, in particular, attack all furnace and ladle refractories, and only olivine sand has adequate resistance to constitute a satisfactory moulding material, tolerably resistant to burn-on.

26.8.2   Heat treatment

HOMOGENISING

High-temperature treatment intended to reduce interdendritic segregation.

ANNEALING

Heating above the critical range (Ac_3) for about 1 h per 25 mm of maximum cross-section and furnace cooling to nearly room temperature. Removes brittleness associated with coarse as-cast grain size or Widmanstätten structure, gives most complete relief of internal stresses, gives minimum yield stress and tensile strength, good ductility but poor impact values. Best magnetic properties in low carbon steels.

SUB-CRITICAL ANNEALING

Heating to a temperature below the Ac_1, and cooling slowly. Used for stress relief after welding, etc., and for softening high alloy steel castings.

NORMALISING

Similar to annealing except that cooling is in still air. Gives a smaller ferrite/pearlite grain size, higher yield stress, tensile strength and impact, but slightly lower elongation values than annealing. Medium and higher carbon steels which harden appreciably are usually tempered subsequently. Normalising may be preceded by annealing, or a prior normalising treatment at a higher temperature to break down the cast structure.

QUENCHING (OR HARDENING) AND TEMPERING

Heating above the critical range, but not so high as for annealing or normalising, and rapidly cooling in water, oil or air blast followed by reheating to a temperature below the critical range until the desired properties are achieved followed by air cooling, furnace cooling (if stress relief is also required) or cooling in water (to minimise temper embrittlement). Gives highest physical properties; high tempering temperatures usually gives lower strength but higher elongation and impact values. Normally preceded by annealing.

SURFACE HARDENING

Heating the surface layers by flame or induction to a temperature above the critical range and quenching by water jets following the heat source or by immersion.

[1] For each 0.01% carbon below the max an increase of 0.04% Mn is permitted up to a max of 1.10%.
[2] Residual elements: total shall not exceed 0.80%.
[3] Only mandatory if specified by the purchaser.
[4] Either a bend test or an impact test may be specified.
[5] Mn/C ratio shall be greater than 3:1.
[6] The heat treatment to be applied shall be at the discretion of the manufacturer.
[7] Properties in the blank carburised and heat treated condition.
[8] Residual elements.
[9] The maximum carbon content may be increased to 1.35% by agreement.
[10] Not applicable to free machining steels.
[11] For free machining grades the minimum elongation shall be 12%.
[12] Gy agreement the Nb may be replaced by Ti in the range 5 × C/0.70%.
[13] If required with specified low temperature impact properties the carbon content shall be 0.06% max and the niobium 0.90% max.

Notes for Table 26.42a and b

[1] For each 0.01% carbon below the maximum an increase of 0.04% manganese will be permitted up to a maximum of 1.10%.
[2] For each 0.01% carbin below the maximum an increase of 0.05% manganese will be permitted up to a maximum of 1.60%.
[3] Ni + Cr + Mo + Cu = 0.80% max.
[4] Ni + Cr + Cu = 0.80% max.
[5] Either a bend test or an impact test may be specified but not both.
[6] Residual elements.
[7] This value may be increased to 15% min, subject to agreement at the time of enquiry and order.
[8] When specifically ordered.
[9] When used for deoxidation shall not exceed 0.25 kg/t.
[10] 1% Proof stress.
[11] C content 0.06 max and Nb 0.9 max when low temperature properties are specified.
[12] Ti 5XC/0.70 may be substituted for Nb by agreement.
[13] Values at 20°C and 50°C are included for design purposes only and are not subjected to verification. All values except those at 50°C that are obtained by interpolation are based on tests according to BS 3688 and thus values at 20°C differ from the corresponding room temperature values given in this specification.
[14] Only apply to sections <32 mm.
[15] Properties minima unless stated.
[16] A—Annealed, N—normalised, T—tempered, Q & T—quenched and tempered, H & T—hardened and tempered, ST—solution treated.

Notes:
[1] Total residual elements shall not exceed 0.8%
[2] A restricted range of oncomposition may be agreed if welding or brazing is intended. Castings in composition range
   are subject to Patent applications.
[3] Hardness values are for maraged castings.
*   Angle of bend 120°. Radius of bend 1.5t, t = thickness of test piece.
** Angle of bend 120°. Radius of bend 2t, t = thickness of test piece.

26.9 Cast irons

Data Source BCIRA.

26.9.1 Classification of cast irons

Cast irons may be divided into two main groups, comprising the general purpose grades which are used for the majority of engineering applications and the special purpose or alloy cast irons which are used where the operating conditions involve extremes of heat, corrosion or abrasion.

26.9.2 General purpose cast irons

These materials may be further classified into four groups, depending on the graphite form.

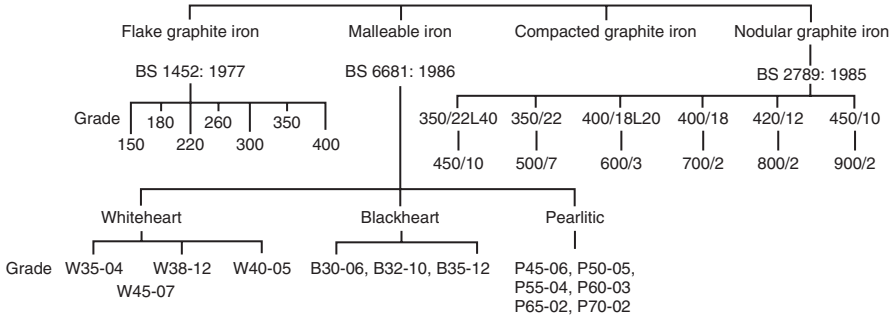
British Standards specifications exist for each of these materials. New metric specifications incorporating SI units are available for malleable, grey and nodular irons. The grade number denotes the tensile strength and the % elongation, e.g. BS 2789 Grade 400/18 has a minimum tensile strength of 400 MPa and a minimum elongation of 18%. In the case of grey irons, which all fail with an elongation less than 1%, the grade number denotes tensile strength only in test specimens of standard dimensions.


Figure 26.1 *Classification of general purpose cast irons*

GREY IRONS

The grade number denotes the minimum tensile strength requirement on a test piece machined from a 30 mm (1.2 in) diameter as-cast bar and this, rather than analysis, is the basis for specification of cast irons for engineering purposes.

For unalloyed irons the main constituents influencing tensile strength are carbon, silicon and phosphorus. Their combined effect may be expressed as a carbon equivalent value (CEV), where

$$CEV = \text{total carbon \%} + \frac{\text{phosphorus \%} + \text{silicon \%}}{3} \tag{26.1}$$

Typical analysis and CEVs are given in Table 26.53.

Grey irons are section sensitive, their structure and mechanical properties depending on cooling rate in the mould, which in turn depends to a first approximation on section thickness. This effect is shown in Figure 26.2, with tensile and test bar diameter requirements in Table 26.54.

Excessive rates of cooling lead to the formation of free carbides, or chilling. This effect is more severe with the higher strength irons, and occurs first at free edges of castings, where the cooling rate is a maximum, as shown in Table 26.55.

Inoculation of high duty grey irons, from Grade 260 to 400, is carried out using a technique in which a small amount of inoculant, usually containing silicon, is added to the metal immediately before pouring so as to increase the silicon content by 0.3–0.5%. Some commonly used inoculants include ferrosilicon, calcium silicide, SMZ (silicon–manganese–zirconium).

Figure 26.3 *Effect of inoculation on chill depth*

Graphite is also a powerful inoculant. Several other proprietary inoculants, most of which are based on one or more of these substances, are also effective. The efficiency of a graphite inoculant depends on high purity, but that of other types depends on the presence of minor constituents such as aluminium, calcium, barium, strontium and cerium.

The tensile strength of hypo-eutectic grey irons (i.e. CEV less than 4.3) can be significantly increased by inoculation, particularly with silicon-containing inoculants. When the CEV is in the range 3.9–4.1 maximum strength is obtained when the inoculant adds 0.2–0.3% silicon, corresponding to an increase of approximately 15 MPa (1 tonf in^{-2}) compared with uninoculated material. With CEV below 3.9 the addition of inoculant sufficient to give a 0.5% increase in silicon content can add up to 60 MPa (4 tonf in^{-2}) to the tensile strength, the effect being progressive with increasing additions up to at least this level.

The chilling tendency of grey irons is also reduced by inoculation, enabling significantly thinner chill free sections than those in Table 26.50 to be cast. The effect is progressive up to at least 0.4% of added silicon.

The chill reducing effect forms the basis for most control tests for inoculation. A sand cast wedge or a small block cast in sand with one face against a metal plate may be made from the metal before and after inoculation. The test pieces are then fractured and the change in depth of chill measured as an assessment of the success of the treatment. Typical results are illustrated in Figure 26.3.

In castings which are susceptible to shrinkage defects inoculation will accentuate these problems, and its use should be restricted only to those castings where chilling or strength considerations make it necessary.

Charge materials for production of grey irons include pig irons, cast iron scrap, steel scrap and ferro alloys.

The main purposes served by pig irons is the provision of carbon, silicon, manganese and, where required, phosphorus and alloying elements. They also limit the sulphur content of cupola melted iron.

Blast furnace pig irons are available in a variety of grades which differ mainly in phosphorus content. Each grade is generally available within different ranges of silicon and manganese contents.

The carbon content will generally be at the lower end of the above ranges when the silicon content is at the upper end of the corresponding range. The silicon content can be specified in increments of 0.25 or 0.50% within the ranges given.

Table 26.51   ANALYSES OF PIG IRONS

	Typical composition				
	TC %	Si %	Mn %	S % *max*	P %
Hematite	3.7–4.5	0.5–3.5	0.5–1.2	0.05	0.05 max
Low phosphorus	3.8–4.2	1.0–4.5	0.7–1.1	0.05	0.065 max
	3.8–4.2	1.0–4.5	1.1–1.5	0.05	0.065 max

Medium phosphorus	3.5–4.0	2.0–3.5	0.8–1.0	0.05	0.5–0.7
High phosphorus	3.3–3.8	2.0–4.5	0.6–0.8	0.05	0.7–1.2
	3.3–3.8	2.0–4.5	0.8–1.2	0.05	0.7–1.2

Table 26.52   COMPOSITION OF SCRAP

	Approximate composition %				
Type of scrap	C	Si	Mn	S	P
Light section scrap, usually less than $\frac{1}{4}$ in thick	3.2–3.5	2.2–2.8	0.5–0.7	0.10–0.15	1.0–1.5
Textile and machine scrap, generally up to $1\frac{1}{2}$ in average section	3.0–3.3	1.8–2.2	0.5–0.8	0.10–0.15	0.5–1.0
Railway chairs	2.8–3.5	1.5–2.5	Up to 0.5	Up to 0.25	1.0–1.5
Automobile engine scrap	3.1–3.3	2.0–2.2	0.5–0.8	0.08–0.15	<0.2
Ingot mould scrap (heavy section)	3.5–3.8	1.4–1.8	0.5–1.0	0.08	<0.1
Blackheart malleable scrap	2.2–3.1	1.3–1.6	0.3–0.6	0.09–0.25	0.06–0.08
Whiteheart malleable scrap	0.2–2.3	0.5–0.8	0.2–0.3	0.15–0.25	0.06–0.08

Refined alloy and special pig irons are produced to the customer's specific requirements in a wide range of compositions. They may contain alloying elements if required, within specified ranges of alloy content.

Silvery pig iron (10–12% silicon, 12–14% silicon) provides silicon in a more dilute form than ferrosilicon. It is used to minimise variation in silicon content of cupola melted iron when a substantial quantity of silicon is added, and to reduce the risk of aluminium contamination of the metal which may arise if large additions of ferrosilicon are made.

Special irons, generally of high carbon content, but with a very low content of residual elements are also available, their main use being for the production of nodular graphite iron.

Return scrap is the best source of scrap for re-melting providing this is of known and consistent composition and this should be fully utilised.

Purchased scrap is available in several fairly readily identifiable types as given in Table 26.51.

In comparison with pig iron and cast iron scrap, steel scrap is low in carbon and silicon contents, and the phosphorus and sulphur contents are generally below 0.05%. It is used to lower carbon and silicon contents, particularly in the production of higher strength irons.

Ferro-alloys are used to remedy deficiencies of certain elements, particularly silicon and manganese in the charges.

FERROSILICON

The two most common grades, in lump form, contain 75–80% and 45–50% of silicon. Ferromanganese in lump form contains 75–80% manganese.

BRIQUETTES

For relatively small additions of silicon, manganese and chromium, briquettes may be used for convenience and consistency. They contain a fixed amount of the alloy and avoid the necessity of weighing the addition.

Table 26.53 LOSSES OF ALLOYING ELEMENTS

	Melted in cupola	Added to ladle
Copper	0 of amount charged	0
Nickel	0 of amount charged	0
Molybdenum	0–5% of amount charged	5% of amount added
Manganese	20–30% of amount charged	5–10% of amount added
Chromium	10% of amount charged	15% of amount added
Silicon	10–15% of amount charged	10% of amount added

Table 26.54 SUMMARY OF STRUCTURAL EFFECTS OF ALLOYING ELEMENTS ON CAST IRON

Element	% used in pearlitic irons	'Chill'	Effect on carbides (at high temps)	Effect on graphite structure	Effect on combined carbon in pearlite	Effect on matrix
Chromium chill inducing	0.15–0.5	Increases*	Strongly stabilises	Mildly refines	Increases	Refines pearlite and hardens
Vanadium	0.15–0.3	Increases	Strongly stabilises	Refines	Increases	
Boron	—	Strongly increases	—	—	—	—
Manganese mildly chill inducing	0.3–1.25	Mildly increases	Stabilises	Mildly refines	Increases	Refines pearlite and hardens
Molybdenum	0.3–1.0	Mildly increases	About neutral	Strongly refines	Mildly increases Increases	Refines pearlite and strengthens

* Chill inducing effect of 1 part of chromium about balances chill restraining effect of $1\frac{1}{2}$ parts silicon or $2\frac{1}{2}$ parts nickel.
[†] Chill restraining effect of nickel about half that of silicon.
[‡] Strong refining action of titanium takes place when small amounts are added, particularly when oxygen is also present.

Table 26.55

Element	Graphitising value (Si = 1)	Element	Graphitising value (Si = 1)
Aluminium	0.5	Manganese	−0.25
Copper	0.35	Molybdenum	−0.35
Nickel	0.3–0.4	Chromium	−1.2

Melting range varies widely with composition, the melting temperature falling with increase of carbon content so that low carbon irons must be cast at considerably higher temperatures than high carbon irons. With grey irons containing high phosphorus, melting of the steadite (phosphide eutectic) begins at about 960°C, giving a relatively long melting range.

FLUIDITY OF CAST IRON

The fluidity of cast iron depends primarily upon composition and pouring temperature. The fluidity, as measured by a special test spiral casting, may be improved by increasing the carbon, silicon or phosphorus contents, or by increasing the pouring temperature. Of these variables, carbon content is the most effective from the point of view of composition, but an increase of 15–20°C in the pouring temperature improves the fluidity as much as an increase of 0.10% carbon, 0.30% silicon or 0.20% phosphorus.

Heat treatment of grey cast irons may be carried out to eliminate residual stresses, improve machinability or to increase wear resistance.

Stress relief heat treatment is carried out by slow heating at 50–100°C per hour to 600°C ± 10°C, holding at 600°C for one hour plus an additional half hour per cm (0.4 in) of maximum section thickness, and cooling at 50–100°C per hour to below 200°C followed by air cooling.

Annealing heat treatment is applied when improved machinability is required. There are two distinct sets of conditions in which annealing may be carried out.

1. To break down free carbide or chill formed as a result of failure to match carbon equivalent value to minimum free edge thickness. Annealing must then be carried out at 900°C for 1–5 h to ensure complete breakdown of carbide, followed by air cooling to ensure a pearlitic matrix. This treatment is carried out as an emergency measure to salvage otherwise unmachinable castings.
2. To provide castings which can be machined at a very high rate. Castings which are fully pearlitic can be annealed to give a mainly ferritic matrix with a hardness of 140–180 HB by holding at 780–820°C for 1–2 h followed by slow cooling.

Hardening by quenching and tempering is carried out where high surface hardness is required, with corresponding improvement in wear resistance. Hardening temperatures in the range 850–880°C are used, followed by oil quenching and tempering at 300°C to reduce internal stresses. Tensile strength is not increased to the same extent as hardness (Figure 26.4) and because of the risk of cracking during quenching, this process is usually restricted to small castings of simple shape.
Figure 26.4   *Effect of heat treatment on the strength and hardness of alloy cast iron*

Surface hardening, by flame or induction heating, is widely used to improve the wear resistance of critical surfaces on large castings such as slideways on machine tools. For good response to this treatment the as-cast structure must be fully pearlitic, and the phosphorus content must be below 0.2% to avoid pitting. Hardness in the range 450–500 HV are obtained with depths of 1–3 mm (0.040–0.125 in).

MALLEABLE IRONS

Malleable irons are brittle as cast, their structure consisting of iron carbide in a pearlitic matrix. By suitable heat treatment the carbides are broken down resulting in a structure that consists of graphite aggregates (temper carbon) in a matrix which may be ferritic or pearlitic, depending on composition and heat treatment conditions.

The British Standards (BS 309, 310 and 3333) specify neither composition (apart from maximum phosphorus content of 0.12%) nor heat treatment.

In practice, whiteheart malleable irons have an initial total carbon content of about 3.5% which is reduced to the range 0.25–2.0% by heat treating the castings at 900°C in an oxidising environment,

Table 26.59   MECHANICAL PROPERTIES OF WHITEHEART MALLEABLE IRON

Grade BS 6681:1986	Diameter of test bar d. mm[†]	Tensile strength min. R_m MPa	0.2 Proof stress min. $R_{p0.2}$ MPa	Elongation min. A %	Hardness typical max HB

	15	480	280	4	

* Although all grades of whiteheart malleable are weldable with correct procedure, W38-12 should be selected where strength and avoidance of post weld heat treatment is required.

[†] Test bar diameter should be representative of the important sectional thickness of the casting. Ref. British Cast Iron Research Association.

and slowly cooling. The required conditions may be produced by packing the castings in an oxidiser (e.g. hematite ore) or by use of a controlled atmosphere furnace. This results in a carbon gradient within the castings, the outer layer being normally ferritic and graphite-free while the core structure consists of temper carbon aggregates in a pearlitic matrix. Small castings of thin section may have a fully decarburised structure throughout, and this is sometimes referred to as a weldable grade of malleable iron.

Blackheart and pearlitic malleable irons have a lower initial total carbon content in the range 2–3%. Heat treatment in a neutral atmosphere at 850–875°C followed by slow cooling results in a uniform structure of temper carbon in a ferritic matrix.

Malleable irons Pearlitic have a structure consisting of temper carbon in a pearlitic matrix. This is produced either by fapid cooling after annealing or by the addition of 0.5% or more manganese. Pearlitic malleable irons have a good response to surface hardening by flame or induction heating, and hardness values of HV 500 can be consistently achieved in production.

NODULAR IRONS

In nodular (spheroidal graphite) irons free graphite is present as spheres or nodules in the as-cast condition. Graphite in this form has a much smaller weakening effect on the matrix than the dispersed graphite flakes in grey ions. Nodular irons therefore have considerably higher strength, ductility, and impact values than grey irons.

Cerium and magnesium additions both produce nodular structures, but the latter has been found to be more adaptable and economical. Both elements are desulphurisers and nodule formation is not possible until the sulphur content has been lowered to about 0.02%. Very small amounts of trace elements, such as 0.003% bismuth, 0.004% antimony, 0.009% lead and 0.12% titanium prevent nodule formation. The effect of these elements is additive, but it can be neutralised by the addition of sufficient cerium to give a residual content of 0.005–0.01%.

Magnesium may be added directly to the ladle as nickel–magnesium, nickel–silicon–magnesium or iron–silicon–magnesium alloy. Higher magnesium recovery is obtained using a plunging technique in which lower density, higher magnesium content additions such as magnesium impregnated coke are held below the liquid metal surface by means of a plunging head. Maximum recovery results from the addition of pure magnesium to the molten iron in a closed pressure-tight converter vessel. Because of equipment costs the use of this latter method is normally restricted to large-scale production.

In all cases the amount of magnesium to be added is given by:

$$Mg = \frac{\frac{3}{4}(\text{initial sulphur content}) + \text{residual magnesium content (usually } 0.03\text{–}0.05\%)}{\text{expected magnesium recovery}}$$

Nodular irons are inoculated with 0.4–0.8% silicon after nodulising to refine the structure and minimise chilling.

The carbon content of nodular irons is usually kept above 3.5% in the interests of good castability. Silicon, manganese and phosphorus should be below 2.3%, 0.4% and 0.06% respectively to give maximum ductility and impact value in the ferritic condition.

Nodular irons are slightly more prone to shrinkage defects than grey irons.

Adequate feed metal should be provided and moulds of high rigidity are to be preferred. Running systems should be designed to minimise turbulence, so as to prevent the entrapment of dross which tends to be formed as a result of the magnesium content.

Although nodular irons are much less section sensitive than grey irons, depending on the trace amounts of carbide stablising elements present, their matrix structures may range from fully pearlitic to completely ferritic, and chilling may occur in sections thinner than 5 mm (0.2 in).

By close control of analysis and inoculation practice nodular irons can be produced in the ascast condition over a wide range of section thicknesses with any required matrix structure from fully ferritic to fully pearlitic.

Alternatively, the matrix structure of nodular iron castings can be modified by appropriate heat treatments, since the presence of free carbon in the form of graphite enables diffusion of carbon to or from the graphite particles to take place. This is not possible with steels, which contain no free graphite. The effect of variation in matrix structure on mechanical properties is much more pronounced with nodular iron than with flake graphite cast iron, and by heat treatment of an iron of fixed composition foundries can produce castings conforming to the complete range of the grades of BS 2789:1985.

Practical heat treatments include:

Annealing Heat to 850–900°C where the matrix becomes completely austenitic and slow furnace cool at 20–35°C per hour to below 700°C. Alternatively, cool more rapidly to 700–720°C and hold for 4–12 h, followed by air cooling. Ferritic iron produced in this way confirm to BS 2789: 1985 grades 350/22 to 420/12.

Normalising This is carried out by air cooling from 850 to 900°C, and produces a mainly pearlitic matric conforming to grades 700/2 and 800/2 in castings of light and medium section. The use of alloying elements is often necessary to produce a pearlitic matrix in heavier section castings.

Hardened and tempered structures These are produced by oil quenching from 850 to 900°C and tempering at 550–600°C. Material conforming to BS 2789 Grade 800/2 and 900/2 is sometimes invariably produced by this method.

Austempering is carried out by heating castings to 850–950°C, followed by quenching to an isothermal treatment temperature within the range 230–400°C and holding this temperature typically for 1–2 h. A variety of bainitic structures can be obtained, resulting in combinations of strength, ductility and toughness which cannot be achieved in ductile irons by other means. These austempered ductile irons (ADI) are used for many different engineering applications such as gears, crankshafts, vehicle suspension components and parts of earthmoving equipment. Provisional specifications for various countries to cover ADIs are summarised in Table 26.63. The various grades can be typically produced from the same ductile iron by adjustment of the austempering time and temperature.

ADI exhibits section size sensitivity and test bars are not representative of heavy sections. At −40°C high toughness grades may show a drop of 15% in yield strength as well as a drop in tensile strength compared with room temperature values. No changes have been found in elevated temperature properties up to 300°C. Also of concern is the low temperature toughness and the ductile–brittle transformation temperature although notched specimen results indicate gradual toughness transition as temperature decreases.

Mixed matrix structures Structures intermediate between the annealed and normalised grades have a range of mechanical properties depending on the ratio of ferrite to pearlite. The corresponding grades of BS 2789 are 400/10, 500/7 and 600/3. In practice these structures are produced by austenitising at 850–900°C followed by either controlled rapid cooling at lapproximately 100°C per hour through the critical temperature range of 720–800°C or by rapid air cooling from an appropriate intermediate temperature, e.g. 730°C, within the critical range.

26.9.3   Compacted graphite irons

Although the existence of compacted graphite containing irons has been known for many years, it is only relatively recently that they have been commercially exploited. Such irons are characterised by the graphite being present in the form of relatively short, thick flakes with rounded extremities and undulating surfaces.

In general compacted graphite irons have mechanical and physical properties intermediate between those of conventional flake graphite irons (grey irons) and nodular graphite irons. The outstanding characteristics are good thermal conductivity combined with useful ductility and higher tensile and fatigue strengths than for grey irons.

At present no British Standard exists for these materials.

The presence of certain element combinations in irons which would otherwise solidify with a conventional flake graphite form may promote the formation of the compacted type of graphite. At present the production of compacted graphite irons is largely based on additions of magnesium and/or cerium to irons of low sulphur content. The magnesium based treatments are similar to those employed for nodular graphite iron production while the cerium methods are usually simple ladle addition processes.

In the magnesium process, as the magnesium content is increased, the graphite structure changes from conventional flake, through compacted flake to fully nodular. The range of magnesium contents to facilitate compacted flake structures is very narrow and it is usually necessary to employ additions of titanium and cerium to extend the range and provide a practical ladle based process. Magnesium and titanium are usually present in the ranges 0.015–0.035 per cent and 0.08–0.15 per cent respectively with a trace of cerium.

Fully compacted graphite irons have combinations of properties intermediate between those of conventional flake and nodular irons, as shown in Table 26.64. They behave elastically over a range of stresses although their limit of proportionality is lower than nodular irons. The tensile properties of compacted graphite irons are less sensitive to variations in carbon equivalent than conventional flake irons (Fig. 26.5) but they are section sensitive (Fig. 26.6).

Compacted graphite irons have intermediate thermal conductivity values between flake and nodular iron and comparative figures are given in Table 26.65.

Si16	0.8	16.0/18.0	0.5	0.25	0.1	—	Corrosion resistance at expense of strength

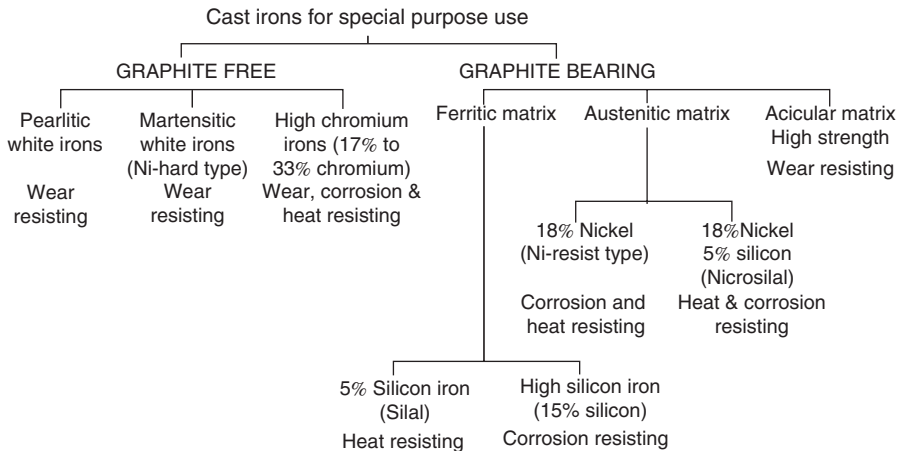
Heat treatment: Castings to be stripped from moulds while hot and as soon as possible after solidification, the hot castings to be charged to a furnace preheated to approximately 600°C and kept at this during charging. Then heat to not less than 750°C and not more than 850°C. Soak for 2 hours for castings of simple form and thickness less than 18 mm and for 8 hours for heavy castings. Cool slowly after soak to 300°C before unloading.


Figure 26.7   *Classification of special purpose cast irons*

The combination of relatively high strength and good thermal conductivity has resulted in compacted graphite irons primarily finding application where containment of stress at high temperature or under thermal cycling conditions are important. Applications for ingot moulds, cylinder heads, brakedrums and discs and manifold castings are typical.

British Standards are summarised for Austenitic irons BS 3468: 1986 Table 26.66, for alloy cast irons BS 4844: 1986 in Table 26.67 and for corrosion resisting high silicon irons BS 1591: 1975 in Table 26.68.

26.9.4   Applications of special purpose cast irons

HIGH TEMPERATURE

Irons in the general engineering group are suitable for applications up to at least 350°C where long-term dimensional stability is required. There are also many instances of the use of grey irons in the temperature range up to 700°C provided that appreciable growth and scaling can be tolerated.

For extended life at temperatures up to 850°C one of the alloyed irons, such as Ni-resist, Silal or Nicrosilal, may be used. The austenitic materials Ni-resist and Nicrosilal have good thermal shock resistance, but Silal is limited to applications where severe temperature gradients are absent. Above 850°C the most suitable material is 30% chromium iron, which has good oxidation resistance and a useful level of creep strength up to 1 050°C.

Table 26.69   TYPICAL ANALYSES OF OTHER SPECIAL PURPOSE CAST IRONS

Type or trade name	C %	Si %	Mn %	S %	P %	Ni %	Cr %	Mo %	Characteristics

* Trade name–International Nickel Ltd.
[†] Trade name–Ferranti Ltd.

CORROSION

Ni-resist, Nicrosilal, high silicon iron and high chromium iron have good corrosion resistance in appropriate media. For example, Ni-resist and Nicrosilal have good resistance to sea water, strong alkalis, inorganic salts and weak acids. These materials are machinable without difficulty. High silicon irons have excellent resistance to sulphuric and nitric acids at all temperatures and concentrations, but have the disadvantage that they are brittle and can only be machined by grinding. High chromium (30%) irons are the only cast irons which can be regarded as stainless so far as atmospheric exposure is concerned. They develop a passive film under oxidising conditions and their outstanding characteristic is the ability to withstand attack by nitric acid at temperatures up to boiling point and concentrations up to 70%. This grade of iron is machinable without difficulty provided the carbon content is restricted to a maximum of 1.5%.

ABRASION

A graphite-free structure is essential for good resistance to abrasion. The irons which meet this requirement, as shown in Figure 26.7 are the unalloyed pearlitic white irons, martensitic white irons of the Ni-hard type and high carbon high chromium irons.

It is difficult to relate wear characteristics determined in a laboratory to practical service conditions, and there is considerable overlapping between the fields of application for these materials. In the absence of experience of similar conditions, evaluation of material must sometimes be made by trial. In general, martensitic white irons have better abrasion resistance than pearlitic white irons. High chromium, high carbon irons are particularly useful where abrasion is combined with impact loading and where abrasive and corrosive conditions exist together. *See* Chapter 25. Some proprietary special purpose cast irons are listed in Table 26.69.

27 Engineering ceramics and refractory materials*

27.1 Physical and mechanical properties of engineering ceramics

Intensive development of ceramic materials has increased the availability of well-characterised engineering ceramics capable of use over a range of temperatures and atmospheres. Table 27.1 summarises the properties of the most commonly used engineering ceramics while Table 27.2 gives more information about a range of ceramics. However, the data in the tables should be regarded as representative since actual values are a strong function of exact composition and microstructure. Furthermore, since these materials are often used at high temperatures the properties at use rather than room temperature (RT) are important.

Table 27.2   PROPERTIES OF PURE CERAMIC MATERIALS

Material	Melting point °C	Bulk density g cm^{-3}	Thermal conductivity Wm^{-1} K^{-1} at temp. °C	Thermal expansion coefficient 10^{-6} to temp. °C		Strength MPa (technique, measured temp. °C)	Remarks
Chromium diboride, CrB$_2$	2 100	5.2	32 at 20	7.5	20	—	Stable in presence of carbon
Hafnium diboride, HfB$_2$	3 250	11.2	6.3 at 20	5.3 5.5	500 1 000	—	No reaction with basic slags for 6 minutes at 1 520°C. Stable in presence of carbon, no reaction with steel for 6 min at 1 620°C
Tantalum monoboride, TaB	2 340	14.0	—	—		—	Oxidation severe at 1 100–1 400°C. Unstable in presence of carbon
Tantalum diboride, TaB$_2$	3 200	12.4	10.9 at 20 13.9 at 200	—		—	Oxidised in air at 800°C. Stable in presence of carbon
Titanium diboride, TiB$_2$	2 980	4.5	26 at 20 26 at 200	7.6	1 000	—	Very stable, even in presence of carbon. Oxidation in air severe at 1 100–1 400°C. Max. working temperature 2 000°C reducing, 800°C oxidising
Zirconium diboride, ZrB$_2$	3 060	6.1	23 at 20 23–26 at 200	5.5–6.6 7.0	1 000 1 500	—	No reaction with basic slags at 1 520°C for 6 min. No reaction with carbon steel at 1 620°C for 2 h. Stable in presence of carbon. Oxidation in air severe at 1 100–1 400°C. Stable under inert or reducing conditions to over 2 000°C
Boron carbide, B$_4$C	2 350	2.51	29 at 20 84 at 425	4.8 5.5 6.5 7.1	500 1 000 2 000 2 500	2 900 (comp, 20), 155 (comp, 980), 300 (MOR*, 20)	Attacked by iron, Thermal shock resistance poor. Resistant to air up to 1 000°C but max. working temp. 2 000°C reducing, 600°C oxidising
Hafnium monocarbide, HfC	3 890	12.2	—	6.3 6.25	500 1 000	—	Oxidation in air severe at 1 100–1 400°C. Stable to 2 000°C in He
Silicon carbide, SiC	2 700	3.17	42 at 20 21 at 1 000	4.6 5.5 5.9	500 1 500 2 500	550 (comp, 20)	Quite resistant to oxidation by air up to 1 650°C. Thermal shock resistance very good. Reacts with Fe and MgO in basic slags to give silicides. Reacts with iron. High resistance to acid or neutral slags and coal ash: Used in gasifiers, zinc retorts. Also used as abrasive. Used in electrical heating elements. Max. working temp. 2 320°C reducing, 1 650°C oxidising (see also Table 27.1)
Tantalum monocarbide, TaC	3 880	14.7	22 at 20	6.3 6.7 8.4	500 1 000 2 500	—	Oxidation in air severe at 1 100–1 400°C. Useful in He to 3 760°C

* MOR, Modulus of Rupture

Table 27.2   PROPERTIES OF PURE CERAMIC MATERIALS—*continued*

Material	Melting point °C	Bulk density g cm^{-3}	Thermal conductivity Wm^{-1} K^{-1} at temp. °C	Thermal expansion coefficient 10^{-6} to temp. °C		Strength MPa (technique, measured temp. °C)	Remarks
Titanium monocarbide, TiC	3 140	4.25	32 at 20 5.5 at 1 000	7.7 9.7	1 000 2 500	750 to 1 300 (comp, 20)	Oxidation in air becomes severe at 1 200°C. Max useful temp. 3 000°C in He
Tungsten carbide, WC	2 777	15.7	84 at 20	4.9 5.8 to 6.1	1 000 2 000	—	Oxidation in air severe 500–800°C useful to 2 000°C in He. Extremely hard (9+Mohs. Vickers pyramid 2 400) used in drill tips. Max. working temp. 2 000°C reducing, 550°C oxidising
Zirconium monocarbide, ZrC	3 540	6.7	21 at 20	6.1 6.6 7.6	500 1 000 2 000	1 640 (comp, 20)	Oxidation in air becomes severe at 1 100–1 400°C. Max. useful temp. 2 350°C in He
Graphite, C	3 650 (sub-limes)	1.50 to 2.25	63 to 210 at 20, parallel to grain. 42 to 130 at 20, perpendicular to grain. 47 at 1 300 34 at 2 500	Parallel: 1 to 4 20 Perpendicular: 2.5 to 4.5 4.0 1 000 to 9.8 5.5 1500 to 11 compression		Parallel 3.5 to 7.6 at 20°C Perpendicular 3.5 to 70 at 20°C compression 36 at 2 500°C compression	Thermal shock resistance very good. Not wetted by iron. Resistant to acidic and basic slags. Oxidised in air above 300°C. Resistant to non-oxidising gases. May be 'welded' using molybdenum disilicide. Excellent conductor of electricity
Aluminium nitride, AlN	2 230	3.26	150–180 at 20°C	4.8 5.5	500 1 000	300 (MOR, 20)	Oxidised by O$_2$ above 1 000°C. Unstable in water vapour. Stable in N$_2$–H$_2$ mixtures at 1 200–1 600°C
Boron nitride, BN (hexagonal)	2 330 (sub-limes)	2.1	15 at 20 27 at 1 000 (Perpendicular values are approx. half of these.)	Parallel to pressing direction 2.0 1 000 Perpendicular 13.3 1 000		Parallel to pressing direction 310 (comp, 20) Compressive perpendicular 235 (comp, 20)	Thermal shock resistance very good when dry. No reaction with iron at 1 600°C for 30 min. Oxidation in air severe at 1 100–1 400°C. Stable to 1 000°C in O$_2$. Resists attack by molten metals and glasses. Low coeff. of friction. Fabricated by hot pressing. Machines easily. Max. working temp. 2 200°C reducing, 1 000°C oxidising
Silicon nitride, Si$_3$N$_4$	1 900 (sub-limes)	3.2	2.3 to 13 at 20 9.4 at 1 200	α phase 2.1 500 3.7 1 500 β phase 1.5 500 3.1 1 500		—	Thermal shock resistance good. Reacts with iron. Useful to 1 850°C in reducing or inert conditions. Stable in air to 1 200°C. Resistant to molten glasses, molten Al, Pb, Zn, Sn and to HCl, H$_2$SO$_4$ and HNO$_3$. Reacts with molten Cu. Slowly attacked by boiling water. May be partially nitrided, machined, then fully nitrided. Used in aluminium handling thermo-couple sheaths, cutting tools, wear resistant parts. *See* Table 27.1 for different types

Table 27.2   PROPERTIES OF PURE CERAMIC MATERIALS—*continued*

Material	Melting point °C	Bulk density g cm⁻³	Thermal conductivity Wm⁻¹ K⁻¹ at temp. °C	Thermal expansion coefficient 10⁻⁶ to temp. °C		Strength MPa (technique, measured temp. °C)	Remarks
SIALONS, α (glass bonded)	1 800d	3.22	10.9 (20)	3.2 (20–1 200)		833 (bend, 20)	Sialons ≡ Si_3N_4 with Al and O replacing some Si and N
β (glass bonded)	1 800d	32.5	22 (20)	3.04 (20–1 200)		945 (bend, 20)	respectively. α-sialons incorporate cations e.g. Ca,Mg into crystal structure. Commercial sialons use 2nd phases e.g. glass or yttrium aluminium garnet to provide bonding. Good thermal shock resistance and better oxidation resistance than pure nitrides.
Titanium mononitride, TiN	2 900	5.3	29 at 20 8.5 at 1 000	—		—	No reaction with basic slags. Slightly wetted by carbon steel at 1 620°C. Poor oxidation resistance to O_2 at 600°C and to CO_2 at 1 200°C
Zirconium mononitride, ZrN	2 950	7.1	27 at 20 6.7 at 1 000	6.13 7.03	450 680	—	Slight reaction with cast iron at 1 450°C for 2 h. Oxidation in air severe at 1 100–1 400°C. Slow hydrolysis in water
Aluminium oxide, Al_2O_3	2 050	3.97	39 at 20 9.2 at 600 5.9 at 1 400 7.1 at 1 800	7.6 8.5 8.9 to 9.1	500 1 000 1 400	2 940 (comp, 20) 48 (comp, 1 600) 203 (shear, 20) 23 (shear, 1 500)	Thermal shock resistance fair. α stable form, range of metastable cubic transition aluminas (e.g. χ, δ, γ, θ, etc.) form e.g. on calcination of Gibbsite converting to α at high temperature. Good resistance to basic and acidic slags. Max. working temp. 1 900°C (see Table 27.1 for zirconia-toughened alumina)
Beryllium oxide, BeO	2 530	3.00	202 at 100 29 at 1 000 15 at 1 700	7.6 8.6 to 9.0 10.3 11.1	500 1 000 1 500 2 000	786 (comp, 20) 48 (comp, 1 600)	Becomes volatile at 2 100°C; very poisonous. Not reduced by carbon or hydrogen. Attacked by acids, fluxed by alumina
Calcium oxide, CaO	2 572	3.32	15.5 at 100 8 at 1 000	11.8 13.1 15.3	500 1 000 1 500	—	Thermal shock resistance fair. Poor resistance to attack by slags containing FeO and SiO_2. Subject to hydration
Cerium dioxide, CeO_2	2 600	7.3	—	8.2 8.9	500 1 000	—	Useful in air to 2 400°C. Not useful in reducing conditions. Subject to hydration
Dichromium trioxide, Cr_2O_3	2 435	5.21	—	8.4 8.6 8.8	500 1 000 1 500	—	Slag resistance good under oxidising conditions. Less resistant to basic slags Cr^{6+} known carcinogen may form in use.
Hafnium dioxide, HfO_2	2 810	9.68	—	Monoclinic 5.5 5.8 6.4 Tetragonal 1.3 3.0	500 1 000 1 700 1 700 2 000	— —	Useful in air to 2 400°C. Stable in H_2 to 1 925°C

Table 27.2   PROPERTIES OF PURE CERAMIC MATERIALS—*continued*

Material	Melting point °C	Bulk density g cm^{-3}	Thermal conductivity Wm^{-1} K^{-1} at temp. °C	Thermal expansion coefficient 10^{-6} to temp. °C	Strength MPa (technique, measured temp. °C)	Remarks
Magnesium oxide, MgO	2 800	3.58	46 at 20 8.4 at 800 6.3 at 1 400 9.2 at 1 800	12.8 500 13.6 1 000 15.1 1 500 15.9 1 800	83 (shear, 20) 39 (shear, 1 300)	Thermal shock resistance poor; can be improved by small amounts of spinel. Resistance to both acidic and basic slags excellent. Limits of usefulness: to 1 600°C in vacuum; 1 700–1 980°C in reducing atmosphere; 2 400°C in air. Melts at 2 680°C in oxygen-free helium. Subject to hydration
Silicon dioxide SiO$_2$	1 710	2.32	1.5 at 20 2.5 at 1 600	α quartz 22.2 575 β quartz 27.8 575 14.6 1 000 Vitreous 0.55 1 000		Thermal shock resistance of vitrified silica is excellent. Polymorphic forms of silica are quartz, tridymite and cristobalite. The last two of these are metastable under ordinary conditions. Transition temps: quartz-tridymite 870°C. Tridymite-cristobalite 1 470°C. Vitreous silica devitrifies at 1 100°C
Thorium dioxide ThO$_2$	3 205	9.7	10 to 15 at 20 2.9 at 1 000 2.5 at 1 400	8.6 500 9.1 1 000 to 9.4 10.4 1 400	1 480 (comp, 20) 10 (comp, 1 500) 8.3 (shear, 1 300)	Thermal shock resistance poor. High resistance to basic slags. Reduced by carbon at high temp. Becomes volatile in He at 2 300°C
Zirconia, ZrO$_2$	2 690	5.75	2.0 at 25 2.3 at 800 2.7 at 1 400	Monoclinic 6.5 500 7.7 1 050 Tetragonal 7.9 600 8.3 1 400	2070 (comp, 20) 102 (comp, 20) 19 (comp, 1 500)	Zirconia phase changes monoclinic → cubic at 1 050°C. Thermal shock resistance influenced by volume change accompanying phase change. Stable in oxidising atmosphere. Fairly stable in reducing atmosphere. Excellent resistance to basic and acidic slags. See Table 27.1 for stabilised zirconias
Mullite, 3Al$_2$O$_3$·2SiO$_2$	1 830	3.16–3.22	7.1 at 25 4.0 at 800 3.8 at 1 400	5.1 to 5.8 1 000°C	150–500 (comp, 20) 16.6 (shear, 1 100)	Thermal shock resistance good. Max. working temp. 1 650°C (see also Table 27.1)
Magnesia spinel, MgO. Al$_2$O$_3$	2 135	3.51	18 at 25 8 at 600 5.5 at 1 200	8.4 1 000 to 8.6 9.4 1 400	1 370 (comp, 550) 59 (comp, 1 600) 65 (shear, 20) 37 (shear, 1 300)	Resistant to slags containing iron oxide. More resistant than alumina to action of reducing slags. Stable to 1 400°C in H$_2$. Thermal shock resistance fair. Max. working temp. 1 950°C

(*continued*)

Table 27.2 PROPERTIES OF PURE CERAMIC MATERIALS—*continued*

Material	Melting point °C	Bulk density g cm^{-3}	Thermal conductivity Wm^{-1} K^{-1} at temp. °C	Thermal expansion coefficient 10^{-6} to temp. °C		Strength MPa (technique, measured temp. °C)	Remarks
Zircon, $ZrO_2 \cdot SiO_2$	2 550	4.56	6.1 at 100 4.2 at 800 4.0 at 1 400	3.8 4.6 5.3	500 1 000 1 500	60 (shear, 20) 16 (shear, 1 300)	Dissociates above 1 700°C. Due to action of slags containing FeO, zircon would dissociate in steel-making environments. Thermal shock resistance good
Molybdenum disilicide, $MoSi_2$	2 030	5.95 to 6.24	31.5 at 20 to 200 17 at 1 100	7.8 8.5 9.0	500 1 000 1 500	2 280 (comp, 20)	Carbon reduces melting point to 1 870°C. Corrosion in air becomes severe at 1 700°C. No attack by O_2 to 1 100°C. Used in electrical heating elements
Tungsten disilicide, WSi_2	2 165 to 2 180	9.25		7.8 8.3	500 1 000		Corrosion in air severe above 1 950°C

27.2 Prepared but unshaped refractory materials

These materials are commonly used for installation and/or repair of refractory linings. By definition, unshaped or monolithic refractory materials are prepared mixtures for use either as delivered or after the addition of an appropriate liquid. This definition covers the refractory cements, mouldable and castable materials, ramming and gunning mixes. One major difference between materials in this group and brick or blocks (shaped refractories) is the considerably reduced number of joints in a structure, i.e. these materials tend towards a monolithic construction. Monolithics now account for over 50% of refractories sold worldwide. Both unshaped monolithic and shaped brick refractories have a microstructure consisting of large (often mm scale) isolated grain or aggregate phases held together by a much finer and more reactive bond or matrix system. Typical grain materials listed in Table 27.3 include bauxite, graphite and magnesite while bond systems may be clay based or use a range of fine powders such as fumed SiO_2, hydratable alumina or aluminous cements (section 27.3). In addition many steelmaking refractories are bonded with very fine carbon derived by pyrolysis of phenolic resin or pitch binders (Table 27.5). Table 27.4 lists properties of typical fired bricks while Table 27.5 gives properties of blocks which are installed unfired and then fired in situ. Properties of low thermal mass (LTM) refractories are given in Table 27.6.

27.3 Aluminous cements

Hydraulic aluminous cement is manufactured by fusing or sintering a mixture of bauxite and limestone. In general the silica content is kept as low as the raw materials permit and it is preferred that the iron should be in the ferric rather than ferrous condition. Commercial aluminous cements vary somewhat in composition but usually lie in the following ranges: SiO_2 4–7%, Al_2O_3 36–42%, Fe_2O_3 8–12%, FeO 4–8%, TiO_2 2–3% and CaO 36–42%. These cements depend on the presence of calcium aluminates for their properties and by adding various forms of alumina, calcined bauxite, chrome and magnesia, it is possible to produce hydraulic cements with excellent refractory properties.

Calcium aluminate cements have unique properties in that they can be moulded, air-hardened and used directly as the bond system in refractories. They are relatively slow-setting (1–2 h) but rapid-hardening (24 h). In general, the higher the temperature of firing and within limits the higher the percentage of alumina they contain, the more refractory they become. They are notable for their relatively small shrinkage on heating to 400°C and small expansion on heating to 1 350°C (0.5–1.5%). Their resistance to heat is very good and the best products can be used up to 1 600°C

* Loss on ignition.

without softening. Calcium aluminate cements lose strength when heated to 400°C, but then remain unchanged up to 1 000°C and gradually recover again at higher temperatures.

27.4   Castable materials

These are mixtures of graded refractory aggregate and either a hydraulic cement or a chemical bonding agent. The material is usually supplied dry, and at the appropriate moisture content it may be cast. The mix is controlled to be either vibratable where vibration is used to remove bubbles increasing density or self flowing where no additional vibration is needed during installation. Modern castable compositions are designed to have reduced levels of calcium aluminate cement (termed low cement, ultra low or cement free castables) since the lime degrades high temperature properties. Properties of typical materials in this group are shown in Table 27.7. Castable materials are used increasingly in furnace linings, production of special shapes, covers of soaking pits, burner blocks, floors of aluminium holding vessels, cyclones and incinerators.

27.5   Mouldable materials

These are mixtures of graded refractory aggregates and plasticisers, usually clay, supplied mixed with water in a workable condition. Chemical bonding agents may also be incorporated. The workability of the material is such that it may be placed by hand malleting. These materials usually have good thermal shock resistance, but a low compressive strength which does, however, improve after the production of a ceramic bond. The thermal conductivity is usually lower than that of the equivalent shaped and fired material.

Properties of a typical material from this group are shown in Table 27.7.

27.6   Ramming material

This is a mixture of graded refractory aggregate with or without the addition of a plasticiser and with or without water usually supplied at a consistency which requires a mechanical method of application. The material is placed in position by means of hand or pneumatic rammers. It is most important that all the material should be compacted to the same extent (i.e. an even density of packing) and that laminations should be avoided.

Properties of a phosphate-bonded ramming mix are given in Table 27.7.

27.7   Gunning material

Many of the materials which fall into the above groups may be suitably prepared for application by gunning techniques. The suitably prepared material is introduced into a high pressure compressed air line in a specially designed gun and the material is blasted at the desired area to be lined. In dry gunning water is mixed with the powder batch at the gun nozzle whereas in wet gunning or shotcreting the powder and water are pre-mixed. The benefit of the latter process is reduced dust hazard and material rebound.

27.8   Design of refractory linings

A refractory lining usually comprises a safety or backup layer behind the working lining in contact with the furnace contents. The whole body is encased in a metal shell. The temperature gradients in the system and the properties of all materials must be considered.

Essential to the designer of refractory structures is a knowledge of the mechanical properties of materials to be used (e.g. thermal expansion, thermal conductivity, Young's modulus and ultimate strength). Standard test methods do not necessarily give the most useful data. The cold crushing strength of a fired brick is generally much greater than its crushing strength at higher temperatures; rectangular blocks heated from one end do not expand as expected from the free thermal expansion; nor is the Young's modulus of a stressed block the same as that of an unstressed block.

Table 27.8 indicates the amount of data needed when installing a refractory. Since the values may change substantially with temperature it is important to have data over the range of temperature. In particular, the designer of any refractory lining should be aware of the free thermal expansion and hot strength of all materials used. This is most important in any system operating above 1 100°C. In order to establish shell temperatures, interface temperatures etc. thermal conductivity values should also be known. Finite element methods are frequently used to determine temperature/property profiles.

The first stage of design is to carry out a thermal analysis under the worst thermal conditions expected with the aim of ensuring that no material exceeds a safe operating temperature. There are several commercial computer programs that perform these calculations. Most materials should not be allowed to come within 100°C of their 'maximum service temperature' but for fibre materials the margin should be increased to 200°C. Once service temperatures are determined, stability of the lining should be considered. Linings in tilted vessels such as steel ladles or electric arc furnaces must not be allowed to come loose (bricks will fall out or metal penetration of joints will occur). On the other hand, expansion of refractories should not be such as to cause excess stresses leading to lining failure by cracking, shell fracture, anchor failure or other problems. It is not easy to devise a simple rule dealing with such conditions and if this may be a concern (especially for vessels more than 2 m wide) expert engineering advice should be sought. If high stresses are expected, expansion allowances should be used where possible. Pieces of cardboard, fibre blanket, wood etc. may be placed between bricks during installation to give expansion allowance. For monolithic (castable)

linings, gaps are left between panels. These methods are more difficult when the lining will hold molten metal, because metal may penetrate the expansion allowances. For vessels holding molten metal, expansion allowances are often introduced by installing a layer of soft ramming material behind the working lining. During operation, the working lining expands outwards to compress the ramming layer. Where soft ramming layers are used, it is important to install the correct thickness of a suitable material, and this is another matter on which expert advice should be sought. When considering high-temperature properties the hot modulus of rupture (flexural or bend strength) of refractories is often given although refractoriness-under-load test data are sometimes available but should be interpreted carefully. An index of standards applicable to refractories is given in Table 27.9.

28   Fuels*

28.1   Coal

There are a number of different sets of National Standards in use and the major ones are the British Standards, ASTM (US), EN (Europe), and the Russian and Chinese standards. There are many common features amongst these standards many of which emanate from the British Standards that are listed below.

28.1.1   Analysis and testing of coal

SAMPLING FOR ANALYSIS

In order to be representative, the gross sample is compiled by collecting a number of increments spaced evenly throughout the mass of the consignment of coal and, for the specific method, BS 1017: 1989 should be consulted. The mass of an increment is determined by the maximum size of the coal shown in Table 28.1.

  The minimum number of increments required may be obtained from Table 28.2 and is determined by the class of coal and the purpose of the sample. Separate general analysis and total moisture samples may be desirable, e.g. when the coal is very wet, otherwise a common sample can be taken from which both total moisture and general analysis samples are prepared.

  Reference standards for the precision of measurements on the samples are given in Tables 28.3 and 28.4. The levels of precision represent the 95% probability limits of the deviation of any single value from the true value.

  Sampling from a stopped belt is the ideal method for sampling commercial coal and it should be used whenever practicable as the standard against which other methods are checked.

PROXIMATE ANALYSIS CONSISTS OF THE FOLLOWING DETERMINATIONS (BS 1016: 1991):

Total moisture which accounts for the 'free' or adventitious moisture, together with the 'inherent' or original moisture always associated with the coal. Moisture is determined by heating the air-dried coal, ground to pass a 0.2 mm sieve, to 105–110°C in a vacuum oven or in a stream of nitrogen. The loss in weight is the moisture on the air-dried sample (BS 1016: Section 104.1; 1991).

Table 28.1   MINIMUM MASS OF INCREMENT AND SIZE OF ENTRY INTO SAMPLING IMPLEMENT

Nominal upper size of coal, mm	<10	10–25	25–50	50–75	75–100	100–125	125–150	>150
Minimum size of entry into sampling implement, mm	30	75	150	200	250	320	375	>375
Minimum mass of increment, kg	0.5	1.5	3.0	4.5	6.0	8.0	14.0	>14

---

Volatile matter is the % loss in weight corrected for moisture when 1 g of the less than 0.2 mm coal is heated in the absence of air to 900°C (BS 1016, Section 104.3; 1991).

Ash is determined by placing 1 g of the 0.2 mm coal in a muffle furnace at room temperature, raising the temperature to 500°C in 30 min, to 815°C in a further 60–90 min and maintaining this temperature until the residue, which is the ash, is constant in weight (BS 1016: Section 104.4; 1991).

% *Fixed carbon* is defined as:

$$100 - (\% \text{ moisture} + \% \text{ ash} + \% \text{ volatile matter})$$

ULTIMATE ANALYSIS

Requires in addition to ash and moisture determinations (described above) figures for carbon, hydrogen, nitrogen and sulphur.

CALORIFIC VALUE

For practical purposes may be expressed as the number of heat units liberated by the complete combustion of unit weight of coal in a bomb calorimeter. Corrections are made for the formation of nitric and sulphuric acid originally present as nitrogen and sulphur in the coal (BS 1016: Part 105; 1992).

CALCULATION OF CALORIFIC VALUE FROM ULTIMATE ANALYSIS

The calorific value of a fuel may be checked from the ultimate analysis. Usually the calculated value agrees to within 1–2% of the determined value.

In the following formula, which gives the *gross* calorific value (CV), the symbols used give the percentages of: C, carbon; H, hydrogen; O, oxygen; N, nitrogen; S, sulphur.
Grummell Davies:

$$\text{CV} = (0.015\,22\,H + 0.937)[C/3 + H - (O - S)/8]\,\text{MJ kg}^{-1}$$

Gross and net calorific values   All coals contain hydrogen and water, and in the determination of calorific value the water vapour resulting from the combustion of the hydrogen and the vaporisation of the original water is condensed to the liquid state. In boiler practice it is not possible to cool the flue gases to a temperature below the dew point and thus the latent heat of condensation of the steam is not recovered.

The *gross* calorific value as determined by the bomb is, therefore, corrected for boiler efficiency work by deducting 2.454 MJ kg^{-1} (1 055 Btu lb^{-1}) of water obtained on combustion. The corrected figure is termed the *net* calorific value.

BS SWELLING NUMBER

Provides a means of assessing the tendency of a coal to swell when it is carbonised or used in a combustion appliance. If 1 g of less than 0.2 mm coal is heated in a squat-shaped silica crucible of

standard dimensions by a Meker burner (with rich gas) or a Teclu burner with coal gas or a specially designed electric furnace, a coke button of a definite size and shape is produced. By reference to standard profiles a BS swelling number may be assigned to the coal (BS 1016: Section 107.1; 1991).

ROGA TEST[1]

A mixture of 1 g of less than 0.2 mm coal and 5 g of a standard anthracite is carbonised in a crucible. The resulting coke button is tested in a Roga drum for its resistance to abrasion. From the results obtained the coal coking index (Roga index) is calculated.

International standard ISO 335-1994(E).

GRAY KING COKE TYPE

The caking properties of a coal or blend of coals is assessed by carbonising in a laboratory assay under standard conditions. The coke residue is classified by comparison with a series of described standard coke types (BS 1016: Section 107.2; 1991).

AUDIBERT-ARNU DILATOMETER TEST[1]

The test assesses the coking properties of coal or coal blends. A pencil of powdered coal is inserted in a narrow tube and topped by a steel rod which slides in the bore of the tube. The whole is heated at a constant rate. The displacement of the piston is recorded as a function of the temperature. The maximum dilatation and contraction are recorded as a percentage of the original length of the pencil, and the temperatures of the points of softening, maximum dilatation and maximum contraction are noted.

ASH FUSION POINT

Ash fusion point of a coal ash is considered to be a rough guide to its clinkering propensities. The fusion point in a reducing atmosphere is lower by about 40°C than that in an oxidising atmosphere.

Group 1   Fusion temperature 1 425–1 710°C, Clinkering troubles absent.
Group 2   Fusion temperature 1 200–1 425°C. Clinkering manageable.
Group 3   Fusion temperature 1 040–1 200°C. Clinkering troubles excessive, unless adequate precautions are taken.

The determination is made on a trilateral pyramid, a cube or a right cylinder prepared in a mould from finely ground ash (BS 1016: Part 113; 1995). The test-piece is heated in an oxidising or a reducing atmosphere defined as follows:

A reducing atmosphere   An atmosphere consisting by volume of 50% hydrogen and 50% carbon dioxide with a tolerance of ±5%.

or

An oxidising atmosphere   An atmosphere consisting of either carbon dioxide or air.

The temperatures determined are:
(a) *Deformation temperature.* The temperature at which the first sign of rounding of the tip of the test specimen occurs.
(b) *Hemisphere temperature*. The temperature at which the height of the specimen is equal to half the base, its shape being approximately hemispherical.
(c) *Flow temperature*. The temperature at which the height of the specimen is equal to one third of that at the hemisphere temperature.

CALCULATION OF THE MINERAL MATTER CONTENT OF COAL

All classification systems are based on coal free from mineral matter and moisture. The analytical data for the coal 'as received' thus require correction in the sense of the following equations. The symbols have the following meanings: W_a, moisture; A, ash; V, volatile matter; C, carbon; H, hydrogen; S, sulphur; N, nitrogen; M_b and M_k, estimates of the mineral matter content; all expressed as

percentages on the air-dried basis. Q is the calorific value $MJ\,kg^{-1}$ (Btu lb^{-1}), on air-dried basis and W_t is the total moisture % on the 'as received' or 'as fired' basis.

(a) To convert 'air dried' to 'as received':

Multiply A, V, C, H, S, N, Q by $\left[\dfrac{100 - W_t}{100 - W_a}\right]$

(b) To convert 'air dried' to 'dry ash-free':

Multiply V, C, H, S, N, Q by $\left[\dfrac{100}{100 - (W_a + A)}\right]$

(c) To convert 'air dried' to mineral matter-free basis:

Multiply C, H, N, Q by $\left[\dfrac{100}{100 - (W_a + M_k)}\right]$

The volatile matter on a dry mineral matter-free basis is given by[2]

$$\frac{100(V - c)}{[100 - (W_a + M_k)]}$$

According to the analysis available the correction c is given by

$$c = 0.13A + 0.2S_{pyr} + 0.7CO_2 + 0.7Cl - 0.20$$
$$\text{or } c = 0.13A + 0.2S_{total} + 0.7CO_2 + 0.7Cl - 0.32$$
$$\text{or } c = 0.13A + 0.2S_{total} + 0.7CO_2 - 0.12$$

The mineral matter (M_k) is most accurately expressed by a modification of the King, Maries and Crossley[3] formula:

$$M_k = 1.13A + 0.5S_{pyr} + 0.8CO_2 - 2.8S_{ash} + 2.8S_{sulph} + 0.5Cl$$

in which A is the determined ash; CO_2, carbon dioxide; S_{pyr}, pyritic sulphur; S_{ash}, sulphur in ash; S_{sulph}, sulphate sulphur in coal; Cl, chlorine.

Where full analytical data are not available the mineral matter (M_b) may be approximately assessed for some British and US coals.[4]

$$M_b = 1.1A + 0.53S_{total} + 0.74CO_2 - 0.32 \simeq 1.15A$$

28.1.2 Classification

Three major classification systems have been devised based on the proximate analysis of coals.[1–5]

These are the Fuel Research Board/National Coal Board (NCB) classification,[2] the American ASTM classification,[5] and the International Classification[1] of Hard Coals by Type devised by the Economic Commission for Europe (ECE). The Fuel Research Board/NCB classification is described below and outlines are given of the others. The technological characteristics of coals are better defined in terms of their petrographical constituents and a coal classification system on this basis is in prospect.

FUEL RESEARCH BOARD/NCB CLASSIFICATION[2]

Coals are assigned code numbers according to their volatile matter content on a dry, mineral matter-free basis and their caking propensities are assessed by the Gray–King low temperature assay (BS 1016: Part 12; 1959). Clean coal must be used for determining the Gray–King coke type, and if the coal has initially a higher ash content than 10% it is floated at such a specific gravity as will give the maximum yield of coal with not more than 10% of ash.

Using the criterion of volatile matter alone, a first division into the following groups is obtained:

	Volatile matter	*Code no.*
Anthracites	Under 9.1%	100
Low-volatile steam coals	9.1–19.5%	200
Medium-volatile coals	19.6–32.0%	300
High-volatile coals	Over 32%	*See* Table 28.5

In the first three groups, i.e in coals of volatile matter up to 32%, there is a close relationship between volatile matter content and caking properties. Consequently, the effect of subdividing into progressive ranges of volatile matter content is also to produce classes with progressive ranges of caking power. The corresponding Gray–King coke types are given in Table 28.5 as an indication of caking properties.

Table 28.5   COAL CLASSIFICATION SYSTEM USED BY NATIONAL COAL BOARD
(REVISION OF 1964)
Notes:
(1) Coals that have been affected by igneous intrusions ('heat-altered' coals) occur mainly in classes 100, 200 and 300, and when recognised should be distinguished by adding the suffix H to the coal rank code, e.g. 102H, 201bH.
(2) Coals that have been oxidised by weathering may occur in any class, and when recognised should be distinguished by adding the suffix W to the coal rank code, e.g. 801 W.

In the fourth group, i.e. in coals with more than 32% of volatile matter—there is a wide range of caking properties at any given volatile matter content, and subdivision has been made on the basis of the Gray–King coke type. Six ranges of caking properties, listed in Table 28.5, are recognised for these high-volatile coals.

Each of the 400–900 classes can be further subdivided according to volatile-matter content: a 1 in the third figure of the code number indicates that the volatile matter lies between 32.1 and 36.0, and a 2 that it is over 36%. Also, a subdivision is made of the 301 class into 301a and 301b with volatile ranges of 19.6–27.5% and 27.6–32% respectively.

A full list of code numbers, with ranges of volatile contents and caking properties, is given in Table 28.5.

ASTM CLASSIFICATION OF COALS BY RANK[5]

Coals are classified according to their fixed carbon and calorific value expressed in Btu lb^{-1} on a mineral matter-free basis. The higher rank coals are classified according to fixed carbon on the dry basis; the lower rank coals are classified according to calorific value on the moist basis. Agglomerating character is used to differentiate between certain adjacent groups. There are four classes: I anthracite, II bituminous, III sub-bituminous, IV lignite, each containing a number of named groups. The position of a coal in the scale of rank can be expressed in a condensed form, e.g. (62–146) in which the parentheses signify that the contained numbers are on a mineral matter-free basis. The first number represents the fixed carbon on the dry basis reported to the nearest whole per cent, the second the calorific value expressed as hundreds of Btu lb^{-1} to the nearest hundred.

ECE INTERNATIONAL CLASSIFICATION OF HARD COALS[1]

Coals are first placed in classes according to their volatile matter on the dry ash free basis. Then coals with a volatile matter greater than 33% are placed in classes according to their gross calorific value, Table 28.6.

Each class is further subdivided into groups according to their caking properties expressed either by their crucible swelling number or their Roga index, Table 28.7.

Each group is then subdivided into subgroups according to their coking properties assessed by their maximum dilatation in the Audibert–Arnu dilatometer test or by their Gray–King coke type, Table 28.8.

Table 28.6   DIVISION OF COALS INTO CLASSES (ECE)

Class number	Volatile matter % d.a.f.	Class number	Gross calorific value moist ash free kcal kg^{-1} (MJ kg^{-1})
1A	3–6.5	6	>7 750 (32.5)
1B	>6.5–10	7	>7 200–7 750 (30.1–32.5)
2	>10–14	8	>6 100–7 200 (25.5–30.1)
3	>14–20	9	>5 700–6 100 (23.9–25.5)
4	>20–28		
5	>28–33		
6–9	>33		

Table 28.7   DIVISION OF COAL CLASSES INTO GROUPS (ECE)

Group number	Crucible swelling number	Roga index
1	$0-\frac{1}{2}$	0–5
2	1–2	5–20
3	$2\frac{1}{2}$–4	20–45
4	>4	>45

Table 28.8 DIVISION OF COAL GROUPS INTO SUBGROUPS (ECE)

Subgroup number	Maximum dilatation	Gray–King coke type
0	Non-softening	A
1	Contraction only	B–D
2	0 and less	E–G
3	>0–50	G1–G4
4	>50–140	G5–G8
5	>140	>G8

A three-digit code number is used to describe the classified coal. The first digit indicates the class, the second digit the group, and the third digit the subgroup.

28.1.3 Physical properties of coal

Methods for predicting the specific heat, enthalpy, and entropy of coal, char, tar and ash as a function of temperature and material composition are presented in reference 7.

The mean thermal conductivity, k, of coking coals between 0°C and t°C is given approximately by

$$k = 130 + 0.67t + 0.000\,67t^2 \text{ mW m}^{-1}\text{ K}^{-1}$$

Table 28.9 PHYSICAL PROPERTIES OF COAL

	Density kg m^{-3}	Bulk density* kg m^{-3} (lb ft^{-3})	Specific heat† kJ kg^{-1} K^{-1}	Coeff. linear thermal exp.‡ 10^6 K^{-1}			
				30°C	90°C	220°C	330°C
Fusain	—	—	0.88–0.92	—	—	—	—
Bituminous coal	1 250–1 450	600–670 (38–42)	1.00–1.09	33	—	45	60
Anthracite	1 400–1 700	700–790 (44–49)	0.92–0.96	—	—	—	—
Anthracite parallel to bedding plane	—	—	—	—	15	16.5	18
Anthracite perp. to bedding plane	—	—	—	—	27	29	29
Coal ash	—	—	0.67–0.71	—	—	—	—

* The approximate bulk densities refer to dry graded coals loosely packed in large containers. The bulk density is influenced by: (1) size and grading; (2) size of the container; (3) % 'free' moisture in excess of the inherent moisture; (4) shape of particles; (5) method of packing.
† Reference 6. The specific heat of coal increases with increase in volatile content and decrease in the carbon/hydrogen ratio.
‡ Data supplied by British Coal Utilisation Research Association.

28.2 Metallurgical cokes

28.2.1 Analysis and testing of coke

SAMPLING FOR ANALYSIS AND SHATTER TEST

Analysis In order to obtain a representative sample cokes are divided into four classes as follows:

Class 1: Large or graded gas coke from which breeze has been removed.
Class 2: Large or graded oven cokes from which breeze has been removed.
Class 3: Gas or oven cokes from which breeze has not been removed.
Class 4: Breeze.

In order to obtain a specified accuracy for any particular determination the number of increments required depends on the type of coke, its moisture, the degree of accuracy chosen and, in many

Table 28.10 TYPICAL ANALYSES OF SOLID FUELS

The table attempts to give analyses for fuels falling into each of the classes given but it should be understood that they can only be considered as a guide and that wide variations will be encountered among fuels belonging to each class

Table 28.12   WEIGHT OF INCREMENT AND SAMPLING IMPLEMENTS

Maximum size of coke	*Sampling implement*
38 mm ($1\frac{1}{2}$ in) (i.e. not more that 5% over $1\frac{1}{2}$ in)	1.14 kg ($2\frac{1}{2}$ lb) scoop
76 mm (3 in) (i.e. not more than 5% over 3 in)	2.3 kg (5 lb) scoop
101 mm (4 in) (i.e. not more than 5% over 4 in)	4.5 kg (10 lb) scoop
Over 101 mm (4 in)	6.8 kg (15 lb) scoop

cases, the conditions under which the sampling is to be carried out. The number of increments is independent of the total weight of coke sampled.

The number of increments of the various classes of coke for ash and moisture determinations required to give an accuracy of ±1% at the 95% probability level is given in Table 28.11 and the weight of the increments in Table 28.12 according to BS 1017: 1989.

Shatter test   According to BS 1016: 1994 the gross sample of 25 kg for the shatter test should be collected specifically for the test according to BS 1017: 1989 and should contain all the sizes over 51 mm (2 in) in approximately the same proportion as are found in the original size analysis.

GENERAL

The qualities of coke which have the most influence on metallurgical practice are purity, hardness and combustibility. The purity of any particular sample is determined by chemical tests, but the physical properties of hardness and combustibility may only be assessed by empirical tests.[8]

CHEMICAL ANALYSIS

Chemical analysis normally includes determinations of water, ash, volatile matter and sulphur. Phosphorus is important in the manufacture of acid pig iron.

The carbon content of a coke is an index of its thermal value and is roughly assessed by subtracting the 'impurities', as determined by chemical analysis, from 100.

OTHER TESTS

The size of coke is specified by the size of the square meshed screen through which it passes or on which it rests, the results being expressed as cumulative percentages on screens of decreasing sizes.

Bulk density of coke   This is an indication of the weight of the lump material that will fill a known (large) volume. The cubical container used has a capacity of 0.1 m^3 (2 ft^3), 465 mm (15 in) side internally (BS 1016: 1991).

Apparent density is the ratio of the weight of a given volume of coke to the weight of an equal volume of water (BS 1016: 1991).

True density is the ratio of the weight of a given volume of dry coke passing a 0.2 mm test sieve to the weight of an equal volume of water at the same (atmospheric) temperature (BS 1016: 1991).

Porosity may be either 'apparent' or 'total'.

$$\% \text{ Apparent porosity} = \left[\frac{\text{Volume of open pores}}{\text{Volume of coke}} \right] \times 100$$

$$= \left[\frac{W_3 - W_1}{W_3 - W_2} \right] \times 100$$

where W_1 = weight of dried coke, W_2 = weight of coke saturated with water weighed in a tank of cold water, W_3 = weight of coke saturated with water.

It can also be shown that:

$$\% \text{ Total porosity} = \left[\frac{\text{Real specific gravity} - \text{Apparent specific gravity}}{\text{Real specific gravity}} \right] \times 100$$

The real specific gravity in the above expression is determined by the specific gravity bottle method on material passing a 0.2 mm sieve, care being taken, however, to boil the coke with water in order to remove air and to saturate it (BS 1016: 1991).

The apparent specific gravity may be obtained from weighings required by the apparent porosity:

$$\text{Apparent specific gravity} = \frac{W_1}{W_3 - W_2}$$

The micum indices of a coke should measure its liability to attrition in the blast furnace. It is determined as follows: 25 kg of coke over 60 mm in size and with less than 5% moisture is placed in a special drum and rotated for 100 revolutions. A size analysis of the coke is then made and the percentages of coke remaining on a 40 mm sieve (M_{40}) and passing through a 10 mm sieve (M_{10}) are normally reported (BS 1016: 1973).

The 'shatter index' is a measure of the liability of a coke to form breeze during loading, unloading and charging operations.

To determine this index 25 kg of greater than 51 mm (2 in) coke is dropped four times from a special box which is placed 1.83 m (6 ft) above a cast iron or steel plate. The shattered coke is then screened and the average of three tests of the percentages retained on 51 mm (2 in), 38 mm ($1\frac{1}{2}$ in), 25 mm (1 in) and 13 mm ($\frac{1}{2}$ in) square aperture screens are reported as respective shatter indices (BS 1016: Part 13; 1969).

The reactivity of coke determines its behaviour towards air or oxygen or the rate with which it reduces carbon dioxide to monoxide.

The 'critical air blast' (CAB), determines the reactivity of coke to air by finding, by trial and error, the minimum rate of blast which will maintain combustion in an ignited bed of 1.2–0.6 mm coke contained in a glass or quartz tube of specified dimensions (BS 1016: 1973).

The thermal value of the volatile matter remaining in the coke (volatile therms) is a measure of its ignitability and, indirectly, of its reactivity to air (BS 1016: 1973).

28.2.2 Properties of metallurgical coke

BLAST FURNACE COKE

A specification for blast furnace coke proposed by the BSC/BISRA iron-making panel of the Iron and Steel Institute (Publication P127: 1969) is shown in Table 28.13.

A size range of 20–80 mm as charged and with higher ash is more usual. Consistency of the properties of the coke supplied is of the utmost importance.

FOUNDRY COKE

The range of properties specified[9] for foundry coke from various plants in the UK is given in Table 28.15. These supersede the recommendations of TS 47 1959.[10]

Table 28.13 SPECIFICATION FOR BLAST-FURNACE COKE

Moisture content
This shall not exceed 3%; a mean of 2% is desired
Variation -2 to $+3$ on single samples
$\quad\quad\quad -0.3$ to $+0.5$ on weekly average

Size
The overall size range shall be 19–64 mm ($\frac{3}{4}$–$2\frac{1}{2}$ in); this
implies pre-crushing of the coke

Shatter index
The 38 mm ($1\frac{1}{2}$ in) shatter index shall not be less than 90
Variation ± 2 on single samples
$\quad\quad\quad \pm 0.3$ on weekly average

Micum index
The M_{40} index shall not be less than 75
Variation ± 3 on single samples
$\quad\quad\quad \pm 0.45$ on weekly average

The M_{10} index shall not exceed 7
Variation ± 1 on single samples
$\quad\quad\quad \pm 0.45$ on weekly average

Ash content
The ash content should not exceed 3%
Variation ± 1.7 on single samples
$\quad\quad\quad \pm 0.27$ on weekly average

Sulphur content
The sulphur content should not exceed 0.6%
Variation ± 0.17 on single samples
$\quad\quad\quad \pm 0.03$ on weekly average

Table 28.14 PROPERTIES OF COKES

Real density, $kg\,m^{-3}$	1 700–2 000
Apparent density, $kg\,m^{-3}$	700–1 100
Total porosity, %	36–55
Apparent porosity, %	35–47
Calorific value, $MJ\,kg^{-1}$	33.14
Ash, % dry	8–11
Volatile matter	0.6–1.1
Sulphur	0.57–1.4
Phosphorus	0.01–0.14
Critical air blast, $1\,min^{-1}$	1.56–2.4

Table 28.15 SPECIFICATION FOR FOUNDRY COKE

Moisture, % maximum	3.0–5.5
Ash, % maximum	9
Volatile matter, % maximum	0.7–1.0
Sulphur, % maximum	0.85–1.0
Shatter index, 50 mm (2 in) minimum	90
Mean size minimum, mm	102–107
(in)	(4–4.2)
Undersize, not more than 4% less than 50 (2 in)	

There are indications[11] that a narrow range of size of coke as charged is more important to the operation of the cupola furnace than the mean size in the size range 40–110 mm and that there is little to be gained by using large coke. Consistency in the properties of the coke supplied is most important.

Table 28.16   CHARACTERISTICS OF FORMED COKE PROCESSES

Process	Forming	Feed	Binder

* Non-calcined;   na—not available.

FORMED COKE

Processes developed to produce formed coke briquettes[12] from weakly coking coals are shown in Table 28.16. Properties of formed cokes used in blast furnace trials are given in Table 28.17.

BULK DENSITY OF COKE

A graded coke 20–40 mm with normal ash and moisture has a bulk density of 420–480 $kg\,m^{-3}$, and run of oven coke 460–510 $kg\,m^{-3}$.

SPECIFIC HEAT OF COKE[13]

The relationship between the specific heat of coke and the ash content is a linear one. Values for the mean specific heat between 21° and t°C are given in Table 21.18, where A denotes % ash present in the coke.

28.3   Gaseous fuels, liquid fuels and energy requirements

28.3.1   Liquid fuels

Liquid fuels are easy to handle, store and control. The two main groups are derived from (1) petroleum and to a far lesser extent, (2) coal carbonisation. Distillate fuels contain practically no ash, and residual fuels contain very little ash in comparison with solid fuels. Sulphur in residual fuel oil depends mainly on the source of the crude oil from which it was obtained. High sulphur contents are usually undesirable metallurgically. Slagging troubles occur at over 700°C owing to the presence of

Table 28.18   MEAN SPECIFIC HEAT OF COKE

400	—	4.6	8.0	—

Na_2O, S and V_2O_5 in the fuel. The higher flame emissivity of very heavy fuel oils and coal tar fuels is an advantage in high temperature processes.[14]

British Standards specifications[15,16] for liquid fuels are intended as a guide but more details should be specified for metallurgical use of fuel. Tables 28.20 and 28.21 refer to typical properties of petroleum and tar fuels respectively.

(A) CALORIFIC VALUE

In the absence of a bomb calorimeter determination, approximate values may be calculated for petroleum oils, or tars. However, the correlations are separate for each group.

$$\text{Gross calorific value} = 51.91 - 8.79d^2 - \{0.519\,1 - 0.087\,9d^2(\%H_2O + \%ash + \%S)\}$$
$$+ 0.094\,2(\%S) \text{ MJ kg}^{-1}$$
$$\text{or} \quad 22.320 - 378\,0d^2 - \{223 - 37.8d^2(\%H_2O + \%ash + \%S)\}$$
$$+ 40.5(\%S) \text{ Btu lb}^{-1}$$
$$\simeq 59.91 - 8.79d^2 \text{ MJ kg}^{-1}$$
$$\text{or} \quad 22\,320 - 3\,780d^2 \text{ Btu lb}^{-1} \text{ (reference 17)}$$

$$\text{Net calorific value} = 46.5 + 3.14d - 8.84d^2 \text{ MJ kg}^{-1}$$
$$\text{or} \quad 20\,000 + 1\,350d - 3\,800d^2 \text{ Btu lb}^{-1} \text{ (reference 17)}$$

where d is the specific gravity (relative density) at 15.6°C (60°F) for petroleum oils.

The net calorific values are about 2.8 MJ kg^{-1} (1 200 Btu lb^{-1}) less than the gross values for distillate fuels down to about 2.3 MJ kg^{-1} (1 000 Btu lb^{-1}), less for heavy fuel oils.

(C) SPECIFIC HEAT

For petroleum oils.[17]

$$\text{Specific heat} = \frac{1.69 + 0.003\,4t}{\sqrt{d}} \text{ kJ kg}^{-1} \text{ K}^{-1}$$

$$+2\% \text{ for naphthenic base crudes}$$
$$-2\% \text{ for paraffin base crudes}$$

where

$$d = \text{Specific gravity } 15.6/15.6°C \text{ (60/60°F)}$$
$$t = \text{Temperature, } °C$$

For coal tar fuels.[18]

$$\text{Specific heat} = 1.46\text{–}1.68 \text{ kJ kg}^{-1} \text{ K}^{-1}$$

$$(0.35\text{–}0.40 \text{ Btu lb}^{-1} \text{ }°F^{-1})$$

(D) THERMAL CONDUCTIVITY

For petroleum oils:[17]

$$K = \frac{0.118\,4 - 0.000\,0\,195T}{d}\ \text{W}\,\text{m}^{-1}\,\text{K}^{-1}$$

$$\text{or}\quad \frac{0.821 - 0.000\,2\,44t}{d}\ \text{Btu}\,(\text{ft}^2\,\text{h})^{-1}(^\circ\text{F}\,\text{in}^{-1})^{-1}$$

where

T = temperature, °C

t = temperature, °F

For tar fuels,[18]

$$K = 0.138\text{--}0.147\ \text{W}\,\text{m}^{-1}\,\text{K}^{-1}$$
$$\text{or } 0.96\text{--}1.02\ \text{Btu}\,(\text{ft}^2\,\text{h})^{-1}\,(^\circ\text{F}\,\text{in}^{-1})^{-1}$$

(E) VISCOSITY[19]

British fuel oil kinematic viscosities are quoted in centistokes (cSt) at a specified temperature (BS 4708: 1971), and, formerly, by seconds Redwood I at 100°F (Redwood II is approximately 1/10 seconds Redwood I). Coal tar fuels are numbered according to the temperature in °F at which their viscosity is 100 seconds Redwood I, i.e. about 24 cSt at 37.8°C. Suitable handling temperatures are quoted for each class of fuel.

Table 28.24   VISCOSITY OF LIQUID FUEL

| Class | Kinematic viscosity | | Storage °C | Pumping °C | Atomising temperature °C |
	Temperature °C (°F)	cSt (10^{-2} m^2 s^{-1})			
Gas oil	37.7 (100)	4	—	—	Ambient
Light fuel oil	82.2 (180)	12.5	10	10	55
Medium fuel oil	82.2 (180)	30	25	30	90
Heavy fuel oil	82.2 (180)	70	35	45	125
CTF 50	37.8 (100)	13	—	—	15
CTF 100	37.8 (100)	24	35	35	38–50
CTF 200	37.8 (100)	300	35	40	80–95
CTF 250	30	35 000	55	75	115–130
CTF 300	55	25 000	85	100	140–155
CTF 400	—	—	135	150	190–205

(F) FLASH POINT

Special precautions are required by statute[20] for liquids with flash points below 32°C (90°F). Typical values for fuels are:

	Flash point °C (°F)
Petrol	−40 (−40)
Kerosine	+43 (+110)
All coal tar fuels	over 65 (150)
Gas oil	77 (170)
Light fuel oil	82 (180)
Medium fuel oil	93 (200)
Heavy fuel oil	115 (240)

28.3.2   Gaseous fuels

Table 28.25 shows the properties of most fuel gas constituents.[21]

(A) BLAST FURNACE GAS

This is the byproduct of iron or ferromanganese production, obtained from the top of the furnace after cooling and suitable dust removal. Injection processes for steam, oil, coal, gas and oxygen tend to vary the typical analyses. Below 3.7 MJ m^{-3} (100 Btu ft^{-3}) calorific value the gas should be enriched[22] or pre-heated before combustion.

The specific gravity relative to air varies from 1 to 1.07.

(B) LIQUEFIED PETROLEUM GAS, LPG

This type of industrial gas is a byproduct of the petroleum industry. These gases are transported in liquid form and vaporised before combustion. They may be used directly, mixed with other gases or distributed as a mixture with air.[23] The liquids have large coefficients of thermal expansion.

(C) NATURAL GAS

Natural gas, supplied is from many gas fields in the world. It is a rich hydrocarbon gas, predominantly methane, but they contain higher hydrocarbon and nitrogen. Large users have been supplied on an interruptible basis often necessitating the use of dual-fuel burners.[27] Its limits of inflammability are narrow (*see* Table 28.30) and flame speed low when compared with hydrogen containing fuels.

Table 28.27   TYPICAL RICH GASEOUS FUELS

	Natural gas	LPG[24,25]		Refinery gas[26]		
		Propane	Butane	Low	Medium	High

Liquid coefficient of cubical expansion per °C		0.0016	0.0011			

(D) PRODUCER GAS

Producer gas[28] is formed by partial oxidation of a solid fuel bed. The process is modified by the introduction of steam (blue water gas) and by thermal cracking of a hydrocarbon fuel such as natural gas, propane, butane, petroleum distillate, gas oil or heavy fuel oil (carburetted water gas).

Normally oxidation of the fuel bed is carried out with air, but total gasification processes also use oxygen. Tar in hot raw producer gas may increase the calorific value to around 74 MJ m^{-3} (200 Btu ft^{-3}).

(E) REFINERY GAS

Refinery gas may be a byproduct of distillation, cracking or reforming of gas in the petroleum industry. Typical gases are shown in Table 28.27.

(F) TOWN GAS

Town gas is used in only a few location in the world and is made almost exclusively by coal carbonisation. It can be made of a complex mixture of gases,[29] including coke oven gas, natural gas, liquefied petroleum gas, water gas, refinery gas, reformed hydrocarbon fuels or hydrocarbon fuels diluted with air. To make gas safer the $CO + H_2O = CO_2 + H_2$ shift reaction may be used to reduce the quantity of CO present.[30] CO_2 may be removed to increase calorific value and to reduce the specific gravity.

Gases are grouped according to the Wobbe index.

$$WI = \frac{\text{Gross calorific value MJ m}^{-3}\text{ (st) dry}}{\sqrt{[\text{Specific gravity (air} = 1.0)]}} \quad \text{or}$$

$$\frac{\text{Gross calorific value Btu ft}^{-3}\text{ STP (ISC) sat.}}{\sqrt{[\text{Specific gravity (air} = 1.0)]}}$$

| Gas group | Wobbe index | |
	Btu ft^{-3} STP *sat.*	MJ m^{-3} (st) *dry*
G3	800 ± 40	30.4 ± 1.52
G4	730 ± 30	27.7 ± 1.14
G5	670 ± 30	25.4 ± 1.14
G6	615 ± 25	23.3 ± 0.95
G7	560 ± 30	21.3 ± 1.14
Natural gas	$1\,335 \pm 5\%$	$50.68 \pm 5\%$

Table 28.28   ANALYSES OF PRODUCER GAS

| Representative of type | Gas analysis (% volume) | | | | | Specific gravity (air = 1.00) | kJ m^{-3} sat. at 15.6°C (Btu/SCE sat.) | |
	CO	CO$_2$	H$_2$	CH$_4$	N$_2$		Gross	Net
Producer gas								
Coke, no steam	31.3	2.1	0.5	—	66.1	0.978	3 770 (101.2)	3 763 (101.0)
Coke, steam	29.3	5.6	12.4	—	52.7	0.889	4 952 (132.9)	4 720 (126.7)
Anthracite	24.0	7.5	16.5	1.2	50.8	0.858	5 253 (141.0)	4 900 (131.5)
Bituminous coal	27.0	4.5	14.0	3.0	51.5	0.857	5 980 (160.5)	5 707 (150.5)
Blue water gas								
Coke, steam	43.5	3.5	47.3	0.7	5.1	0.560	11 050 (296.7)	10 150 (272.4)
Fixed bed slagging gasifier	65.5	4.0	29.0	0.4	1.0	0.727	11 380 (305.5)	10 830 (290.6)

Table 28.29 shows the typical properties of some manufactured gaseous fuels.

For a given piece of equipment the gases within a group as defined by the Wobbe index are interchangeable[31] without burner and nozzle adjustment. However, when changing gaseous fuels, blow-off and flame speed and flash-back must be carefully considered.

(G) ANALYSIS OF FUEL GASES[32]

The following constituents may also be found in fuel gases.

Dust is found in insufficiently cleaned blast furnace and producer gas.

Hydrogen sulphide should be below 5 ppm in natural gas.

7–20 g m^{-3} may be present in unpurified coal gas.

45 g m^{-3} may be present in refinery gas.

Organic sulphur Up to 1 g m^{-3} (40 gr per 100 ft^3) may be present in town gas. This figure will be lowered by oil washing, benzole stripping, etc. Below 0.02% by weight sulphur is usually present in LPG. Natural gas contains little organic sulphur, 0.3–9.0 ppm v/v and a limit of about 30 mg m^{-3} will be set.

Condensable vapours are chiefly benzene and toluene in carbonisation gas, the quantity depending chiefly on temperature of carbonisation, volatile matter in coal, and degree of benzole removal.

Tar may be found in producer gas, made from coal.

Water vapour   The majority of fuel gases contain water vapour, hence the usual determinations used to assume that the gases were saturated with water vapour at 30 in Hg total pressure (1013.75 mbar) and at 60°F (15.6°C). Natural gas properties are quoted on a dry basis (st).

(H) LIMITS OF INFLAMMABILITY

The limits of inflammability[33] of gaseous fuels and vapours are shown approximately in Table 28.30.

These limits are affected by direction of propagation, temperature, pressure and inert diluents.

(I) OXYGEN AND PRE-HEAT

Regeneration to about 1 100°C and recuperation to about 800°C as a mean of pre-heating combustion air are valuable methods of waste heat recovery in large furnaces. The recuperative burner can be employed on smaller furnaces.[34] Lean fuels such as blast furnace and producer gas can be pre-heated to about 500°C without cracking, to raise the adiabatic flame temperature of the fuel.

Oxygen is available from 200 to 1 700 tonnes per day units (700 m^3 t^{-1} STP). In bulk, oxygen must be handled in oil- and grease-free equipment. Pipelines are required to be of stainless or special carbon steel, the oxygen velocity should not exceed 8 $m\,s^{-1}$. Non-ferrous valves, flow controllers

and water-cooled oxygen-free copper lance tips are desirable for controlling the flow of oxygen in refining processes.

Tonnage oxygen for steelmaking is normally supplied with a purity of 99.5% O_2 for the following purposes:

(a) Oxidation refining processes.
(b) Raising flame temperature.
(c) To obtain extra output from a given furnace system by burning more fuel per unit combustion space.[35,36,37]
(d) Reducing metallic losses, e.g. electric steelmaking.
(e) Reducing nitrogen pick-up by metal from combustion air.

Tonnage oxygen for copper smelting, carried out outside the UK, is normally supplied with a purity of 95% O_2.

Use of oxygen lowers the volume of waste gases and hence the heat loss from a furnace as compared with atmospheric air for combustion. Oxygen enrichment of combustion air has a similar effect to increasing its pre-heat temperature.

The adiabatic flame temperature is a guide to the maximum furnace temperature obtainable from a fuel. Its value is lowered by the following conditions:

(a) Dilution with inert gases such as N_2, CO_2.
(b) Dissociation of H_2O and CO_2, particularly over 2000°C.
(c) Heat loss by radiation.

29 Heat treatment

29.1 General introduction and cross references

This chapter is composed of two sections; the first is concerned with the heat treatment of steels and the second with age hardenable aluminium alloys. All compositions are given as wt. % unless specified otherwise. Related information may be found at the following locations:

- Information on alloy specifications and designations—Chapter 1.
- Crystallographic data on some of the phases discussed here, information on relevant metallographic techniques and phase diagrams—Chapters 6, 10 and 11 respectively.
- Diffusion data—Chapter 13.
- Data relevant to temperature measurement by thermocouple and pyrometer techniques—Chapters 17 and 18, respectively.
- Mechanical property data—Chapter 22.
- Furnace design and vacuum systems—Chapter 40.

29.2 Heat treatment of steel

29.2.1 Introduction

Heat treating is defined by the IFHTSE (International Federation for Heat Treating and Surface Engineering) as: 'a process in which the entire object, or a portion thereof, is intentionally submitted to thermal cycles and, if required, to chemical and additional physical actions, in order to achieve desired (change in the) structures and properties'.[1] Krauss has added the additional caveat that 'heat treatment for the sole purpose of hot-working is excluded from the meaning of this definition'.[2] The thermal cycles referred to in this definition are the various heat treatment steps which include: stress relieving, austenitising, normalising, annealing, quenching, and tempering. Steel is heat treated to: control the microstructure, increase the strength and toughness, release residual stresses and prevent cracking, control hardness (and softening), improve machinability and to improve mechanical properties including: yield and tensile strength, corrosion resistance and creep performance. Each step of the heat treatment process is performed for a particular purpose. Taken together, these heat treatment steps are like 'links in a chain'.[3] The acceptability of the final properties are limited by the weakest link.

   In this section, an overview of the metallurgy involved in heat treatment will be provided which includes a discussion of common microstructures and phase diagram interpretation. The use of ITD (isothermal transformation diagrams), also known as TTT (time-temperature-transformation) curves, and CCD (continuous cooling diagrams), also known as CCT (cooling time-transformation) curves, to predict microstructure formation during heat treatment will be discussed. This will be followed by an overview of the different heat treatment steps including: austenitising, stress relief, normalising, annealing, quenching and tempering. Quantitative equations for estimating appropriate heat treatment temperatures and times will be given, where possible.

29.2.2 Transformations in steels

Properties such as hardness, strength, ductility and toughness are dependent on microstructure and grain size. The first step in the heat treating process is to heat the steel to its austenitising temperature.

The steel is then cooled rapidly to avoid the formation of ferrite and maximise the formation of martensite, which is a relatively hard transformation product, to achieve the desired as-quenched hardness.

The most common transformation products that may be formed from austenite in quench-hardenable steels are in order of formation with decreasing cooling rate: martensite, bainite, pearlite, and pearlite/proeutectoid ferrite. Each of these microstructures provides a unique combination of properties. The standard description of austenite and its transformation products used in ASTM E7 [4] and other sources will be used here (the transformation products are listed in order of their formation with increasing cooling velocity, temperatures and compositions are from Chapter 11):[5]

1. *Austenite*—A solid solution of carbon or other elements in face centred cubic gamma iron (γ-Fe). It is the desired solid solution microstructure produced prior to hardening. Gamma iron is the solid nonmagnetic phase of pure iron which is stable at temperatures between 912–1 394°C.[4]

2. *Ferrite*—This is a designation commonly applied to body centred cubic alpha iron (α-Fe) containing alloying elements in solid solution. Alpha iron is the solid phase of pure iron which is stable at temperatures below 912°C. It is ferromagnetic below 768°C. Increasing carbon content decreases markedly the high temperature limit of this phase at equilibrium. Fully ferritic steels are only obtained when the carbon content is very low. However, ferrite may frequently be found to nucleate on austenite grain boundaries, leaving a layer of ferrite at the prior location of these boundaries.

3a. *Pearlite*—A metastable microstructure formed, when local austenite areas undergo the eutectoid reaction, in alloys of iron and carbon containing greater than 0.022 percent but less than 6.67 percent carbon. The structure is an aggregate consisting of alternate lamellae of ferrite and cementite, formed on slow cooling, during the eutectoid reaction. In an alloy of given composition, pearlite may be formed isothermally at temperatures below the eutectoid temperature by quenching austenite to a desired temperature (generally above 550°C) and holding for a period of time necessary for transformation to occur. The interlamellar spacing is directly proportional to the transformation temperature, that is, the higher the temperature, the greater the spacing.[4]

3b. *Cementite*—A very hard and brittle compound of iron and carbon corresponding to the empirical formula of Fe_3C. It is commonly known as iron carbide and possesses a primitive orthorhombic lattice. In 'plain carbon steels', some of the iron atoms in the cementite lattice are replaced by manganese (manganese is added to plain carbon and other steels to 'tie-up' deleterious sulphur in the compound MnS). In 'alloy steels' the iron in cementite may be partially substituted by other elements such as chromium and tungsten. Cementite will often appear in hypo-eutectoid steels as distinct lamellae (as a constituent of pearlite) or as spheroids or globules of varying size (depending on the heat-treatment employed). Cementite is in metastable equilibrium and has a tendency to decompose into iron and graphite, although the reaction rate is very slow and is not normally observed in steels.[4] The highest cementite contents are observed in white cast irons.[5]

3c. *Ledeburite*—An intimate mixture of austenite and cementite in metastable equilibrium, formed on relatively rapid cooling during the eutectic reaction in alloys of iron and carbon containing greater than 2.14 percent but less than 6.67 percent carbon. Further slow cooling causes decomposition into ferrite and cementite (in the form of pearlite) as a result of the eutectoid reaction.[4] (An eutectic reaction, or equilibrium, is defined as a reversible univariant transformation in which a liquid that is stable only at a superior temperature, decomposes into two or more conjugate solid phases, for example: $L = \beta + \gamma$. In the case of a eutectoid reaction, the high-temperature phase is a solid, for example: $\alpha = \beta + \gamma$).

4. *Bainite*—A metastable microstructure resulting from the transformation of austenite at temperatures between those which produce pearlite and martensite. The formation of bainite can occur on continuous (slow) cooling if the transformation rate of austenite to pearlite is much slower than that of austenite to bainite. Ordinarily, bainite may be formed isothermally by quenching austenite to the desired temperature (below the range at which pearlite forms, but above that at which martensitic transformation is possible) and holding for a specific period of time necessary for transformation to occur. If the transformation temperature is just below that at which the finest pearlite is formed, typically 350°C (660°F), the bainite (upper bainite) has a feathery appearance. If the temperature is just above that at which martensite is produced, the bainite (lower bainite) is acicular, slightly resembling tempered martensite. At higher resolutions using a transmission electron microscope, upper bainite is observed to consist of plates of cementite in a matrix of ferrite. These discontinuous plates tend to have parallel orientation in the direction of the longer dimension of the bainite areas. Lower bainite consists of ferrite needles containing carbide platelets in parallel arrays cross-striating each needle axis at an

Table 29.1 FEATURES OF THE IRON–CARBON SYSTEM

Phase or mixture of phases	Name
Solid solution of carbon in α-iron	Ferrite
Solid solution of carbon in γ-iron	Austenite
Iron carbide (Fe$_3$C)	Cementite
Eutectic mixture of carbon solid solution in γ-iron with iron carbide	Ledeburite
Eutectoid mixture of carbon solid solution in α-iron with iron carbide	Pearlite

angle of about 60°. Intermediate bainite resembles upper bainite; however, the carbides are smaller and more randomly oriented.[4]

5. *Martensite*—A metastable phase resulting from the diffusionless athermal decomposition of austenite below a certain temperature known as the M_s temperature (martensite start temperature). This is a mechanical shear transformation in which the parent and product phases have a specific crystallographic relationship. Martensitic transformation occurs during quenching from the austenitic condition, when the cooling rate of a steel is sufficiently high, such that the pearlite and bainite transformations are suppressed. Since the transformation is diffusionless, the composition of the martensite is identical with that of the austenite from which it is formed. Therefore, martensite is a supersaturated solid solution of carbon in distorted alpha iron (ferrite) having a body centred tetragonal lattice. At low austenite carbon contents, martensite forms by dislocation motion and the result is laths with a high dislocation density, dovetailed into packets (only the latter are visible in the light microscope). At high austenite carbon contents, martensite forms by twinning and the result is midrib twinned plates. Low carbon martensite packets may appear needle-like or vermiform in cross-section.[4] The extent of transformation depends on the martensitic temperature range (M_s–M_f) of the alloy concerned, since there is a distinct temperature where martensitic transformation begins (M_s) and ends (M_f).[5]

Table 29.1 provides a summary of the features of the iron–carbon system.[6]

IRON–CARBON (Fe–C) PHASE DIAGRAM

The fundamental elements of heat treatment design are derived from the Fe–C equilibrium phase diagram (as modified by the alloying additions for the steel of interest), since the science of heat treatment is dependent on the formation of the desired phases and microstructures from the transformation of austenite. For this discussion, the iron–carbon (Fe–C) phase diagram shown in Chapter 11 will be considered. Although commonly used, the term 'iron–carbon phase diagram' is strictly incorrect when applied to a diagram that contains cementite on the extreme right of the diagram. When cementite is involved, this diagram should be more properly designated as the iron–cementite (Fe–Cm) metastable equilibrium diagram. This distinction arises from the fact that cementite is not truly a stable equilibrium phase and degrades to iron and graphite over very long periods of time, typically much longer times than those encountered in commercial practice. The dashed lines in the Fe–C phase diagram show the metastable equilibrium between Fe$_3$C and different phases of iron. Solid lines show the equilibrium between iron and graphite, but graphitisation rarely occurs in steel. Thus, all references in the present section to the Fe–C diagram refer to the metastable Fe–Cm system. Thus, in the present section, the extent of the different phase fields as a function of temperature and composition are those governed by the metastable equilibrium between Fe and Fe$_3$C and not the stable equilibrium between Fe and graphite.

Note, both martensite and cementite are 'metastable' phases in the sense that they both have only the appearance of equilibrium after suitable cooling to room temperature and are capable of transformation into the equilibrium phases with a suitable thermal exposure.[5] However, the thermal exposure needed to temper martensite is of a much shorter duration than that required to transform cementite to iron plus graphite.

When referring to the Fe–C system, as with any phase diagram, it is important to properly characterise constituents, phases and microstructures. A constituent is defined as '. . . a phase or combination of phases that occurs in a characteristic configuration in an alloy microstructure'.[4] A phase is defined as 'a physically homogenous and distinct portion of a material system'.[4] A microstructure is defined as 'the structure of a material revealed by a microscope at magnifications greater than

25x'.[5] The phases shown in the Fe–C diagram include: molten alloy, austenite, ferrite, cementite and graphite. Pearlite and bainite are constituents and important microstructures but they are not phases!

The Fe–C diagram shows the effect of adding carbon to iron up to 7 percent by weight. Steels are iron alloys containing up approximately 2 percent of carbon by weight; most often the total carbon content is less than 1 percent by weight. If the total carbon content is >2 percent by weight, the alloy is classified as a cast iron. The presence of carbon stabilises austenite and expands the temperature range within which this phase is stable. Carbon goes into interstitial solid solution in both ferrite and austenite, but is much more soluble in austenite (maximum solubility 2.14 wt. % at 1 148°C) than in ferrite (maximum solubility 0.022 wt. % at 727°C).[7]

Carbon solubility in ferrite and austenite is temperature dependent, as shown in the Fe–C phase diagram. When the insertion of carbon atoms into interstices of the relevant Fe structure exceeds the

carbon solubility, a new primitive orthorhombic crystal structure of cementite or iron carbide (Fe_3C) which is capable of greater carbon solubilisation will be created.[7]

The austenite phase field shown in the phase diagram is the basis for selecting hot working and heat treating temperature limits for carbon steels. Annealing, normalisation and austenitisation processes are conducted in this region to facilitate the dissolution of carbon in iron. For example, the Fe–C phase diagram shows that if the steel is cooled slowly, the structure will change from austenite to ferrite and cementite (producing a ferrite + pearlite microstructure). With faster cooling martensite is formed. Austenite is only stable at elevated temperatures, but can be retained as an unstable phase in high-carbon martensite.

The temperature range designated as the 'critical temperature range' or 'transformation range' is defined as 'those ranges of temperature within which austenite forms during heating and transforms during cooling. . .'.[5] The transformation ranges on heating and cooling may overlap, but never coincide exactly and are dependent on the alloy composition and the rate of temperature change. Table 29.2 provides the recommended maximum hot working temperatures for various steels.[8] Table 29.3 provides a table showing a correlation of surface colours and approximate temperatures.

The transformation temperature indicates the limiting temperature of a transformation range. For irons and steels, the following standard terms are applied:[5]

Ac_{cm}—The temperature at which the transformation from cementite to austenite is completed during heating (in a hypereutectoid steel).

Ac_1—The temperature at which austenite begins to form during heating.

Ac_3—The temperature at which the transformation of ferrite to austenite is completed during heating (in a hypoeutectoid steel).

Ac_4—The temperature at which austenite transforms to delta ferrite during heating (in a hypoeutectoid steel).

Ar_{cm}—The temperature at which the precipitation of cementite starts during cooling (in a hypereutectoid steel).

Ar_1—The temperature at which transformation of austenite to ferrite or to ferrite and cementite is completed during cooling.

Ar_3—The temperature at which austenite begins to transform to ferrite during cooling (in a hypoeutectoid steel).

Ar_4—The temperature at which delta ferrite transforms to austenite during cooling (in a hypoeutectoid steel).

Ar'—The temperature at which transformation from austenite to pearlite begins during cooling.

Ar''—The temperature at which transformation from austenite to martensite begins during cooling.

A summary Ac_1, Ac_3, Ar_1 and Ar_3 values for different steels is provided in Table 29.4.[8]

STRUCTURAL CLASSIFICATION OF STEELS

The Fe–C phase diagram depicted in Chapter 11 illustrates an important characteristic in the steel composition range which is called the 'eutectoid' which refers to the composition of a solid phase

[1] Represents the case of 4 600 grades of carburising steels.

[2] Represents the case of 8 600 and 9 300 grades of carburising steels respectively.

[3] When two temperatures are given for Ar₁, the higher temperature represents the pearlite reaction and the lower temperature the bainite reaction.

which, upon cooling, undergoes a univariant transformation into two, or more, other solid phases.[4] For a carbon steel, the eutectoid point occurs at 0.77 wt. % carbon. This is the basis of steel classification into: hypoeutectoid, eutectoid and hypereutectoid steels.

Hypoeutectoid steels are those steels with less than ∼0.80 wt. % carbon (strictly 0.77 wt. % C, but a less demanding definition is used in commercial practice). Hypoeutectoid steels can, upon initial cooling from the austenite single phase field, exist as two different phases, proeutectoid ferrite and austenite, each with different carbon contents. Upon further cooling, the remaining austenite undergoes the eutectoid reaction to ferrite plus cementite (i.e. pearlite) and so the microstructure of these steels typically exhibits proeutectoid ferrite grains and pearlite islands.

Eutectoid steels contain 0.76 wt. % carbon (in practice, steels with 0.75–0.85 wt. % carbon are often classified as eutectoid steels). These steels form as a solid solution at any temperature in the austenitic range and all carbon is dissolved in the austenite. At the critical (eutectoid) temperature of the iron-cementite system (1 340°F, 727°C), there is a transformation from austenite to lamellar pearlite. However, if the steel is cooled slowly to a temperature just below Ar₁ and held for a suitable duration, spheroidal cementite particles in ferrite are obtained, instead of lamellar pearlite. This microstructure is called spheroidite and exhibits improved machinability and formability.

Hypereutectoid steels contain ∼0.8–2.0 wt. % carbon. Upon cooling to Ar_cm, proeutectoid cementite separates from austenite. Below 1 340°F, 727°C, the remaining austenite transforms to pearlite. Hence, at room temperature, the microstructure consists of proeutectoid cementite and pearlite.

ISOTHERMAL AND CONTINUOUS COOLING TRANSFORMATION DIAGRAMS FOR STEELS

Microstructures that are formed upon cooling and the proportions of each are dependent on the austenitisation conditions (which influence the austenite grain size and the solutioning of alloying elements in austenite), the time and temperature cooling history of the particular alloy and composition of the alloy. The transformation products formed are illustrated typically with the use of transformation diagrams, which show the temperature-time dependence of the microstructure formation process, for the alloy being studied.

Two of the most commonly used transformation diagrams are firstly TTT (time-temperature-transformation), which is also referred to as an ITD (isothermal transformation diagram) and secondly CCT (continuous cooling transformation), which is also referred to as a CCD (continuous cooling diagram). When selected properly, either of these types of diagrams can be used to predict the microstructure and hardness of a given steel after heat treatment or they may be used to design a heat treatment process when the desired microstructure and hardness are known.

TTT diagrams (ITD)

TTT diagrams are generated by heating small samples of steel to the desired austenitising temperature and then cooling rapidly to a temperature intermediate between the austenitising and the M_s temperature. After holding at this temperature for a fixed period of time, the transformation products are then determined. At any given holding temperature, holding times up to those at which the transformation is complete need to be investigated. This is done repeatedly for a series of temperatures until a TTT diagram is constructed such as that shown in Figure 29.1. TTT diagrams can only be read along the isotherms.

The fraction transformed to ferrite, pearlite and bainite in isothermal processes can be calculated from:[9]

$$M = 1 - \exp\left(-bt^n\right)$$
Figure 29.1   *Isothermal transformation diagram (ITD), also known as a time-temperature-transformation (TTT) diagram, of an unalloyed steel containing 0.5% carbon (Source: Verlag Stahleisen m.b.H. Düsseldorf).*

where M is the fraction of the phase transformed, t is the time in seconds, $b = 2 \times 10^{-9}$ and $n = 3$. By convention, the beginning of the transformation is defined as 1% of the parent phase transformed and the end is defined as 99% of this phase transformed.

Only martensite formation occurs without diffusion. The Hougardy equation may be used to predict the amount of martensite formed in structural steels:[9,10]

$$M = 1 - 0.929 \exp\left[-0.976 \times 10^{-2}(M_s - T)^{1.07}\right]$$

where M = the amount of martensite, M_s is the martensite start temperature and T is the temperature of interest below the M_s temperature.

The accuracy of TTT diagrams with respect to the isothermal positions on the diagram is typically accepted to be $\pm 10°C$ ($\pm 20°F$) or $\pm 10\%$ with respect to time.

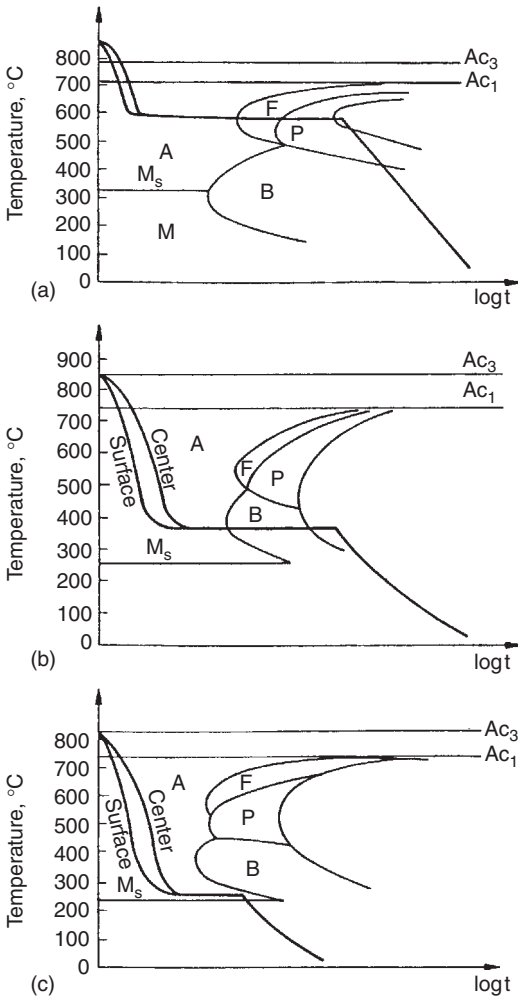
Examples of heat treatment processes where it is only appropriate to use a TTT diagram are: isothermal annealing, austempering and martempering. These processes are illustrated schematically in Figure 29.2.[9]


Figure 29.2 *Isothermal processes for which only ITDs (TTT diagrams) may be used (reprinted from reference 9, p. 546—courtesy of Marcel Dekker, Inc.): (a) isothermal annealing; (b) austempering; (c) martempering.*

CCT diagrams (CCD)

Steel may also be continuously cooled at different specified rates using a dilatometer allowing the proportion of transformation products formed after cooling to various temperatures intermediate between the austenitising temperature and the M_s temperature to be determined. These data can then be used to construct a CCT diagram. CCT curves correlate the temperatures for each phase transformation, the amount of transformation product obtained for a given cooling rate with time and the cooling rate necessary to obtain martensite. These correlations are obtained from CCT diagrams by using the different cooling rate curves.

The 'critical cooling rate' is the time required to avoid formation of pearlite for the particular steel being quenched. As a general rule, a quenchant must produce a cooling rate equivalent to, or faster than, that rate indicated by the 'nose' of the pearlite transformation curve, to maximise the formation of martensite.

If the temperature-time cooling curves for the quenchant and the CCT curves of the steel are plotted on the same scale, then they may be superimposed to select the steel grade which will provide the desired microstructure and hardness for a given cooling condition.[9] This assumption is limited to bars up to 100 mm in diameter quenched in oil and bars up to 150 mm quenched in water.

CCT diagrams may be constructed in various forms such as those shown in Figure 29.3. Figure 29.3a is a CCT diagram for an unalloyed carbon steel (AISI 1045) which provides curves for the beginning and ending of the different phase transformations.[11] Figure 29.3b, was generated for a DIN 50CrV4 (AISI 6145) steel.[9] In this figure, the fraction of the transformation product formed by a cooling curve is shown on the diagram and the resulting hardness is shown on the isotherm at the bottom of the diagram.

An alternative form of a CCT diagram is shown by Figure 29.3c.[9] This curve was not generated using a dilatometer but instead cooling curves were determined experimentally at different distances from the end of a Jominy test bar. The corresponding Jominy curve is shown along with a diagram for a particular quenchant and agitation condition which permits the prediction of cross-sectional hardness for a round bar.[9,12]

Another form of CCT diagram, originally developed by Atkins,[13] is illustrated in Figure 29.3d. This CCT diagram was generated by determining the cooling curves of round bars of the alloy represented in different quenchant media and then determining the corresponding transformation temperatures, microstructures and hardnesses.[9] The data represented by these curves refer only to the centre of the bar being quenched. A scale of cooling rates is provided at the bottom of the diagram. These diagrams are read along vertical lines with respect to different cooling rates. This diagram is especially useful to quickly identify the relative hardenability of different steels.

There are a number of heat treatment processes where only the use of a CCT diagram is appropriate. These include: continuous slow cooling processes such as normalising by cooling in air, direct quenching to obtain a fully martensitic structure and continuous cooling processes resulting in mixed microstructures as illustrated in Figure 29.4.[9]

The Rose-Strassburg cooling law can be used to predict cooling times and temperatures for steel samples whose cross-sectional area are not excessively large. Therefore their cooling is modelled by the following relationship:[14]

$$T = T_0 \exp\left[-\alpha t\right]$$

where $T_0 =$ austenitising temperature, $\alpha =$ heat transfer coefficient and $t =$ time.

A number of points should be noted:

- The CCT diagram is only valid for the steel composition for which it was determined.
- It is NOT correct to assume that the area of intersection of a cooling curve with the transformation product is equivalent to the amount of that product that is formed.
- Scheil has shown that transformation begins later in time for a continuous cooling process than for an isothermal process.[15] This is consistent with TTT and CCT curve comparison.
- Since increasing the austenitisation temperature will shift the curves to longer transformation times, it is necessary to use CCT diagrams generated at the desired austenitising temperature.

Caution: It is becoming increasingly common to see cooling curves (temperature-time profiles) for different cooling media (quenchants) such as oil, water, air and others, superimposed on either TTT or CCT diagrams. However, superimposition of such data, especially on a TTT diagram, is not a rigorously correct practice. Various errors are introduced into such analyses due to the inherently different kinetics of cooling used to obtain TTT or CCT diagrams versus the quenchants being represented. In particular, a continuous cooling curve can be superimposed on a CCT, but not on a TTT diagram.

29.2.3 Hardenability

Hardenability has been defined as the ability of a ferrous material to develop hardness to a given depth after being austenitised and quenched. This general definition comprises two sub-definitions, the first of which is the ability to achieve a certain hardness.[16] The ability to achieve a certain hardness level is associated with the highest attainable hardness which depends on the carbon content of the steel and more specifically on the amount of carbon dissolved in the austenite after austenitising.

This is illustrated by considering the problem of hardening of high-strength, high-carbon steels. The higher the concentration of dissolved carbon in the austenitic phase, the greater the increase in

mechanical strength after rapid cooling and transformation of the austenite into the metastable phase, martensite. Martensitic steels typically exhibit increasing hardness and strength with increasing carbon content, but they also exhibit relatively low ductility. However, with increasing carbon concentration, martensitic transformation from austenite becomes more difficult, resulting in a greater tendency for retained austenite and correspondingly lower strength.

(a)

(b)

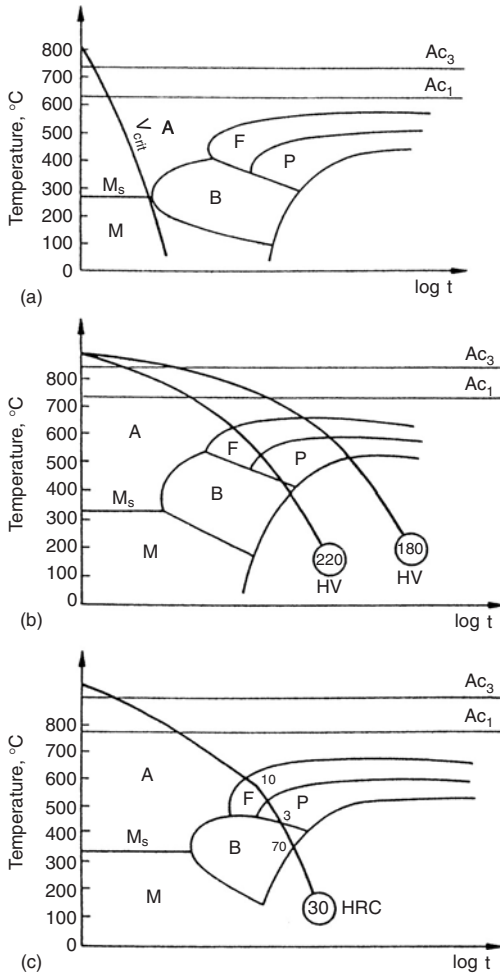
(c)


Figure 29.4   *Heat treatment processes where only CCDs (CCT diagrams) may be used (reprinted from reference 9, p. 544 courtesy of Marcel Dekker, Inc.): (a) direct quenching to obtain a fully martensitic microstructure; (b) slow cooling to obtain a ferrite-pearlite microstructure; (c) continuous cooling for a mixed microstructure*

The second sub-definition of hardenability refers to the hardness distribution within a cross-section from the surface to the core under specified quenching conditions. In this case, hardenability depends on the quantity of carbon which is dissolved interstitially in austenite and the amount of alloying elements dissolved substitutionally in the austenite during austenitisation. Therefore, as Figure 29.5 shows, carbon concentrations in excess of 0.6% do not yield correspondingly greater strength. Also, increasing the carbon content influences the M_f temperature relative to M_s during rapid cooling as shown in Figure 29.6.[17] In this figure, it is evident that for steels with carbon contents above 0.6%, the transformation of austenite to martensite will be incomplete if the cooling process is stopped at 0°C or higher.

The depth of hardening depends on the following factors:

- Size and shape of the cross-section.
- Hardenability of the material.
- Quenching conditions.

The cross-sectional shape exhibits a significant influence on heat extraction during quenching and, therefore, on the hardening depth. Heat extraction is dependent on the surface area exposed to the quenchant. Figure 29.7 can be used to convert square and rectangular cross-sections to equivalent circular cross-sections.[18]
Figure 29.5 *Influence of the carbon content in steel on the yield strength ($\sigma_{0.6}$) after quench hardening. The yield strength values were obtained from compression tests; the additional variation of nickel content causes negligible solid-solution-hardening and was selected to obtain a constant M_s temperature for the start of martensitic transformation (used with the permission of the Association of Iron and Steel Engineers (AISE))*

The effect of steel composition on hardenability may be calculated in terms of the 'ideal critical diameter', D_I, which is defined as the largest bar diameter that can be quenched to produce 50% martensite at the centre, after quenching in an 'ideal' quench, i.e. under 'infinite' quenching severity. The ideal quench is one that reduces surface temperature of an austenitised steel to the bath temperature instantaneously. Under these conditions, the cooling rate at the centre of the bar depends only on the thermal diffusivity of the steel.

The ideal critical diameter may be calculated from:

$$D_I = D_{I\,Base}\,(\text{carbon concentration and grain size}) \times f_{Mn} \times f_{Si} \times f_{Cr}$$
$$\times f_{Mo} \times f_V \times f_{Cu} \times f_{Ni} \times f_x$$

where f_x is a multiplicative factor for the particular substitutionally dissolved alloying element. The base value $D_{I\,Base}$ and one set of alloying factors are provided in Table 29.5.[19,20] (Note: This is not an exhaustive list of alloying factors but these are commonly encountered and they permit calculations to illustrate the effect of steel chemistry variation on hardenability.) D_I values for a range of steels with differing hardenability is provided in Table 29.6.[19,21]

Grain size refers to the dimensions of grains or crystals in a polycrystalline metal exclusive of twinned regions and subgrains when present. Grain size is usually estimated or measured on the cross-section of an aggregate of grains. Common units are: (1) average diameter, (2) average area, (3) number of grains per linear unit, (4) number of grains per unit area and (5) number of grains per unit volume.

Grain size may be determined according to ASTM Test Method E 112.[22] The procedures in Test Method E 112 describe the measurement of average grain size and include the comparison procedure, the planimetric (or Jeffries) procedure, and the intercept procedures. Standard comparison charts are provided. These test methods apply chiefly to single phase grain structures but they can be applied to determine the average size of a particular type of grain structure in a multiphase or multiconstituent specimen.

In addition, the test methods provided in ASTM E 112 are used to determine the average grain size of specimens with a unimodal distribution of grain areas, diameters, or intercept lengths. These distributions are approximately log normal. These test methods do not cover methods to characterise

the nature of these distributions. Characterisation of grain size in specimens with duplex grain size distributions is described in ASTM Test Methods E 1181. Measurement of individual, very coarse grains in a fine-grained matrix is described in Test Methods E 930. These test methods deal only with determination of planar grain size, i.e. characterisation of the two-dimensional grain sections revealed by the sectioning plane. Determination of spatial grain size, i.e. measurement of the size of the three-dimensional grains in the specimen volume, is beyond the scope of these test methods.

The test methods described in ASTM E 112 are techniques performed manually using either a standard series of graded chart images for the comparison method or simple templates for the manual counting methods. Utilisation of semi-automatic digitising tablets or automatic image analysers to measure grain size is described in ASTM Test Methods E 1382.[23]

The ASTM grain size number (G), referred to in Table 29.5, is a grain size designation bearing a relationship to the average intercept distance (L) at 100 diameters magnification, according to the equation:[4]

$$G = 10.00 - 2 \log_2 L$$

The smaller the ASTM grain size, the larger the diameter of the grains.

The effect of quenching conditions on the depth of hardening are not only dependent on the quenchant being used and its physical and chemical properties but also on process parameters such as bath temperature and agitation.

29.2.4 Hardenability measurement

There are numerous methods to estimate steel hardenability. However, two of the most common are: Jominy curve determination and Grossmann hardenability which will be discussed here.
Figure 29.8   *Schematic illustration of the Jominy end-quench test and microstructural variation with increasing distance from the quenched end. The spacing of the pearlite lamellae increases with distance from the quenched end, i.e. along the direction of the arrow (reprinted from reference 16, p. 109—courtesy of Marcel Dekker, Inc.)*

JOMINY BAR END-QUENCH TEST

The most familiar and commonly used procedure for measuring steel hardenability is the Jominy bar end-quench test, as illustrated in Figure 29.8. This test has been standardised and is described in ASTM A 255, SAE J406, DIN 50191 and ISO 642. For this test, a 100 mm (4 inch) long by 25 mm (1 inch) diameter round bar is austenitised to the appropriate temperature, dropped into a fixture, and one end rapidly quenched with 24°C (75°F) water from a 13 mm (0.5 inch) orifice under specified conditions.[16] The austenitising temperature and time is selected according to the specific steel being studied. However, most steels are heated to temperatures of 870–900°C (1 600–1 650°F). The cooling velocity decreases with increasing distance from the quenched end.

After quenching, parallel flats are ground on opposite sides of the bar and hardness measurements made at 1/16 in. (1.6 mm) intervals along the bar as illustrated in Figure 29.9.[16] The hardness as a function of distance from the quenched end is measured and plotted and, together with measurement of the relative areas of the martensite, bainite and pearlite that is formed, it is possible to compare the hardenability of different steels using Jominy curves. As the slope of the Jominy curve increases, the ability to harden the steel (hardenability) decreases. Conversely, decreasing slopes (or increasing flatness) of the Jominy curve indicates increasing hardenability (ease of hardening).

The Jominy end-quench is used to define the hardenability of carbon steels with different alloying elements, such as chromium (Cr), manganese (Mn), or molybdenum (Mo) and having different critical cooling velocities. Jominy curves for different alloy steels are provided in Figure 29.10. These curves illustrate that the unalloyed, 0.4% carbon steel exhibits a relatively small distance for martensite (high hardness) formation. The 1% Cr and 0.2% Mn steel, however, can be hardened up to a distance of 40 mm. Figure 29.10 illustrates that steel hardenability is dependent on the steel chemistry. Unalloyed steels exhibit poor hardenability. Jominy curves provide an excellent indicator of relative steel hardenability.

The Jominy test provides valid data for steels having an ideal diameter from about 25 to 150 mm (1 to 6 in.). This test can be used for D_I values less than 25 mm (1 in.) but Vickers or microhardness tests must be used to obtain readings that are closer to the quenched end of the bar and closer together than generally possible using the standard Rockwell 'C' hardness test method.[16]

The austenitising time and temperature, extent of special carbide solution in the austenite and degree of oxidation or surface decarburisation during austenitising, care and consistency of surface flat preparation and bar positioning prior to making hardness measurements are important factors that influence test results. Therefore, all tests should be conducted in compliance with the standard being followed.[16]

Using the composition of the steel, it is possible to calculate the Jominy end-quench curve for a wide range of steels with excellent correlation to experimental results. In many cases, calculation is preferred over experimental determination.

Figure 29.10   *Jominy curve comparison of the hardenability of one unalloyed and a number of other different alloy steels*

GROSSMANN HARDENABILITY

The Grossmann method of measuring hardenability utilises a number of cylindrical steel bars with different diameters each hardened in a given quenching medium.[16] After sectioning each bar at mid-length and examining it metallographically, the bar that has 50% martensite at its centre is selected, and the diameter of this bar is designated as the *critical diameter* D_{crit}. Other bars with diameters smaller than D_{crit} will have more martensite and correspondingly higher hardness values and bars with diameters larger than D_{crit} will attain 50% martensite only up to a certain depth as shown in Figure 29.11.[16] The D_{crit} value is valid only for the quenching medium and conditions used to determine this value.

To determine the hardenability of a steel independently of the quenching medium, Grossmann introduced the term *ideal critical diameter*, D_I, which is the diameter of a given steel bar that would produce 50% martensite at the centre when quenched in a bath of quenching intensity $H = \infty$. Here $H = \infty$ indicates a hypothetical quenching intensity that reduces the temperature of heated steel to the bath temperature in zero time. Alternatively, excellent correlations with reported H-values are potentially achievable using cooling rates obtained by cooling curve analysis with 13, 25, 38 and 50 mm (0.5, 1.0, 1.5 and 2.0 inch) Type 304 stainless steel probes.[24] (Ideal diameters for various steels are provided in Table 29.6.[19])

To identify a quenching medium and its condition, Grossmann introduced the Quenching Intensity (Severity) factor 'H'. Table 29.7 provides a summary of Grossmann H-Factors for different quench media and different quenching conditions.[16,25] Although this data has been published in numerous reference texts for many years, it is of relatively limited quantitative value. One of the most obvious reasons is that quenchant agitation is not adequately defined with respect to mass flow rate, directionality and turbulence and is often unknown, yet it exhibits enormous effects on quench severity during quenching.

Table 29.7   EFFECT OF AGITATION ON QUENCH SEVERITY AS INDICATED BY GROSSMANN QUENCH SEVERITY FACTORS

H-Factors; © ASM International, Materials Park, OH, used with permission.

	Grossmann H-*Factor*			
Agitation	*Air*	*Oil and salt*	*Water*	*Caustic soda or brine*
None	0.02	0.25–0.3	0.9–1.0	2
Mild	—	0.30–0.35	1.0–1.1	2–2.2
Moderate	—	0.35–0.4	1.2–1.3	—
Good	—	0.4–0.5	1.4–1.5	—
Strong	—	0.5–0.8	1.6–2.0	—
Violent	—	0.8–1.1	4	5

The Grossmann value 'H' is based on the Biot (Bi) number which interrelates the interfacial heat transfer coefficient (α), thermal conductivity (λ) and the radius (R) of the round bar being hardened:

$$Bi = \alpha/\lambda R = HD$$
$$H = \alpha/(2\lambda)$$

Since the Biot number is dimensionless, this expression means that the Grossmann value, H, is inversely proportional to the bar diameter. This method of numerically analyzing the quenching process presumes that heat transfer is a steady state, linear (Newtonian) cooling process. However, this is seldom the case and almost never the case in vaporisable quenchants such as oil, water and aqueous polymers. Therefore, a significant error exists in the basic assumption of the method.

Another difficulty is the determination of the H-value for a cross-section other than one measured experimentally. In fact, H-values depend on the cross-sectional size. Values of H do not account for specific quenching characteristics such as composition, oil viscosity, or temperature of the quenching bath. Tables of H-values do not specify the agitation rate of the quenchant, either uniformly or precisely (*see* Table 29.7). Therefore, although H-values are used commonly, more current and improved procedures ought to be employed when possible. For example, cooling curve analyses and the various methods of cooling curve interpretation that have been reported are all significant improvements over the use of Grossmann Hardenability factors.[24,25]

29.2.5 Austenitisation

As indicated in the discussion thus far, the austenitisation process refers to the formation of austenite by heating the steel above the critical temperature for austenite formation. It is important to note that the term austenitisation means to completely transform the steel to austenite.[2] However, there are a number of critically important variables in the austenitisation process, two of which are heat rate and holding (soaking) time.

The heating rate is critical. There is a specific heating rate that cannot be exceeded without causing warpage or cracking since steels typically posses insufficient plasticity to accommodate increased thermal stresses in the temperature range of 250–600°C. Therefore, this is a particularly critical temperature range especially when the component has both thick and thin cross-sections. Therefore the heating rate is dependent on:[9]

- Size and shape of the component.
- Initial microstructure.
- Steel composition.

For this reason, steel is often heated to the final austenitising temperature in steps of 93–204°C (200–400°F) per hour.

Shapes with corners, or sharp edges, are also susceptible to cracking and this is known as the 'corner-effect'. If heating rates are excessive or non-uniform, the resulting thermal stresses may be sufficient to cause cracking.

The propensity for steel to crack is dependent on composition. For example, increasing carbon content increases the potential for cracking. The effect of composition on the potential for cracking can be modelled by calculation of the carbon equivalent (C_{eq}) using the following equation:[9]

$$C_{eq} = C + \frac{Mn}{5} + \frac{Cr}{4} + \frac{Mo}{3} + \frac{Ni}{10} + \frac{V}{5} + \frac{Si - 0.5}{5} + \frac{Ti}{5} + \frac{W}{10} + \frac{Al}{10}$$

where the elements shown represent wt. % concentrations in the steel. The limits of this equation are: C $\leq$ 0.9%, Mn $\leq$ 1.1%, Cr $\leq$ 1.8%, Mo $\leq$ 0.5%, Ni $\leq$ 5.0%, V $\leq$ 0.5%, Si $\leq$ 1.8%, Ti $\leq$ 0.5%, W $\leq$ 2.0% and Al $\leq$ 2.0%. Crack sensitivity increases with the C_{eq} value. The following general rules were reported by Liscic:[9]

$C_{eq} \leq 0.4$ Steel not sensitive to cracking; may be heated quickly.
$C_{eq} = 0.4$–0.7 Moderate sensitivity to cracking.
$C_{eq} \geq 0.7$ Steel is very sensitive to cracking and should be preheated to a temperature close to Ac_1 and held until the temperature was uniform throughout to minimise thermal stresses when austenitising.

In addition to these effects, steel with high hardness and a non-uniform microstructure should be heated more slowly, due to its crack sensitivity, than a steel with low hardness and a uniform microstructure.

Table 29.8   SAE AMS 2759/1C RECOMMENDED ANNEALING, NORMALISING, AUSTENITISING
TEMPERATURES AND QUENCHANTS FOR VARIOUS STEELS

Material designation[1]	Annealing temperature (°C)	Normalising temperature (°C)	Austenitising temperature (°C)	Quenching medium[3]
1 025	885	899	871	w, p
1 035	871	899	843	o, w, p
1 045	857	899	829	o, w, p
1 095[4]	816	843	802	o, p
1 137	788	899	843	o, w, p
3 140	816	899	816	o, p
4 037	843	899	843	o, w, p
4 130	843	899	857	o, w, p
4 135	843	899	857	o, p
4 140	843	899	843	o, p
4 150	829	871	829	o, p
4 330V	857	899	871	o, p
4 335V	843	899	871	o, p
4 340	843	899	816	o, p
4 640	843	899	829	o, p
6 150	843	899	871	o, p
8 630	843	899	857	o, w, p
8 735	843	899	843	o, p
8 740	843	899	843	o, p

[1] SAE AMS 2759/1C should be consulted for detailed description of the overall heat treatment requirements
   for these alloys.
[2] The cooling rate is not to exceed 111°C/h to below 538°C except for 4 330 V, 4 335 V and 4 340 to
   below 427°C, and 4 640 to below 399°C.
[3] o = oil, w = water and p = an aqueous polymer quenchant.
[4] 1095 parts should be spheroidise annealed before hardening.

The austenitisation temperature for a given steel is typically specified, such as those values shown in Table 29.8. These values were selected to provide optimum hardness and grain size. As the austenitisation temperature increases, the grain size increases. This is important because the grain size affects heat treatment and subsequent performance under various working conditions. For example, increasing grain size increases the brittle to ductile transition temperature and increases the propensity for brittle fracture. Fine grained steels have greater fatigue strength than coarse grained steels. However, coarse grained steels have better machinability than fine grained steels. The Hall-Petch equation predicts the effect of grain size (d) on yield stress (σ_y):[26]

$$\sigma_y = \sigma_0 + K_y d^{-0.5}$$

where σ_0 and K_y are material-specific constants. Increasing the austenitising temperature also:[9]

- Increases the hardenability due to increased carbide solubilisation and increased grain size.
- Decreases the M_s temperature.
- Increases the (incubation) time for isothermal transformation to pearlite or bainite to begin.
- Increases the amount of retained austenite.

For unalloyed steels, the optimum austenitisation temperature is 30–50°C above the Ac_3 temperature for hypoeutectoid steels and 30–50°C above the Ac_1 for hypereutectoid steels. The alloying elements in alloy steels may shift the A_1 temperature either higher or lower and therefore appropriate references such as national standards must be consulted.

A 'rule of thumb' is often used to estimate the appropriate soaking time during austenitisation:

$$t = 60 + D$$

where t is the soaking time in minutes, and D is the maximum diameter of the component in millimetres. However, such rules of thumb are imprecise. Soaking times are dependent on: geometrical factors related to the furnace and the load, type of load, type of steel, thermal properties of the load, load and furnace emissivities, initial furnace and load temperatures, characteristic fan curves, and composition of the furnace atmosphere.

A. Monolayer, horizontally oriented, ordered loads

Packed   Spaced

B. Monolayer, horizontally oriented, random loads

C. Multilayer ordered and random loads

Packed   Spaced   Bulk

D. Vertically oriented loads
Figure 29.12 *Aronov load characterisation diagram for soaking time calculation*

Aronov developed a method for predicting furnace soaking times for batch loads based on 'load characterisation'.[27,28] Load characterisation diagrams are provided in Figure 29.12 and these models are based on the generalised characterisation equation for soaking time (t_s):

$$t_s = T_{Sb}K$$

where T_{Sb} is the baseline soak temperature condition taken from Figure 29.13 and K is a correction factor, the value of which depends upon the type of steel (K = 1 for low alloy steel and 0.85 for high alloy steel).[27,28]

29.2.6 Annealing

A primary purpose of annealing is to soften steel to enhance its workability and machinability. However, annealing may also be performed for:[26]

- Relief of internal stresses arising from prior processing including casting, forging, rolling, machining and welding.
- Improvement or restoration of ductility and toughness.
- Improvement of machinability.
- Grain refinement.
- Improvement of the uniformity of the dispersion of alloying elements.
- Achieving a specific microstructure.
- Reduction of gaseous content within the steel.

Annealing may be an intermediate step in an overall process or it may be the final process in the heat treatment of a component. Table 29.8 provides a summary of annealing temperatures recommended for some common steel alloys.

Soak time (T$_{Sb}$), min

(a)   Load characteristic size, mm

Soak time (T$_{Sb}$), min

(b)   Load characteristic size, mm
Figure 29.13a,b *Aronov soaking times for:* (*a*) *packed load;* (*b*) *spaced load*

Annealing processes may be classified as: full annealing, process (subcritical) annealing, isothermal annealing, recrystallisation annealing, spheroidising, and normalising. Partial (intercritical) annealing is a subclass of full annealing. Figure 29.14 provides an illustrative summary of these annealing processes.

FULL ANNEALING

Full annealing of steel involves heating the steel 30–50°C above the upper critical temperature (Ac$_3$) for hypoeutectoid steels, followed by furnace cooling through the critical temperature range, at a specified cooling rate, which is selected based on the final microstructure and hardness required.[29] Full annealing results in a relatively coarse microstructure. This process is typically used for steels
Figure 29.13c,d   *Aronov soaking times for:* (*c*) *vertical load;* (*d*) *disks*

with carbon contents of 0.30–0.60%, for example, to improve machinability. Unless otherwise noted, the term 'annealing' often refers to full annealing.[1]

PARTIAL (INTERCRITICAL) ANNEALING

Partial annealing, as illustrated in Figure 29.14, is conducted by heating the steel to a point within the critical temperature range (Ac_1–Ac_3) followed by slow furnace cooling. Partial annealing, also known as 'intercritical annealing', may be performed on hypereutectoid steels to obtain a microstructure of fine pearlite and cementite instead of coarse pearlite and a network of cementite at the grain boundaries, as observed in the case of full annealing.[26] For hypereutectoid steels, this results in grain refinement which usually occurs at 10–30°C above Ac_1. Partial annealing is performed to

improve machinability. However, steels with a Widmanstätten or coarse ferrite/pearlite structure are unsuitable for this process. Krauss has noted that the term 'partial annealing' is an imprecise term and to be meaningful, the type of material, the time-temperature profile of the process and the degree of cold working must be specified.[2]

PROCESS (SUBCRITICAL) ANNEALING

Process annealing (Figure 29.14) is performed to improve the cold-working properties of low-carbon steels (up to 0.25% carbon) or to soften high-carbon and alloy steels to facilitate shearing, turning or straightening processes.[30,31] Process annealing involves heating the steel to a temperature below (typically 10–20°C below) the lower critical temperature (Ac_1) and is often known as 'subcritical' annealing. After heating, the steel is cooled to room temperature in still air. The process annealing temperatures for plain carbon and low alloy steels is typically limited to about 700°C to prevent partial reaustenitisation. In some cases this is limited to about 680°C for steel compositions, such as high-nickel containing steels, where the nickel further reduces the Ac_1 temperature.[31]

This process can be used to temper martensitic and bainitic microstructures to produce a softened microstructure containing spheroidal carbides in ferrite.[31] Fine pearlite is also relatively easily softened by process annealing, while coarse pearlite is too stable to be softened by this process.
Figure 29.14   *Annealing-related processes in plain carbon steels*

RECRYSTALLISATION ANNEALING

Prior to cold working, steel microstructures that are either spheroidised or ferritic are highly ductile. However, when steels are cold worked, they become work hardened and ductility is reduced. Work hardening resulting from cold working can be removed by a recrystallisation process which produces strain-free grains, resulting in a ductile, spheroidised microstructure.[2] Nearly all steels which are heavily cold worked undergo recrystallisation annealing, which reduces hardness and increases ductility.[26]

Recrystallisation annealing is performed by heating the steel for 30 minutes to one hour, at a temperature above the recrystallisation temperature shown in Figure 29.14.[32] When heating is complete, the steel is cooled. As opposed to other annealing processes where the processing temperature is fixed, the recrystallisation annealing temperature is dependent upon composition, prior deformation, grain size and holding time.[26] Liscic reported a correlation between recrystallisation temperature (T_R) and the melting temperature (T_m) of the steel in Celsius:[9]

$$T_R = 0.4\,T_m$$

ISOTHERMAL ANNEALING

Isothermal annealing (Figure 29.15) is conducted by heating the steel within the austenite single-phase region (i.e. above Ac_3 for a hypoeutectoid steel, or above Ac_1 for a eutectoid steel) for a time sufficient to complete the solutionising process, yielding a completely austenitic microstructure. The steel is then cooled rapidly at a specified rate within the pearlite transformation range indicated by the TTT diagram for the steel (less than Ac_1, typically between 600–700°C) until complete transformation into ferrite plus pearlite (lamellar pearlite) occurs, at which time the steel is cooled rapidly to room temperature.[1,26] It should be cautioned that it is not rigorously correct to use TTT diagrams which are developed for austenitisation temperatures which do not match those for isothermal annealing.[32]

Isothermal annealing is used to achieve a more homogeneous microstructure within the steel and is faster and less expensive than full annealing. It is typically performed on hypoeutectoid steels and it is usually not performed on hypereutectoid steels.[26,30] When isothermal annealing is used in continuous production lines for small parts or for parts with thin cross-sections, it is called 'cycle annealing'.

SPHEROIDISING (SOFT ANNEALING)

Spheroidising involves the prolonged heating of steel starting from a temperature either just above, or just below the lower critical temperature (Ac_1) as illustrated in Figure 29.14.
Figure 29.15 *Schematic of a heat treatment cycle for isothermal annealing of:* (*a*) *hypoeutectoid steel;* (*b*) *eutectoid steel. Note: the* A_3 *temperature shown in the figure refers to that of the hypoeutectoid steel*

In the simplest case, the steel is heated to just below Ac_1 and held for a protracted period. Since the steel remains in the ferrite plus cementite two-phase field, no phase transformations occur. However, the pearlite gradually spheroidises (driven by the resulting reduction in α–Fe_3C interfacial area and hence total interfacial energy).

In commercial practice, eutectoid steels are heated initially to 20–30°C above Ac_1 and hypereutectoid steels are heated initially to 30–50°C above Ac_1. The Ac_1 temperature can be determined from Table 29.4, obtained from the appropriate TTT diagram or calculated from:[9]

$$Ac_1(°C) = 739 - 22\,(\%C) + 2\,(\%Si) - 7\,(\%Mn) + 14\,(\%Cr) + 13\,(\%Mo)$$
$$+ 13\,(\%Ni) + 20\,(\%V)$$

(Hypereutectoid alloy steels may need to be heated at a higher temperature than suggested by this equation.)

Medium carbon steels may be spheroidised by heating just above or just below the Ac_1 temperature. Heating is followed by furnace cooling to a temperature just below Ar_1. Instead of pearlite, the resulting microstructure consists of ferrite plus fine spheroidal and/or globular cementite (with the cementite morphology depending in part upon the carbon content of the steel). The required cooling rate is given by:[9]

1. For plain carbon and low-alloy steels up to 650°C (1200°F)—cooling rate = 20–25 K/h (furnace cooling)
2. For medium alloy steels up to 630°C (1 166°F)—cooling rate = 15–20 K/h (furnace cooling)
3. For high alloy steels up to 600°C (1 112°F)—cooling rate = 10–15 K/h (furnace cooling)

For alloy steels, the spheroidising temperature (T) may be calculated from:[9]

$$T(°C) = 705 + 20\,(\%Si - \%Mn + \%Cr - \%Mo - \%Ni + \%W) + 100\,(\%V)$$

High carbon and alloy steels are spheroidised to enhance their machinability and ductility.[1] This process is desirable for cold-formed low-carbon and medium-carbon steels and for high-carbon steels that are premachined, prior to final machining.

DIFFUSION (HOMOGENISING) ANNEALING

Diffusion annealing (homogenising) is performed on steel ingots and castings to minimise chemical segregation. Chemical segregation defects occur as dendrites, columnar grains and chemical occlusions. The presence of these defects produces increased brittleness and reduced ductility and toughness. The homogenisation process, illustrated in Figure 29.14, is conducted by heating the steel rapidly to 1 100–1 200°C and holding for 8 to 16 hours. The steel is then furnace cooled to 800–850°C and subsequently cooled to room temperature in still air.[30] The defects are eliminated by solute diffusion.

NORMALISING

For normalising, hypoeutectoid steels are heated to a somewhat higher temperature (40–50°C above the Ac_3) than that used for full annealing. Hypereutectoid steels are heated above the Ac_m temperature as illustrated in Figure 29.14. The holding time depends on the size of the part. The minimum time is 15 minutes at temperature, with longer times being employed for larger parts, to ensure that the part is completely austenitised. Table 29.8 provides normalisation temperatures for various commonly encountered steels.

On completion of the required holding time, specified by the size of the part, the part is cooled in still air.[1,30] For a hypoeutectoid steel, the result will be a fine ferrite plus pearlite microstructure. Plain carbon and low-alloy steels should always be normalised.[32] Some alloy steels produce martensitic microstructures even with air cooling. Therefore, with such alloys, slower cooling rates are required to provide a uniform microstructure of ferrite plus pearlite.

Normalising is conducted:[30]

• To provide the desired microstructure and hence mechanical properties. For a given steel composition, normalised structures will be harder and stronger with lower ductility than if fully annealed.
• To improve hardening response by grain refinement and improved homogenisation.

- To improve machining characteristics, particularly for 0.15–0.40% carbon steels.
- To eliminate carbide networks in hypereutectoid steels.

There are various equations that may be used to calculate the hardness of normalised steel. One method is by using the Bofors equation.[32] The first step in this calculation is to determine the sum of the 'carbon potentials' – C_p:

$$C_p = C\,[1 + 0.5\,(C - 0.20)] + Si \times 0.15 + Mn\,[0.125 + 0.25\,(C - 0.20)]$$
$$+ P\,[1.25 - 0.5\,(C - 0.20)] + Cr \times 0.2 + Ni \times 0.1$$

where C is the carbon concentration in %. The ultimate tensile strength (in MPa) after normalisation is given by:

$9.81\,(27 + 56C_p)$ for hot-rolled steel

$9.81\,(27 + 50C_p)$ for forged steel

$9.81\,(27 + 48C_p)$ for cast steel

For steels which may be used in sub-zero conditions, a double normalising treatment may be specified.[32] In these cases, the steel is first heated to 50–100°C above the usual normalising temperature. This will produce greater dissolution of the alloying elements. The second normalisation step is conducted near the lower limit of the normalisation temperature range for the purpose of producing a finer grain structure.

STRESS RELIEVING

Stress relieving is used typically to remove residual stresses which have accumulated from prior manufacturing processes. Stress relief is performed by heating to a temperature below Ac_1 (for ferritic steels) and holding at that temperature for the required time, to achieve the desired reduction in residual stresses. The steel is then cooled sufficiently slowly to avoid the formation of excessive thermal stresses. No phase transformations occur during stress relief processing. Nayar recommends heating to:[30]

- 550–650°C for unalloyed and low-alloy steels;
- 600–700°C for hot-work and high-speed tool steels.

These temperatures are above the recrystallisation temperatures of these types of steels. Little or no stress relief occurs at temperatures <260°C and approximately 90% of the stress is relieved at 540°C. The maximum temperature for stress relief is limited to 30°C below the tempering temperature.[17]

The results of the stress relieving process are dependent on the temperature and time which are correlated through Holloman's parameter (P):[9]

$$P = T\,(C_{HJ} + \log t)$$

where T is the temperature (K), t is the time (h) and C_{HJ} is the Holloman–Jaffe constant which is calculated from:

$$C_{HJ} = 21.53 - (5.8 \times \%C)$$

P is a measure of the 'thermal effect' of the process and that processes with the same Holloman's parameter exhibit the same effect.

Another similar commonly used expression employed in evaluating the stress relief of spring steels is the Larson–Miller equation:[9]

$$P = T\,(\log t + 20)/1000$$

Stress relieving results in a significant reduction of yield strength in addition to a decrease in the residual stresses to some 'safe' value. Typically heating and cooling during stress relieving is performed in the furnace, particularly with distortion and crack-sensitive materials. Below 300°C, faster cooling rates can be used.

29.2.7 Quenching

QUENCHANT SELECTION AND SEVERITY

Quench severity, as expressed by the Grossman H-value (or number), is the ability of a quenching medium to extract heat from a hot steel workpiece. A typical range of Grossmann H-values (numbers) for commonly used quench media is provided in Table 29.7. Although Table 29.7 is useful to obtain a relative measure of the quench severity offered by different quench media, it is difficult to apply in practice because the actual flow rates for 'moderate', 'good', 'strong' and 'violent' agitation are unknown.

Alternatively, the measurement of actual cooling rates or heat fluxes provided by a specific quenching medium does allow a quantitative metric of the quench severity provided. Some illustrative values are provided in Table 29.9.[9,33] Typically, the greater the quench severity, the greater the propensity of a given quenching medium to cause increased distortion or cracking. This usually is the result of increased thermal stresses not transformational stresses. Specific recommendations for quench media selection for use with various steel alloys is provided by standards, such as AMS 2779. Some additional general comments regarding quenchant selection include:[34,35]

- Most machined parts made from alloy steels are oil quenched to minimize distortion.
- Most small parts or finish-ground larger parts are free-quenched.
- Larger gears, typically those over 8 inches are fixture (die)—quenched to control distortion.
- Smaller gears and parts such as bushings are typically plug-quenched on a splined plug typically constructed from carburised 8620 steel.
- Although a reduction of quench severity leads to reduced distortion, this may also be accompanied by undesirable microstructures such as the formation of upper bainite within carburised parts.
- Quench speed may be reduced by quenching in hot 149–204°C (300–400°F) oil. When hot oil quenching is used for carburised steels, lower bainite, which exhibits properties somewhat similar to those of martensite, is formed.
- Excellent distortion control is typically obtained with austempering, quenching into a medium just above the M_s temperature and then holding until the material transforms completely to bainite. The formation of retained austenite is a significant problem with austempering processes. Retained austenite is most pronounced where Mn and Ni are major components. The best steels for austempering are plain carbon, Cr and Mo alloy steels.[34]
- Aqueous polymer quenchants may often be used to replace quench oils but quench severity is still of primary importance.
- Gas or air quenching will provide the least distortion and may be used if the steel has sufficient hardenability to provide the desired properties.
- Low hardenability steels are quenched in brine or vigorously agitated oil. However, even with a severe quench, undesired microstructures such as ferrite, pearlite or bainite can form.

Table 29.9 COMPARISON OF TYPICAL HEAT TRANSFER RATES

Quench medium	Heat transfer rate $(Wm^{-2}\,K^{-1})$	Reference
Furnace	15	9
Still air	30	9
Compressed air	70	9
Nitrogen (100 kPa)	100–150	33
Salt bath or fluidised bed	350–500	33
Nitrogen (1 MPa)	400–500	33
Air-water mixture	520	9
Helium (1 MPa)	550–600	33
Helium (2 MPa)	900–1 000	33
Still oil	1 000–1 500	33
Liquid lead	1 200	9
Hydrogen (2 MPa)	1 250–1 350	33
Circulated oil	1 800–2 200	33
Hydrogen (4 MPa)	2 100–2 300	33
Circulated water	3 000–3 500	33

It is well known that the cracking propensity increases with carbon content. Therefore, the carbon content of the steel is one of the determining factors for quenchant selection. Table 29.10 summarises the mean carbon content limits for water, brine or caustic quenching of some steels.[33,35]

COMPONENT SUPPORT AND LOADING

Many parts, such as ring gears, may sag and creep under their own weight when heat treated, which is an important cause of distortion. Proper support when heating is required to minimise out-of-flatness and ovality problems which may result in long grinding times, excessive stock removal, high scrap losses and loss of case depth.[36] To achieve adequate distortion control, custom supports or press quenching may be required. Pinion shafts are also susceptible to bending along their length if they are improperly loaded into the furnace. When this occurs, the parts must be straightened, which will add to production cost.

SURFACE CONDITION

Quench cracking may be due to various steel related problems that are only observable after the quench but the root cause of which is not the quenching process itself. Examples include: prior steel structure, stress raisers from prior machining, laps and seams, alloy inclusion defects, grinding cracks, chemical segregation and alloying element depletion.[37] In this section, three surface condition related problems that may contribute to poor distortion control and cracking will be discussed: 'tight' scale formation, decarburisation and the formation of surface seams or 'non-metallic stringers'.

Tight scale problems are encountered with forgings hardened from direct-fired gas furnaces with high-pressure burners.[35,38] The effect of tight scale on the quenching properties of two steels, 1095 carbon steel and 18-8 stainless steel, is illustrated in Figure 29.16.[25] These cooling curves were obtained by still quenching into fast oil. A scale thickness of less than 80 μm (0.003 in.) increased the rate of cooling of 1095 steel, as compared with the rate obtained on a specimen without scale. However, a thick scale of 130 μm (0.005 in.) retarded the cooling rate. A very light scale, 13 μm (0.0005 in.) thick also increased the cooling rate of the 18-8 steel over that obtained with the specimen without scale.

In practice, the formation of tight scale will vary in depth over the surface of the part resulting in thermal gradients due to differences in cooling rates. This problem may yield soft spots and uncontrolled distortion and is particularly a concern with nickel-containing steels. Surface oxide formation can be minimised by the use of an appropriate protective atmosphere.

Another surface related condition is decarburisation which may lead to increased distortion or cracking.[39] At a given depth within the decarburised layer, the part does not harden as completely as it would at the same depth below the surface, if there was no decarburisation. This leads to non-uniform hardness which may contribute to increased distortion and cracking because the decarburised surface transforms at a higher temperature than the core (the M_s temperature decreases with carbon content).[35] This will lead to high residual tensile stresses at the decarburised surface or a condition of unbalanced stresses and distortion. Since the surface is decarburised, it will exhibit lower hardenability than the core. This will cause the upper transformation products to form early, nucleating additional undesirable products in the core. The decarburised side will be softer than the side that did not undergo decarburising, the greater amount of martensite in the latter leading to distortion. The solution to this problem is to restore carbon into the furnace atmosphere or machine off the decarburised layer.

Table 29.10 SUGGESTED CARBON CONTENT LIMITS FOR WATER, BRINE AND CAUSTIC QUENCHING

Hardening method	Shapes	Max. % Carbon
Furnace hardening	General usage	0.30
	Simple shapes	0.35
	Very simple shapes, e.g. bars	0.40
Induction hardening	Simple shapes	0.50
	Complex shapes	0.33
Figure 29.16   *Cooling curves illustrating the effect of scale on cylindrical steel bars (13 mm dia. × 64 mm, 0.5 in. dia. × 2.5 in.) when quenched into an accelerated oil without agitation (copyright ASM International, Materials Park, OH, used with permission): (a) AISI 1095 steel–oil temperature = 50°C (125°F); (b) 18-8 stainless steel–oil temperature = 25°C (75°F)*

Table 29.11   MINIMUM RECOMMENDED MATERIAL REMOVAL FROM HOT-ROLLED STEEL PRODUCTS TO PREVENT SURFACE SEAM AND NON-METALLIC STRINGER PROBLEMS DURING HEAT TREATMENT

	Minimum material removal per side[1]	
Condition	*Non-resulphurised*	*Resulphurised*
Turned on centres	3% of diameter	3.8% of diameter
Centreless turned or ground	2.6%	3.4%

[1] Based on bars purchased to special straightness, i.e. 3.30 mm in 1.52 m (0.13 inch in 5 feet) maximum.

Surface seams or non-metallic inclusions, which may occur in hot-rolled or cold-finished material, are defects that prevent the hot steel from welding to itself during the forging process. These defects act as stress raisers. To prevent this problem with hot rolled bars, a layer of material should be removed before heat treatment. Recommendations made earlier by Kern are provided in Table 29.11.[38]

HEATING AND ATMOSPHERE CONTROL

An important source of steel distortion and cracking during heat treatment is non-uniform heating without the appropriate protective atmosphere. For example, if steel is heated in a direct-gas-fired furnace with high moisture content, the load being heated may absorb hydrogen leading to hydrogen embrittlement and subsequent cracking which would not normally occur with a dry atmosphere.[5,40]

Localised overheating is a problem for inductively heated parts.[34,41] Subsequent quenching of the part leads to quench cracks at sharp corners and areas with sudden changes in cross-sectional area (stress raisers). Cracking is due to increases in residual stresses, at the stress raisers, during the quenching process. The solution to the problem is to increase the heating rate by increasing the power density of the inductor. The temperature difference across the heated zone is decreased by continuous heating or scanning of several pistons together on a single bar.[41]

For heat treating problems related to furnace design and operation, it is usually suggested that:[40]

a. The vestibules of atmosphere-hardening furnaces should be loaded and unloaded in the presence of a purge gas. Load transfer for belt and shaker hearth furnaces should only occur with thorough purging to minimise atmosphere contamination.
b. Hardening furnaces typically contain excessive loads prior to quenching. If the steel at quenching temperature is greater than 20% of the distance from discharge to charge door, this is too large a distance. Either the production rate can be increased or some of the burners can be turned off.

Table 29.12 DIMENSIONAL VARIATION IN HARDENED HIGH-CARBON STEEL WITH TIME AT AMBIENT TEMPERATURE

Steel type	Tempering temperature (°C)	Hardness (HRC)	Change in length (% × 10³) after time (days)			
			7	30	90	365
1.1% C	None	66	−9.0	−18.0	−27.0	−40.0
tool steel	120	65	−0.2	−0.6	−1.1	−1.9
790°C	205	63	0.0	−0.2	−0.3	−0.7
quench	260	62	0.0	−0.2	−0.3	−0.3
1% C/Cr	None	64	−1.0	−4.2	−8.2	−11.0
840 °C	120	65	0.3	0.5	0.7	0.6
quench	205	62	0.0	−0.1	−0.1	−0.1
	260	60	0.0	−0.1	−0.1	−0.1

RETAINED AUSTENITE

Dimensional changes, which are due to the specific volume of the transformation products formed as a result of quenching, may occur either slowly or rapidly. One of the most important, with respect to residual stress variation, distortion and cracking is the formation and transformation of retained austenite. For example, the data in Table 29.12[33] illustrates the slow conversion of retained austenite to martensite, which was still occurring days after the original quenching process, for the two steels shown.[42,43] This is a problem since dimensional control and stability is one of the primary goals of heat treatment. Therefore, microstructural determination is an essential component of any distortion control process.

QUENCHANT UNIFORMITY

Quench non-uniformity is perhaps the greatest contributor to quench cracking. Quench non-uniformity can arise from non-uniform flow fields around the part surface during the quench or non-uniform wetting of the surface.[33] Both lead to non-uniform heat transfer during quenching. Non-uniform quenching creates large thermal gradients between the core and the surface of the part. These two contributing factors, agitation and surface wetting will be discussed here.

Poor agitation design is a major source of quench non-uniformity. The purpose of the agitation system is not only to take hot fluid away from the surface to the heat exchanger, but also to provide uniform heat removal over the entire cooling surface of all of the parts throughout the load being quenched. Even though agitation is a critically important contributor to the performance of industrial quenching practice, relatively little is known about the quality and quantity of fluid flow encountered by the parts being quenched. Recently, agitation in various commercial quenching tanks has been studied by computational fluid dynamics (CFD) and in no case was optimal and uniform flow present, without subsequent modification of the tank.[44] Thus, identifying the sources of non-uniform fluid flow during quenching continues to be an important tool for optimising distortion control and minimising quench cracking.

The second source of non-uniform thermal gradients during quenching is related to interfacial wetting kinematics which is of particular interest for vaporisable liquid quenchants including, water, oil and aqueous polymer solutions. Most liquid vaporisable quenchants exhibit boiling temperatures between 100 and 300°C at atmospheric pressure. When parts are quenched in these fluids, surface wetting is usually time dependent which influences the uniformity of the cooling process and the achievable hardness and potential for the formation of soft spots. This is a problem with oil contaminated aqueous polymer quenchants, sludge contaminated oils and foaming.

29.2.8 Tempering

When steel is hardened, the as-quenched martensite is not only very hard but also brittle. Tempering, also known as 'drawing' (not to be confused with the metal forming process of the same name), is the thermal treatment of hardened (in general quenched, but as already noted some alloy steels will harden even if normalised) steels to obtain the desired mechanical properties which include: improved

Table 29.13   METALLURGICAL REACTIONS OCCURRING AT VARIOUS TEMPERATURE RANGES AND
RELATED PHYSICAL CHANGES OF STEEL DURING TEMPERING

Stage	Temperature range	Metallurgical reaction	Expansion/ Contraction
1	0–200°C 32–392°F	Precipitation of ε-carbide Loss of tetragonality	Contraction
2	200–300°C 392–572°F	Decomposition of retained austenite	Expansion
3	230–350°C 446–662°F	ε-carbides decompose to cementite	Contraction
4	350–700°C 662–1 292°F	Precipitation of alloy carbides. Grain coarsening	Expansion

toughness and ductility, lower hardness and improved dimensional stability. During tempering, as-
quenched martensite is transformed into tempered martensite which is composed of highly dispersed
spheroids of cementite (or other carbides) dispersed in a soft matrix of ferrite, resulting in reduced
hardness and increased toughness. The objective is to allow hardness to decrease to the desired
level and then to stop the carbide decomposition by cooling. The extent of the tempering effect is
determined by the temperature and time of the process.

The tempering process involves heating hardened steel to some temperature below the eutectoid
temperature for the purposes of decreasing hardness and increasing toughness. (Tempering is per-
formed as soon as possible after the steel has cooled to between 50–75°C and room temperature, to
reduce the potential of cracking. If a tool steel cannot be tempered immediately after quenching, it
is recommended that it be held at 50–100°C in an oven until it can be tempered.[32]) In general, the
tempering process is divided into four stages, which are summarised in Table 29.13. The changes
occurring during tempering include:[45]

1. transformation of the martensite,
2. transformation of retained austenite,
3. transformation and coarsening of the decomposition products of martensite.

The tempering process may be conducted at any temperature up to the lower critical temper-
ature (Ac_1). Figure 29.17 illustrates the effect of carbon content of the martensite and tempering
temperature on the hardness of carbon steels.[46] The specific tempering conditions that are selected are
dependent on the desired strength and toughness. Nayar has recommended the following tempering
conditions:[30]

- Heat the parts to 150–200°C to reduce internal stresses and increase toughness without a
  significant loss in hardness. This is often done with surface-hardened parts.
- To obtain the highest attainable yield strength and sufficient toughness, temper at 350–500°C.
- For optimum strength and toughness, heat to 500–700°C. (Note: when tempering at high temper-
  atures, 675–705°C, precautions must be taken not to exceed the Ac_1 temperature, above which
  undesirable austenite may be formed, which upon cooling would transform to pearlite. This is a
  particular concern for nickel-containing steels, since nickel depresses the Ac_1 temperature.[47])

When steel is tempered in air, the heated oxide film on the surface of the steel exhibits a colour,
known as a 'tempering colour' which is characteristic of the surface temperature. Table 29.14 provides
a summary of characteristic surface temperatures for tempering and their colours.[32]

In addition to the four steps shown, there is another step referred to as 'refrigeration' or 'sub-zero'
treatment. Sub-zero treatment is performed on steels to transform retained austenite to as-quenched
martensite. Conversion of retained austenite in this way results in improved hardness, wear resistance
and dimensional stability. Sub-zero treatment is performed using dry-ice or liquid nitrogen and
involves cooling the steel to a temperature less than the M_f temperature of the steels which is
typically between −30°C and 70°C (tool steels will elongate between about 0.5–2 μm per mm of the
original length during heat treatment[3]). An immediate tempering step is required to remove residual
stresses imparted to the steel by this process. Sub-zero treatments are not effective on steels that
have been held at room temperature for several hours and therefore such treatments are typically
performed immediately after hardening.[26] Although the general rule is to allow one hour per 25 mm
(∼1 inch) of the thickest cross-section, tool steels should be held at temperature for a minimum of
two hours for each temper.[3]
Figure 29.17   *Correlation of carbon content of martensite and hardness of different* Fe–C *alloys at different tempering temperatures. (T$_C$ and T$_F$ are the temperature in Centigrade and Fahrenheit respectively; reproduced with permission of Metallurgical and Materials Transactions)*

Table 29.14   TEMPER COLOURS OF STEEL

Abstracted from a much more detailed table in Thelning.[32]

Temperature (°C)	*Range of temper colours*
220–270	Straw yellow to brown
285–310	Purple to light blue
325–400	Various greys

Martensitic stainless steels and alloy steels that contain ≥0.4% carbon and which exhibit M$_s$ temperatures of about 300°C are particularly susceptible to cracking, especially if they are through-hardened.[32] In such cases, cooling may be interrupted at about 80°C followed by an immediate temper at about 170°C to stop the formation of martensite. However, significant amounts of untempered

martensite remain after the steel is cooled to room temperature. Therefore, the steel must be tempered a second time, at the same temperature, to transform the hard and brittle, as-quenched martensite to a softer and more ductile, tempered martensite. This is one form of a 'double tempering' process.

Another form of double tempering occurs for high-alloy chromium steels and high-speed tool steels where significant amounts of retained austenite are transformed to martensite after tempering at about 500°C. Such steels should be retempered to obtain a tougher martensitic structure. Generally, this second tempering step is performed at about 10–30°C below the original tempering temperature.[32]

Steels that exhibit a high M_s temperature, $\geq 400°C$, typically those that contain <0.3% carbon, form martensite which may be tempered during the remaining cooling (quenching) process. This is called 'self-tempering' or 'auto-tempering' and such steels are typically not crack-sensitive, particularly if the M_f temperature is $\geq 100°C$.[32]

Typically, tempering times are a minimum of approximately one hour. Thelning has reported a 'rule of thumb' of 1–2 hours per 25 mm (1 inch) of section thickness, after the load has reached a preset temperature.[32] After heating, the steel is cooled to room temperature in still air. The recommended tempering conditions, in addition to the recommended heat treatment cycles, for a wide range of carbon and alloy steels are provided in SAE AMS 2759.

Tempering times and temperatures may also be calculated by various methods. One of the more common methods is to use the Larson–Miller equation discussed previously. The Larson–Miller equation, although originally developed for prediction of creep data, has been used successfully for predicting the tempering effect of medium/high alloy steels.[31] Bofors have reported that a Holloman–Jaffe constant of $C = 20$ was appropriate for all steels[3] but Grange and Baughman have reported that $C = 18$ should be used.[48]

Figure 29.18[49] shows that the Holloman–Jaffe constant varies with carbon content and desired hardness.[48] The incremental contribution to hardness of each alloying element in a steel may be determined from Table 29.15.[49] The Vickers hardness (HV) is calculated by multiplying the concentration of each of the alloying elements (within the range shown) by the factor for that element at a given constant (C) and then all of these values are added together to provide the hardness (HV). The relationship between tempering time and the Holloman–Jaffe parameter (P) at different tempering temperatures is shown in Figure 29.19.[49]

The relationship between tempering temperature, time and steel chemistry has been reported by Spies:[9,50]

$$HB = 2.84H_h + 75\,(\%\,C) - 0.78\,(\%Si) + 14.24\,(\%Mn) + 14.77\,(\%Cr) + 128.22\,(\%Mo)$$
$$- 54.0\,(\%V) - 0.55T_t + 435.66$$

Figure 29.19   *Time-temperature versus Holloman Parameter chart for C = 18* (© *ASM International, Materials Park, OH, used with permission*)
Figure 29.20   *Loss in room-temperature toughness due to temper embrittlement of oil-quenched wrought Ni–Cr–Mo (AISI 4130) steel; section size = 13 mm (0.5 in.)*

where HB is the Brinell hardness after hardening and tempering, H_h represents the Rockwell C (HRc) hardness after hardening and T_t is the tempering temperature in °C. This equation was developed for the following conditions: $H_h = 20$–65 HRc, C = 0.20–0.54%, Si = 0.17–1.40%, Mn = 0.50–1.90%, Cr = 0.03–1.20% and $T_t = 500$–650°C (932–1 202°F).

The German DIN 17021 standard provides a relationship between the as-quenched hardness (H_h) and the as-tempered hardness (H_t) :[9]

$$H_h(HRc) = (T_t/167 - 1.2)H_t - 17$$

where T_t = tempering temperature in °C.

Temper embrittlement may occur for some steels if they are tempered below 595°C, which is observable by a reduction in notch toughness as illustrated in Figure 29.20 for AISI 4130 (Ni–Cr–Mo), steel which was tempered at 260–370°C.[17] However, temper embrittlement may be avoided by tempering at higher temperatures, with subsequent quenching, to minimise the time the steel will spend in the intermediate temperature range.[17,47]

Tempering may be performed in convection furnaces, salt baths or even by immersion in molten metal. Induction tempering and flame heating are also used but will not be discussed here. Table 29.16 provides a comparative summary of the different heating media.[51] Of the different tempering systems shown, convection furnaces are the most common and it is important that they be equipped with fans and/or blowers to provide uniform heat transfer, when heating the load. Typically, convection tempering furnaces are designed for use in the 150–750°C range.

Salt baths may also be used for various heating processes over the temperature range 150–1 320°C[19] and they provide relatively rapid heat transfer, compared with convection furnaces, although the actual use temperature is dependent on the composition of the salt bath. A comparison of heating rates between salt baths and muffle furnaces is provided in Table 29.17.[32]

Sinha has classified salt baths into three groups:[19]

- Low-temperature salt baths may be used from 150–620°C. These baths are of two types: a binary mixture of equal parts of potassium nitrate and sodium nitrite, which may be used for heating to 150–500°C and binary mixtures of potassium nitrate and sodium nitrate which may be used for heating in the range of 260–620°C. In addition to tempering, these baths may also be used for cooling. It is essential however, that the baths are not contaminated with cyanides, organic compounds or water!

Table 29.16   TEMPERING TEMPERATURE RANGES ACHIEVABLE WITH DIFFERENT TEMPERING EQUIPMENT
© ASM International, Materials Park, OH, used with permission.

Equipment type	Temperature range		Use conditions
	°C	°F	
Convection furnace	50–750	120–1 380	For large volumes of similar parts; for variable loads. Temperature control more difficult.
Salt bath	160–750	320–1 380	Rapid uniform heating. Low to medium volume. Should not be used for complex, hard to clean parts.
Fluidised beds	100–750	212–1 380	Broad range of heat transfer rates are possible by varying the choice of fluidising gas, gas velocity, bed temperature and the bed particle size. More energy efficient than convection furnaces and they provide a safe and ecologically friendly alternative to salts and lead, with similar heat transfer rates.
Oil bath	$\leq$250	$\leq$480	Good if long exposure times are desired; special ventilation and fire control are required.
Molten metal bath	>390	>735	Very rapid heating; special fixturing required; molten metals may be toxic (Pb baths).

- Medium-temperature neutral baths which are suitable for use over the range of 650°C–1 000°C. These baths are binary or ternary mixtures of the following salts: potassium chloride, sodium chloride, barium chloride or calcium chloride. Two examples of typical binary compositions and working temperatures include: NaCl (45%)/KCl (55%) which is suitable for use at 675–900°C and NaCl (20%)/BaCl$_2$ (80%) which is suitable for use at 675–1 060°C. BaCl$_2$, if used at 100%, has a relatively narrow use range of 1 025–1 325°C.[32] An advantage of these baths is that when they are freshly prepared, the steel surface will be clean without surface carburisation or decarburisation.
- High-temperature salt baths are used in the range of 1 000–1 300°C and they typically contain mixtures of barium chloride, sodium tetraborate (borax), sodium fluoride and silicates. These baths may decarburise steels, as oxides build-up after use.

Molten metal, most typically lead, has been used in the past, but due to its toxicity, its use is now restricted to various heating operations where its outstanding heat transfer properties are essential. Lead baths are used from 327°C, which is the melting point of lead, up to 900°C.[19]

Fluidised beds are formed by passing a gas through solid particles such as aluminium oxide and silica sand, which causes the particles to behave like a bubbling liquid. The particles are generally inert and do not react with metal parts but act to facilitate heat transfer between the fluidising gas and the part being processed.

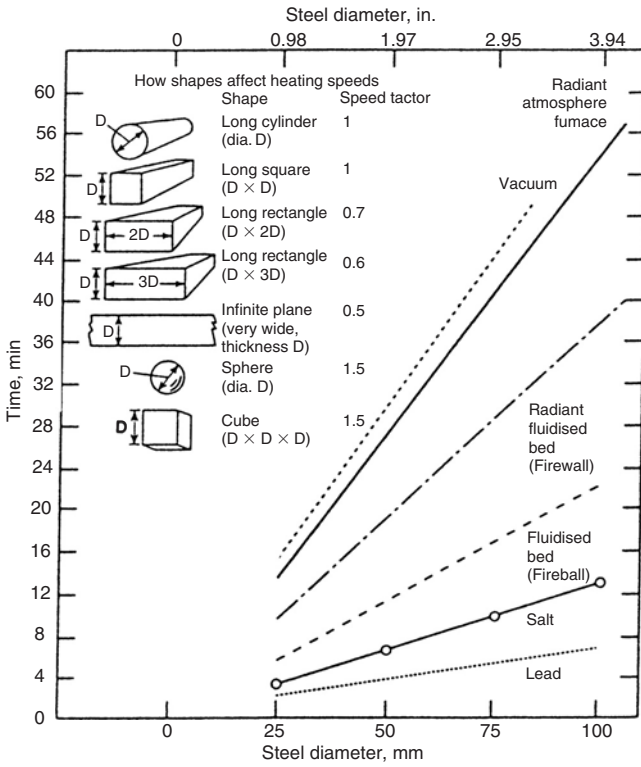
A broad range of heat transfer rates are possible over operating temperatures which may range from 100–1 050°C (212–1 920°F) with fluidised bed furnaces for tempering operations typically ranging from 100–750°C (212–1 380°F) (*see* Table 29.16). Fluidised bed furnaces are not only more energy-efficient than convection furnaces but also exhibit heat transfer efficiency similar to salt baths and lead pots, without the health and environmental safety hazards commonly associated with these systems.


Figure 29.21   *Recommended heating times for various heating media and shapes*

Figure 29.21 provides a comparison of the relative heating rates that can be achieved with these different heating media.[27]

29.2.9   Austempering

Austempering requires that the cooling process be fast enough to avoid the formation of pearlite, as illustrated by the cooling curve for an austempering process, which is superimposed on to an ITD (TTT diagram) of a steel in Figure 29.22A.[9] The steel is cooled below the nose of the pearlite transformation curve for the steel being quenched and just above the M_s temperature, in a molten salt bath. The steel is held at this temperature until the transformation from austenite to bainite is complete. Upper or lower bainite may be formed depending on the molten salt temperature. Austempering eliminates the volumetric expansion due to martensite, which helps to eliminate cracking and provides greater toughness and ductility at a particular hardness.

In practice, austempering is performed by heating the steel to 790–870°C and then quenching into a molten salt bath at a temperature just above the M_s temperature (260–400°C). The steel is kept at the molten salt bath until the transformation is complete, at which time it is cooled to room temperature in air.[30]

The suitability of steels for austempering depends on:[52]

- The location of the nose of the pearlite start (P_s) curve on the ITD and the ability to cool the steel sufficiently fast to avoid pearlite formation.
- The time required for complete transformation from austenite to bainite, at the austempering temperature.
- The M_s temperature of the steel.
Figure 29.22 *Illustration of: (a) austempering; (b) martempering (redrawn, with modifications, after reference 9, p. 456—courtesy of Marcel Dekker, Inc.)*

29.2.10   Martempering

Martempering (also known as marquenching) is a cooling process used to minimise distortion and cracking and to reduce the amount of residual stress formation of a part upon cooling. Typically, martempering involves austenitising steel at a temperature above Ac_1 (815–870°C) and then quenching into hot oil (marquenching oil) or molten salt at a temperature just above the M_s temperature (usually at a temperature ranging from 260–400°C) followed by holding at this temperature until the entire steel workpiece is at the same temperature, at which time the workpiece is cooled to room temperature, at a rate sufficient to achieve a fully martensitic structure. Note that if the part is held at the martempering temperature too long, undesirable formation of bainite may occur.[2] Usually the quenching step is performed in air which minimises thermal gradients and related residual stresses throughout the part while cooling. This process is illustrated in Figure 29.22B.[9] After quenching, the part is tempered per specification.

A variation of this process is to cool the part to a temperature intermediate between the M_s and M_f temperature, until the temperature at the surface and core have completely equilibrated, at which

time the steel is removed from the bath and air cooled or placed directly in the tempering furnace. Table 29.18 provides a summary of M_s and M_f temperatures for a variety of common steels.[17]

Either martempering (hot quenching) oils or molten salt baths may be used for martempering. Molten salts were reviewed briefly above. Martempering oils will be discussed briefly here. Martempering oils are used at temperatures up to 205°C, sometimes as high as 235°C. Molten salts are used for martempering operations performed at 204–400°C.[52] The oils are usually formulated with solvent refined petroleum oils with a very high paraffinic fraction, to maximise oxidative and thermal stability, which is further enhanced by the addition of antioxidants. Accelerated and non-accelerated martempering oils are available. Typical temperature ranges for commercially available martempering oils are summarised in Table 29.19.[53] Because martempering oils are used at relatively high temperatures, a protective, non-oxidising atmosphere is often employed, which allows the use temperatures much closer to the flash point, than is generally recommended for open air conditions.

More hardenable alloy steels are martempered more often than less hardenable plain carbon steels. Steels that are most often martempered to full hardness include: AISI 1090, 4130, 4140, 4150, 4340, 4640, 5140, 6150, 8630, 8640, 8740, 8745. Carburised steels from 3312, 4620, 5120, 8620 and 9310 may also be martempered. Plain carbon steels 1008 through 1040 are insufficiently hardenable to be martempered. Thin sections of some steels of borderline hardenability such as AISI 1541 can be martempered.[52]

29.2.11   Carburising

THERMODYNAMICS OF THE CARBURISING PROCESSES

Carburising systems involve reversible chemical reactions of the form:

$$xA + yB \iff qC + rD$$
for which the equilibrium constant (K_{eq}) is:

$$K_{eq} = (p_C^q \, p_D^r)/(p_A^x \, p_B^y)$$

where p_A, p_B, p_C, p_D are the partial pressures of reactants A and B and products C and D and x, y, c and d represent the stoichiometry of the reaction. In the event that product C is dissolved in the steel, the activity of C in the steel (a_C) would be substituted for p_C.

These reactions attempt to approach equilibrium involving the atmospheric constituents and the substrate material (steel). At equilibrium, the change in Gibbs free energy (ΔG) is zero by definition. Hence:

$$\Delta G = \Delta G^o + RT \ln K_{eq} = 0$$

Thus, at equilibrium, the equilibrium constant, K_{eq}, is given by:

$$\Delta G^o = -RT \ln K_{eq}$$

where:

ΔG^o—standard free energy of the reaction [kJ mol^{-1}],
R—Gas constant (8.314 J K^{-1} mol^{-1}),
T—Absolute temperature [K].

A carbon-rich atmosphere that is capable of carburising steel objects, when held at an appropriate process temperature, is known as a controlled carburising atmosphere. Decarburising/carburising is governed by the following reversible reaction:

$$C(\text{in } \gamma) + CO_2(g) \iff 2CO(g)$$
which has an equilibrium constant of $K_B = p_{CO}^2/(p_{CO_2} \, a_C)$

When using methane as the process enrichment gas, the reaction involved is:

$$CH_4(g) \iff C(\text{in } \gamma) + 2H_2(g)$$
for which the equilibrium constant is $K_M = (p_{H_2}^2 \, a_C)/p_{CH_4}$
As well as the following:

$$C(\text{in } \gamma) + H_2O(g) \iff CO(g) + H_2(g)$$
with an equilibrium constant $K_W = p_{CO} \, p_{H_2}/(p_{H_2O} \, a_C)$, where K_B, K_M, K_W are the equilibrium constants of the reaction concerned, a_C is the carbon activity, p_{CO}, p_{CO_2}, p_{H_2}, p_{H_2O}, p_{CH_4} are the partial pressures of the species shown.

Thus, by selection of an appropriate atmosphere, carbon may be introduced into the austenite as a solid-solution. Alternatively, free carbon may be present in the furnace atmosphere, in the form of soot (graphite). If the atmospheric carbon concentration is high enough, graphitic soot will precipitate out of the atmosphere and begin to concentrate on the work piece, the walls of the furnace and mechanical parts within the furnace, such as the rails, hearth, rollers, burner tubes and elements.

The equilibrium constants for the reactions shown above are:

$$\log K_B = -8\,750/T + 9.022$$
$$\log K_M = -4\,768/T - 5.767$$
$$\log K_W = -6\,908/T + 7.457$$

KINETICS OF THE CARBURISATION PROCESS

Carbon deposition at the steel surface

Consider now the rate at which carburisation occurs. At the steel/gas phase interface the carburisation reaction will be dependent on the difference between the carbon potential (carbon activity) in the atmosphere and at the steel surface. Carbon will diffuse from the atmosphere to the steel surface

when the activity of the carbon in the atmosphere is higher than the activity of carbon in the austenite surface, which is dependent on furnace temperatures and the initial carbon concentration in the steel. Thus, the number of carbon atoms, N, that penetrate a surface area S, in time dt, is dependent on the difference between the carbon activity in the gaseous medium α_{cg} and the carbon activity on the steel surface α_{cp}:

$$\frac{N}{S\,dt} = -\beta(\alpha_{cg} - \alpha_{cp})$$

If the carbon concentration is substituted for activity then:

$$\frac{M}{F\,dt} = -\beta(C_A - C_S)$$

where:

   M—mass of carbon deposited (g),
   F—surface area (m^2) penetrated by carbon of mass M,
   dt—time of carbon penetration (s),
   C_A—carbon potential of the atmosphere ($g\,m^{-3}$),
   C_S—surface carbon content ($g\,m^{-3}$),
   β—surface reaction rate constant ($m\,s^{-1}$).

The carbon transfer coefficient is defined in European norm EN10052: 1993[54] as: 'the transfer of a carbon mass from the carburising medium to the steel surface, through individual carbon molecules to the steel surface by the difference of potentials between carbon potential of medium, and the steel carbon potential at the surface at any given moment. The mass transfer stream of carbon from atmosphere to steel is quantifiable in the following formula':

$$\text{Carbon flux (in } g\,s^{-1}) = \beta_C\,(C_P - C_S)\,F$$

where:

   β_C—carbon transfer coefficient ($m\,s^{-1}$),
   C_P—carbon potential of atmosphere ($g\,m^{-3}$)
   C_S—carbon content of steel surface ($g\,m^{-3}$)
   F—surface area (m^2)

which is identical to the previous equation, apart from the change in nomenclature.

Assuming that steady-state conditions are established, the rate of carbon transport to the steel surface can be described by means of Fick's first law of diffusion, which states, using nomenclature appropriate to the diffusion of carbon, that:

$$J_C = -D_C\frac{\partial C}{\partial x}$$

In this equation, J_C is the carbon flux, i.e. the amount of carbon passing through $1\,m^2$ of reference plane per second ($g\,m^{-2}\,s^{-1}$). C represents the carbon concentration ($g\,m^{-3}$) and x is distance (m), so that the one dimensional carbon concentration gradient is ($\partial C/\partial x$). Note: any convenient measure of the amount of carbon can be used in place of grams in this equation, but a consistent unit must be employed for the amount of carbon in the C and J terms. D_C represents the carbon diffusion coefficient (diffusivity) in the medium in which the carbon is diffusing (and has units of $m^2\,s^{-1}$). The value of D_C will depend strongly on the carburisation temperature.

Re-expressing the carbon flux in Fick's first law in units of $g\,s^{-1}$ yields:

$$\text{Carbon flux (in } g\,s^{-1}) = D_C\frac{dC}{dx}F$$

Given continuity of carbon mass flow from atmosphere to steel and then into the steel surface, it is then possible to equate the two expressions for the carbon flux, which yields the following mass transfer formula:

$$\frac{D_C}{\beta_C} = \frac{C_P - C_S}{dC/dx}$$

The value of the carbon transfer coefficient β_C (and hence the capability to transport carbon to the steel surface) depends on the source and hence the carbon potential of the medium used for carburising. From the literature, the smallest carbon transfer coefficient β_C is $5.4 \times 10^{-10}\,\mathrm{m\,s^{-1}}$, for the mixture CO–CO_2. A somewhat larger value of $1.79 \times 10^{-9}\,\mathrm{m\,s^{-1}}$ has been reported for a mixture of CH_4–H_2–H_2O. Mixtures of CO–CO_2–CH_4–H_2–H_2O exhibit higher β_C values: $3.1 \times 10^{-7}\,\mathrm{m\,s^{-1}}$ for a mixture of 50% CO–CO_2 and 50% CH_4–H_2–H_2O. An industrial endothermic atmosphere composed of fuel gases exhibits a β_C value of $1.2 \times 10^{-7}\,\mathrm{m\,s^{-1}}$.

Diffusion of carbon into the bulk

In the last section, Fick's first law was used to describe the steady-state diffusion of carbon to the surface of the steel, such that a fixed carbon concentration C_S is established at the surface of the steel. Within the steel, however, non-steady state carbon diffusion occurs as the case develops and so it is necessary to employ Fick's second law of diffusion, i.e.:

$$\frac{\partial C}{\partial t} = D_C^\gamma \frac{\partial^2 C}{\partial x^2}$$

In this equation, t is time (in seconds) and D_C^γ is the diffusion coefficient of carbon in austenite at the carburisation temperature. Other terms are as defined previously (although, in the present case they refer to the carbon concentration within the steel). This equation does not permit a general analytical solution. However, the following result can be obtained for the carbon concentration as a function of distance and time, $C(x, t)$, during carburisation of a steel with an initial carbon concentration C_I prior to carburisation:

$$C(x, t) = C_I + (C_S - C_I) \left[1 - \mathrm{erf}\left(\frac{x}{2\sqrt{D_C^\gamma t}} \right) \right]$$

In this case, $x = 0$ is defined as the surface of the steel in contact with the carburising atmosphere, which has a fixed carbon concentration C_S. This equation may be solved with appropriate error function (erf) tables, or a spreadsheet that supports the error function. Alternatively, if all that is required is an order of magnitude estimate of the case depth, then the following approximation can be employed:

$$\text{Case depth} \sim \sqrt{D_C^\gamma t}$$

In both of these equations, the assumption is that the rate controlling step governing the formation of the case is the solid-state diffusion of carbon in austenite. The value of D_C^γ for use in either of these equations can, in turn, be calculated using the Arrhenius equation:

$$D_C^\gamma = (D_0)_C^\gamma \exp\left[-\frac{Q_C^\gamma}{RT} \right]$$

Notice that both the pre-exponential term $(D_0)_C^\gamma$, sometimes called the frequency factor (with units of $\mathrm{m^2\,s^{-1}}$) and the activation energy for diffusion, Q_C^γ (with units of $\mathrm{kJ\,mol^{-1}}$), are material specific to the diffusing solute (carbon) and matrix (austenite) involved. In this equation, R is the gas constant ($8.314\,\mathrm{J\,K^{-1}\,mol^{-1}}$) and T is the absolute temperature (in K) at which carburisation is performed. Table 29.20 contains tabulated values for D_C^γ as a function of temperature. See Chapter 13 for diffusion data.

CLASSIFICATION OF CARBURISING PROCESSES

The most common processes that are encountered industrially are:

a. *Pack carburising*—The pack carburising process is typically conducted by surrounding the steel in a pit furnace or steel box furnace with granules of charcoal or charcoal plus coke. An 'activator' for the charcoal, such as barium borate ($BaBO_3$) is added to facilitate the release of CO_2, which then reacts with excess CO_2 to form CO which in turn reacts with the low-carbon steel surface to form carbon, which diffuses into the steel. Pack carburising is conducted typically at 920–940°C for 2–36 hours.

Table 29.20   EFFECT OF TEMPERATURE ON THE DIFFUSION
COEFFICIENT OF CARBON IN AUSTENITE (D_C^γ)

Temperature		
°C	°F	D_C^γ (m^2 s^{-1})
760	1 400	7.8×10^{-13}
788	1 450	1.2×10^{-12}
816	1 500	1.9×10^{-12}
843	1 550	2.8×10^{-12}
871	1 600	4.2×10^{-12}
899	1 650	6.0×10^{-12}
927	1 700	8.6×10^{-12}
954	1 750	1.2×10^{-11}
982	1 800	1.6×10^{-11}
1 010	1 850	2.2×10^{-11}
1 038	1 900	3.0×10^{-11}
1 066	1 950	4.0×10^{-11}
1 093	2 000	5.2×10^{-11}
1 121	2 050	6.8×10^{-11}

b. *Liquid carburising*—Liquid carburising is conducted typically in internally or externally heated molten salt pots containing a cyanide salt such as sodium cyanide (NaCN). There are generally two types of liquid carburising processes. One type is a *low temperature* process (840–900°C) which is conducted when low case depths of 75 to 760 µm (0.003–0.03 inches) are required. The second liquid carburising process is conducted at a *high temperature* (900–950°C) when case depths of 760 to 3 050 µm (0.03–0.12 inches) are desired. In either case, process times may be 1–4 hours.

c. *Gas carburising*—Currently, the most common carburising process is gas carburising which may potentially be performed with any carbonaceous gas such as: methane, ethane, propane, or natural gas. Carburising times of 4–10 hours are typical. The carburising temperature is greater than the upper critical temperature (in the austenite transformation region, $>954°C$). Case depths are typically less than 1.3 mm (0.05 inches). The conventional gas carburising process allows measurement of the gaseous carbon activity within the furnace process chamber, using the shim test method, dew point test method, CO/CO$_2$ test method and oxygen probe.

d. *Vacuum carburising*—Vacuum carburising is a clean method used to introduce carbon into the surface of the steel and also prevents grain boundary oxidation. Vacuum, or low-pressure, carburising is carried out in a vacuum furnace at pressures below normal atmospheric pressure. The principle of carburising is exactly the same as that of the gas carburising process, the main difference being the use of subatmospheric pressure.

e. *Ion carburising*—Carbonaceous gases such as methane have been used for vacuum carburising because of their widespread availability and current use in gas carburising. Although methane is reactive and controllable when used with endothermic atmospheres, methane alone is extremely stable, even at elevated temperatures. Therefore, when methane is used in vacuum carburising, relatively high pressures of 33 to 53 kPa (250–400 torr) are required. Furthermore, carburising processes conducted at these relatively high pressures produce significant amounts of carbon sooting. These deficiencies however, may be overcome by using an ion process. Methane ionisation is produced with a high-voltage (approximately 1 000 volts) at a relatively low pressure of 1.3 kPa (10 torr). When methane ionises by this 'ion carburising' process, a reactive gas blanket is formed in close proximity to the workpiece, without concurrent soot formation. Other hydrocarbons can be used similarly.

f. *Fluidised bed carburising*—Steel carburising processes may also be conducted in fluidised bed furnaces. Various atmospheres may be used, including conventional endo gas/hydrocarbon mixtures or nitrogen/methanol/hydrocarbon mixtures. Depending on the carburising atmosphere, fluidised bed temperatures of 850–975°C for 30 min to 3 hours may be used. Case depths of up to 700 µm are typical.

Table 29.21 provides a comparative summary of the relative advantages and disadvantages of these processes.

Table 29.21   COMPARISON OF CARBURISING METHODS

Description of method	Disadvantages	Advantages
A. Carburising with solids (*pack carburising*)		
1. The basic component of the carburising medium is ground wood charcoal (around 3–5 mm granules), which is mixed with carbonates of barium, sodium, calcium, lithium or potassium.	1. A long heat up time is necessary to reach the process temperature and to achieve temperature uniformity throughout the box.	1. Low capital equipment cost. cost.
		2. Simple procedure.
		3. Low operating costs.
2. The temperature used for carburisation is about 900°C.	2. Decarburisation of the steel surface will occur if the components are allowed to air cool without protection, or removed from the process box.	
3. It is necessary to place the components into a steel box with a spacing of 25 mm between the components. The box design is very simple, although this does require a lid which can be sealed with clay to contain the liberated gas.	3. It is difficult (but possible) to harden directly from the carburising box. It is usual to allow the box to cool down and then reheat to the required austenitising temperature.	
4. Starting the reactions during heating can be accomplished by: • Burning of a small quantity of the wood charcoal by the introduction of oxygen. • Reaction of an activator with wood charcoal.	4. The method is not reliable in terms of repeatability and cannot be controlled accurately. This is a slow production method.	
5. After the carburising, the carburising boxes can be cooled down within the furnace. Alternatively, the boxes can be removed from the furnace whilst hot and air cooled.	5. Grinding is necessary after the procedure, due to a slight potential for surface porosity.	
B. Liquid carburising		
1. A mixture of molten salts is the carburising medium. Usual mixtures are carbonates or chlorides and cyanides of alkaline metals, sometimes with an addition of SiC. A typical mixture would be: 75% Na_2CO_3, 15% NaCl, 10% SiC.	1. There is a large amount of sludge that collects in the bottom of the salt bath. It is mandatory to clean out the sludge on a frequent basis.	1. Possibility of direct hardening.
2. The temperature used for carburisation is usually between 900°C and 950°C.	2. High operating costs, due to post cleaning and effluent disposal. The process is labour intensive and involves long pre-wiring times for the components.	2. Uniform carburising of clean surfaces.
		3. Elimination of steel boxes that are used in pack carburising procedures.
3. The steel components are placed directly into the molten salts after pre-heating. A cocoon of salt will immediately adhere to the steel surface, thus offering some thermal protection.	3. Carburising stop off is difficult.	4. It has been possible to accelerate the process considerably by applying an electrolytic method.
	4. Components need a long pre-heat time.	
4. In the presence of iron, the cyanide salt decomposes at the high temperature of the bath and cyanate (CN) is liberated, which further decomposes to provide carbon to diffuse into the steel.	5. The probability of distortion remains.	

Table 29.21   COMPARISON OF CARBURISING METHODS—*continued*

Description of method	Disadvantages	Advantages
C. Gas carburising		
1. Atmospheres for carburising are produced in special generators which produce a process gas from natural gas blended with air. The generators are known as endothermic generators. The natural gas will contain a large proportion of methane, plus lower concentrations of other hydrocarbon gases. The air that is mixed with the natural gas will contain moisture which will assist in controlling the carbon potential of the endothermic gas.	1. Limited speed of diffusive satiating, resulting from limitations of the furnace construction as well as the carbon potential of previous carburising atmospheres.	1. Easy to change the carbon potential of the furnace atmosphere, simply by adjusting the enrichment gas in relation to either the moisture present in the atmosphere or by the presence of free oxygen.
2. The temperature used for carburisation is usually between 870–950°C.	2. Carburising atmospheres will contain oxygen in the form of moisture, which will cause intergranular oxidation and also create the potential for grain boundary corrosion. This will cause a deterioration of the fatigue strength of the carburised case.	2. Small waste of energy and economy of time. 3. Parts are relatively clean except from oil quenching if the furnace has an oil quench system, such as is seen on an integral quench furnace.
3. The furnace heating system will assist the gaseous atmosphere to ensure good temperature uniformity within the furnace process chamber. In addition to this, the carbon potential is usually very uniform throughout the process chamber.	3. Considerable emission to atmosphere of harmful substances (oxides of carbon and heated quench oil effluent resulting from quenching). It is advisable to install fume extraction systems to ensure adequate shop ventilation. 4. Oil quenching may lead to distortion and possibly the risk of cracking.	4. Possibility of hardening directly after carburising. However great care must be taken when considering this.
D. Vacuum carburising		
1. The process is conducted at sub-atmospheric (partial vacuum) pressures. Process gases of methane, propane, or acetylene are introduced into the process chamber.	1. High capital cost of equipment. 2. High operating costs. 3. Difficult process control in terms of determining and controlling the atmospheric carbon potential.	1. Fast process times at conventional carburising temperatures.
2. Atomic carbon is generated as a result of the break-up of the process gases. The process of vacuum the carburising involves following stages: • Saturation of the atmosphere with carbon at the process working pressure. • Diffusive transportation of excess carbon into the steel surface in high vacuum.		2. Advantage can be taken of high temperature carburising, up to 1 075°C. Since carburising process temperatures approximately 150°C higher than for conventional gas carburising temperatures can be used, this will result in a shorter gas phase transportation time, resulting in much faster carburising times. The superficial concentration of carbon as a result of an unequal process of break-up of hydrocarbons is, as a rule, very high. Both of these factors will accelerate considerably the diffusive saturation.
3. Single chamber vacuum furnaces can be used in any configuration. Also, front or rear cooling chambers can be fitted, that can facilitate controlled cooling of the processed batch after austenitising. High pressure gas quenching can be accomplished when using blended gaseous mixtures of either nitrogen and helium or nitrogen and hydrogen. Blended gas quenching can (depending on the gas blend and delivery pressure), equal the quench speed of oil.		3. The carburised layer shows the best mechanical properties. 4. Clean finished work surfaces that do not require post cleaning. 5. Environmentally friendly with no toxic gas emissions. Also, lower volumes of effluent gas than for conventional processes.

Table 29.21 COMPARISON OF CARBURISING METHODS—*continued*

Description of method	Disadvantages	Advantages
D. Vacuum carburising—continued		
		6. Mechanical handling equipment can easily be installed into the system for part transportation within and outside of the furnace. Effective, energy-saving process.
		7. Hydrocarbons are the exclusive carrier of carbon. Therefore there is no risk of grain boundary oxidation.
		8. Cooling of the work load can be accomplished, if necessary, under nitrogen. This will eliminate the need for post washing.
		9. The quench gas direction can be manipulated to suit the part geometry, thus reducing the risk of distortion. In addition, the gas flow rate can be adjusted when using a two speed gas circulation drive motor. Thus, the risk of distortion is less than when quenching into oil.
E. Ion carburising		
1. The process depends on placing the steel in a vacuum chamber in a low pressure hydrocarbon atmosphere, with the simultaneous application of a high voltage, on heating.	1. High capital investment.	1. It is possible to control the thicknesses and structure of diffusive layers.
2. The furnace wall is the anode whilst the work load sits on the furnace hearth at the cathode's potential. A voltage is applied in the region of 450 to 800 volts (dependent on the chamber pressure and the workload surface area), which will cause a glow discharge in the process chamber. With the work load at cathode's potential, the process gas is immediately ionised and carburisation will begin to take place.	2. Analysing the carbon potential within the process chamber is difficult. Thus, determination of the carbon potential must usually be accomplished prior to each batch, using data acquired from previously carburised loads.	2. It has been possible to carburise and successfully treat (on a repeatable, continuous basis) stainless steels, heat-proof and acid-resistant steels.
3. The steel surface does not act as a catalyst as occurs with the more conventional carburising procedures. However, the process gases used are still methane, propane or acetylene, along with nitrogen and hydrogen.		3. Case uniformity is excellent, irrespective of the part geometry.

Table 29.21   COMPARISON OF CARBURISING METHODS—*continued*

Description of method	Disadvantages	Advantages
F. Carburising in fluidised beds		
1. A fluidised bed is created usually as a result of the activation by a gas passing through a bed of particles such as sand or aluminium oxide. The particles of the bed are kept in suspension by hot process gas passing upwards and through the particles.	1. No major problems.	1. Simple, but efficient furnace design.
		2. Low operating cost.
		3. Ease of operation.
		4. Not labour intensive.
2. Heat transfer is rapid in a fluidised bed.		5. The parts are not wet as in a salt bath. There is no slag to handle, or desludging of the bed to perform.
3. The fluidised bed furnace can be heated directly or indirectly. Heating can be electrical or by gas, with the enrichment gases being added with the heating gas.		6. Good heat transfer up to the process temperature.
4. The method of operation is exactly the same as is with the salt bath method of heat treatment, with the parts simply being immersed into the fluidised particles.		7. It has been possible to apply direct hardening of components by reducing the carburising temperature to the appropriate austenitising temperature.

STEEL GRADES USED FOR CARBURISING

Construction alloy steels that can carburised successfully are many and varied. When selecting a steel for carburising, it is important to consider machinability, resistance to overheating, susceptibility to deformation during thermal processing, hardenability relative to the cross-sectional size and geometrical features, in addition to mechanical strength, not only in the case but also in the core.

Typically, steels selected for carburising contain <0.25% carbon. The alloy composition is selected to provide case and core hardenability. Plain carbon steels may be carburised but the carburising response is limited owing to the lack of alloying elements. This is illustrated by the selected listing of carburising steels provided in Table 29.22.[55]

Case depths of 75 to 6 350 µm (0.003–0.250 inches) with surface hardnesses of $R_C = 58$–62 are usually specified. An 'effective case depth' is typically defined, which may be determined in various ways. One method is to measure the case depth on a metallographic sample of the part, or of a test bar, by determining the microhardness at various depths from the surface. The required desired case depth is governed by the end application, such as those shown in Table 29.23.[55]

Table 29.24 provides a summary of the common carburising grades of steel used internationally.

HEAT TREATMENT AFTER CARBURISING

After carburising, austenitisation is necessary. If the workpiece is quenched directly from the carburising temperature, retained austenite will form, along with a coarse grain size (depending on the carburising time at temperature). Post-carburisation heat treatment is necessary to provide high surface hardness, that will resist abrasion and wear. Depending on the requirements of the carburised part, the post heat treatment temperatures are selected to provide not only a high surface hardness but also the appropriate core strength. Some options for heat treatment after carburising are shown in Figure 29.23.

The hardening methods summarised in Figure 29.23 are the most commonly used. However, the following procedures are also used, although less commonly:

- Hardening after pearlitic transformation will provide greater energy efficiency and will assure grain size reduction.

Table 29.22 SELECTED LIST OF STEEL COMMONLY USED FOR CARBURISING AND THEIR FEATURES

Steel grade	Features and benefits
4620	Relatively low cost, chromium/nickel/molybdenum steel. Used only where nominal hardenability and core response are required.
8620	Most commonly specified steel for carburising. Excellent carburising response, with good hardenability for most section sizes.
4320	Higher hardenability for improved core response in thicker cross-sections.
4820	Increased nickel content for improved core toughness, slower response results in longer processing times.
9310	Maximum nickel content for maximum core toughness, slower response results in longer processing times.

Table 29.23 REQUIRED CASE DEPTHS OF SELECTED APPLICATIONS FOR CARBURISED PARTS

Application	Case depth	
	µm	inches
High wear resistance, low to moderate loading. Small and delicate machine parts subject to wear.	≤508	≤0.020
High wear resistance, moderate to heavy loading. Light industrial gearing.	508–1 016	0.020–0.040
High wear resistance, heavy loading, crushing loads or high magnitude alternating bending stresses. Heavy duty industrial gearing.	1 016–1 524	0.040–0.060
Bearing surfaces, mill gearing and rollers.	1 524–6 350	0.060–0.250

- Hardening can be performed after initially normalising the structure of the outer layer and core; this method is similar to double hardening, except that the steel is cooled slowly after carburising. The core possesses a normalised structure with less strength but more ductility.

Depending on the alloy selected and the component shape, the carburised steel may be quenched in water, oil or a water polymer solution. Specific recommendations are provided in SAE Standard AMS 2759.

Given the various limitations of both oils and water, there is continuing research into alternative quench media in the heat treating industry. For example, there has been a long search for quenchants, which would exhibit faster cooling rates than those produced by many quench oils, to avoid pearlitic microstructure formation in many steels. This has led to the development and use of aqueous polymer quenchants, as an alternative to many quench oils.

Water quenching of gas carburised parts will provide cooling rates in excess of the critical velocity for martensitic transformation. However, water quenching is likely to cause hardening cracks. A new quenching procedure has been developed using water as the medium and it is known as intensive quenching.

Quenching in oil, on the other hand, reduces the risk of cracking, but often it is not possible to achieve the desired martensitic microstructure throughout the entire carburised case. Only water soluble polymer quenchant solutions provide cooling rates ranging between those attainable with water and those achievable with oil. The Grossmann H-factor obtained for polymer solutions may vary from $H = 0.2$–1.2 (water typically exhibits an H-factor between 0.9 and 2, whereas the H-factors for oil may vary from 0.25 to 0.8). Therefore, the use of an aqueous polymer quenchant will provide a relatively 'mild' quench severity, sufficient to provide the desired martensitic transformation for both case and core.[56–61]

After hardening the carburised case by quenching, it is necessary to temper the steel by selecting a low tempering temperature in the region of 180–275°C to reduce the residual stress caused by the phase transformation from austenite to martensite. A reduction in the quantity of retained austenite may be achieved by cryogenic treatment before tempering, especially after hardening variants '2' and '4' in Figure 29.23 in the case of alloy steels.

Table 29.24   SUMMARY OF COMMON INTERNATIONAL CARBURISING GRADES OF STEEL

Alloy group	Grade	Equivalent grade	ASTM norms	*Average composition (wt. %)*					*Temperature (°C)*		*Minimum mechanical properties*				Applications

Treatment	Carburized surface	Core
1. Pot quenching (direct hardening).	Dissolved carbides, retained austenite.	Increased hardness.
2. Single hardening from a temperature optimised for the carburised surface.	Excess of undissolved carbides.	Soft and workable.
3. Single hardening from an intermediate temperature.	Slightly coarsened grains, limited extent of carbide dissolution.	Greater strength and more ductility than 1.
4. Single hardening from a temperature optimised for the core.	Slightly larger grains, well dissolved carbides, occurrence of retained austenite.	Peak hardened, with a better compromise between strength and ductility than 2.
5. Regenerative quenching (double hardening).	Limited extent of carbide dissolution, reduced occurrence of retained austenite.	Soft and workable, high level of ductility and resistance to high strain rate deformation (impulse strength).
6. Pot quenching with isothermal holding.	Treatment with single stage diffusion of carbon, excess of carbides decays, reduced retained austenite content, minimum of deformation.	Increased hardness.

Figure 29.23   *Heat treatment after carburising* (*not drawn to exact scale*)

Steels that are hardened after vacuum or ion carburising are often quenched in a high-pressure gas. The high-pressure gas may also be blended (helium/nitrogen) to achieve the desired cooling rates required for the alloy being quenched and the geometry of the part. The heat transfer coefficient of a gas quenching medium depends on the gas type, delivery pressure, velocity, turbulence and directionality. In addition to producing clean parts, a major advantage of gas quenching is that is does not harm the environment.

STRUCTURE–PROPERTY RELATIONSHIPS

Despite the progress and range of applications of carburising technology, the influence of case structure on properties continues to be controversial. One of the most significant issues is the influence, on properties, of retained austenite and carbides in the structure of case-hardened layers and of the carbon concentration in the surface zone of those layers. For example, an improvement in bending resistance has been observed for 10–30% retained austenite. However, others have reported an unfavourable influence without specifying the percentage values.[62–68] Reference 62 states that fatigue strength increases as the amount of retained austenite increases and recommends that the minimum retained austenite content should be about 25%. Other work has reported a detrimental influence without stating the bending resistance limit.[62–68]

The differences of opinion on the influence of retained austenite are due to a lack of understanding of the detailed conditions and mechanisms involved in microstructure formation and consequently of the structure–property relationships of case-hardened layers. Variable process methodologies that have been utilised also contribute to the different results obtained. The problem is related to the ways in which retained austenite forms in the surface zone of carburised layers and the need to account for the influence, on properties, of changes in other layer parameters of case-hardened steels. These additional parameters include: the carbon content in hardened structures, chemical composition of the matrix, size of former austenite grains, martensite morphology, internal stress state, etc.

There have been reports that carbide precipitation does not unfavourably influence properties.[62,64–67] However, others have reported detrimental effects. These reports should be regarded with great caution, since lower properties than expected may also be due to an overabundance of carbon or tensile stresses in the surface zone of the layer, related to this overabundance. Also, the manner in which the carburised part is loaded can have an effect on the observed properties. The presence of carbides in the structure of carburised cases, with appropriate hardness, allows the production of machine parts and tools which will have high abrasive wear and bending resistance. The carbide form and fraction in the case structure will depend on how the carburising process is conducted, especially on the carbon potentials of the atmosphere, and the temperature and time of the process (*see* Table 29.25).

One of the factors that exhibits a great influence on the properties of machined parts and tools is grain size. Austenite grain formation in the diffusion layer and in the core influences the morphology of martensite being formed.[62,66,69,70] Austenite grain formation also affects the plastic properties of the carburised steel. Grain size variation during carburisation influences the resistance to bending fatigue[71] or the value of the fracture toughness K_{IC}.[72] The small effect of austenite grain size in the case, or in the core, can be examined by controlling the formation of carbides, the chemical composition of the steel or through process control.

According to previous work[73,74] austenitising from a two-phase austenite–cementite region reduces the occurrence of plate martensite microcracking. Austenitising in the temperature range where a two phase structure, austenite plus carbide is formed, leads to cracking of the martensite. Austenitising at this temperature is favoured for small austenite grain material. The favourable influence of austenitisation temperatures less than A_{cm} has been reported.[75,76] The influence of austenitisation temperature on the properties exhibited by the carburised case has also been addressed[63,77–79] (*see* Table 29.25). In addition, the effect of the mechanical loading mode on the relationship between structure and properties of the diffusion layer has been considered[66] (*see* Table 29.25).

A low M_s temperature results in a reduction of the temperature range for which self-tempering of martensite may occur, which favourably affects many properties. In other words, a low M_s temperature leads to significant inhibition of self-tempering processes occurring during hardening, and, therefore, to a high carbon content in solid solution (in martensite) which will increase the strength and hardness. A minimum M_s value corresponds to the highest compressive stresses.

The presence of hard carbides can have a significant effect on the hardness of the overall coating. Carbide microhardness in carburised carbon steel has been measured at 1 000 HV, and in 2% Ni–Cr steel ~880 HV.[80] Therefore, carburised and hardened surfaces containing 25 to 50% of dispersed

Table 29.25   INFLUENCE OF DIFFERENT STRUCTURAL PARAMETERS ON THE CHARACTERISTIC MECHANICAL PROPERTIES OF CARBURISED LAYERS

Structural parameter	Mechanical property				
	Hardness H	*Fatigue strength* σ_D	*Contact fatigue strength*	*Intensity of cracking*	*Abrasive wear resistance*
Thickness of layer (t_c)	Hardness can be maximised throughout the entire thickness of the layer. It is possible to produce cases with a hardness in the range 700–900 HV.	Data has been reported for samples subject to bending (specifically bent-rotating loading). The optimum coating thickness according to Dawes and Cooksey is 0.08 of that of the part.[87] Tauscher gives a value in the range 0.014–0.21.[88] Weigand and Tolash specify values of 0.07–0.075.[89] This large dispersion of results is a consequence of varying levels of internal stress, strength of the core and internal oxygenation in these different samples.[90] Overall, it seems that the value of the optimum thickness of the layer relative to the thickness of part (i.e. that which correlates with the maximum σ_D) is in the range 0.06–0.07, when accompanied by a core strength of 1.080 GPa.[90]	In general, the most effective thickness is double the depth subjected to the maximum stress (however, other factors such as possible geometrical defects, overloads etc. must be considered).	Cracking generally decreases with increasing thickness. However, cracking depends on numerous parameters, in addition to the thickness of the layer carburised. These additional parameters include: the species present in the steel and the details of preliminary processing, as well as the nature of the applied load.[91,92] Processing parameters influencing the intensity of cracking are the following:[91,92] nickel content in the steel, hardening (especially in warm oil at 80–160°C) and tempering after carburising.	The optimum thickness of the layer is dependent on the nature of the abrasive employed.

Strength of core	An unequivocal relationship between the strength of the core and hardness is not observed.	Optimum for a UTS in the range of 1.080–1.240 GPa.[89]	Optimum for a UTS in the range of 850–1 080 MPa.[89]	Decreases, as the strength of the core increases.	An unequivocal relationship between the strength of the core and abrasive wear resistance is not observed.
Residual austenite γ_R	On increasing γ_R, hardness diminishes.	γ_R seems to be tolerated up to about 25%, but not above this value. The influence of residual austenite in carburised layers on fatigue strength is controversial. Some authors affirm improvement of the resistance to bending fatigue with a limited content of residual austenite of between 10 and 30%.[93] Other authors remark on an ufavourable influence of γ_R on σ_D. A γ_R of 80 to 85% induces a reduction in σ_D of about 25%[94] to 30%.[95] In accord with the above results, the acceptable content of residual austenite is in the range of 15 to 25%[96] or 20 to 30%.[97]	γ_R is tolerated at levels up to 50% Various studies show how residual austenite can have a beneficial influence on contact fatigue resistance, for rolling or rolling with a slide.[98–101]	The residual austenite content has only a small influence on the intensity of cracking.[95]	Abrasive wear resistance falls if γ_R increases.
Carbides	The hardness is slightly sensitive to which carbide phase forms, but depends more on the quantity of carbides.	It has been observed that σ_D can fall when carbides are present.[101] When meshes of interlinked carbides are produced, these lower the fatigue strength.[102] In contrast, the presence of globular carbides (either dispersed, or even when these form a network), has only a small influence on σ_D.[103]	Globular carbides are acceptable and have only a small influence on contact fatigue strength, even when these are superficial.[99]	An unequivocal relationship between the intensity of cracking and the presence of carbides is not observed.	Carbides are an acceptable part of the structure, but not when these are present in the form of a network.

(*continued*)

Table 29.25   INFLUENCE OF DIFFERENT STRUCTURAL PARAMETERS ON THE CHARACTERISTIC MECHANICAL PROPERTIES OF CARBURISED LAYERS—*continued*

Structural parameter	*Mechanical property*				
	Hardness H	*Fatigue strength σ_D*	*Contact fatigue strength*	*Intensity of cracking*	*Abrasive wear resistance*
Internal oxygenation	The hardness drops, as the thickness of the region with internal oxygenation grows.	σ_D drop, as the thickness of the region with internal oxygenation grows. Changes in σ_D are proportional to the thickness of the region of internal oxidation. Thus it may be possible to tolerate thickness for this region of up to 6 to 10 μm.[104] However, for a thickness of 13 μm, the reduction in the fatigue limit can reach 20–25% and 45% for a depth of 30 μm.[105]	The thickness of the region of internal oxygenation has only a small influence on contact fatigue resistance.	An unequivocal relationship between the intensity of cracking and internal oxygenation is not observed.	Internal oxygeneration has an unfavourable influence on abrasive wear resistance.

carbides should exhibit higher hardness, 65 to 67 HR_C (830 to 900 HV),[81] than carburised surfaces without carbides.

The presence of carbides in the case also has an indirect influence over the occurrence of internal stresses. The nature and extent of carbide precipitation's influence on the matrix depends on the quenching method. This influence can occur either as a result of the effect that carbide formation has on the chemical composition of the carbides' surroundings (a micro-scale effect), or the influence that the carbides themselves have on the overall stress state in the coating (a macro-scale effect). With slow cooling the micro-scale influence of the carbides on the matrix dominates, while for fast cooling the macro-scale influence is the important consideration. If the matrix of a case containing carbides transforms into martensite, the resulting macrostresses will probably be compressive. The magnitude of these stresses depends on the amount of retained austenite and on the martensite type (plate or lath) (*see* Table 29.25). Slow formation of large carbides will leave the eutectoidal carbon content in the matrix, which for high-alloy steels is a relatively low content. If the formation of increased amounts of plate martensite in the matrix is favoured during quenching, this results in higher compressive macrostresses.

It has also been shown[82] that surfaces containing large amounts of carbides result in the formation of lower compressive stresses (-60 MPa) than a surface without carbides (-500 MPa). Other work has shown how various carbides influence surface internal stresses (*see* Table 29.25).[83] In cases where the formation of carbides has led to lower compressive stresses, the extent to which this is desirable depends on the operating conditions under which the hardened carburised case is used.

Contact fatigue life for four different carburised surfaces is presented in reference [84], based on the results of sliding and rolling tests on carburised and tempered 2% Cr–Mn steel (*see* Table 29.25). Tests showed that coarse carbides can also (like coarse-grain martensite) influence contact fatigue (*see* Table 29.25).

The presence of sufficient amounts of hard carbides might be expected to guarantee that surfaces will have both abrasive and adhesive wear resistance. Indeed, it is generally found that increasing the surface carbide content will increase abrasive wear resistance, in cases where spheroidised carbides appear in a non-martensitic matrix. In contrast, when the structure of the matrix consists of martensite and retained austenite in various amounts, the amount of carbides present does not significantly influence wear resistance.[85] A microstructure that produces the best contact fatigue resistance also increases abrasive wear resistance.[86] It should be further noted that contact fatigue and abrasive wear resistance are also influenced by the quality and condition of lubrication employed in the system.

Carbide network continuity, carbide coarsening and excessive penetration depth reduce fatigue resistance. A high manganese fraction in a low-alloy steel may be the cause of carbide networks in carburised cases. The form and amount of carbides are influenced not only by the diffusion process temperature and time, but also temperature and duration of subsequent treatments (e.g. annealing, or hardening of the system—*see* Table 29.25).

Table 29.25 provides factors relating structural and working properties of the carburised case.[62]

29.2.12 Carbonitriding

THE PHYSICAL–CHEMICAL BASIS OF THE CARBONITRIDING PROCESSES

Process overview

Carbonitriding is dependent on the simultaneous diffusion of carbon and nitrogen into the surface layers of the steel. The process is usually conducted in the temperature range of 850–880°C. The process gas for the treatment is based upon the use of either a nitrogen/methanol blended gas or an endothermic atmosphere, with the addition of a hydrocarbon enrichment gas as a source of carbon, plus ammonia to supply the nitrogen.

The carbonitriding process combines simultaneously nitriding and carburising, and while these two processes are distinguishable, they are not completely independent.

Deposition of carbon and nitrogen and diffusion into the steel

The diffusion of carbon from the process atmosphere into the steel surface is controlled by Fick's laws of diffusion (as discussed earlier in this chapter, with respect to carburising). However, the simultaneous diffusion of two interstitial solutes (i.e. carbon and nitrogen) in the austenite does raise the possibility of interactions between these, which might lead to a change in the diffusivity of each solute. Furthermore, both carbon and nitrogen are derived from the process atmosphere and undergo

adsorption onto the steel surface (followed by diffusion into the surface) and so the deposition reactions might act in concert. The above raises a question, 'what ability (if any) does nitrogen have to facilitate the carbon adsorption process and does the nitrogen assist carbon absorption into the steel surface?'

At the carbonitriding process temperature, the primary equilibrium thermal disassociation processes producing carbon and nitrogen are:

$$C + CO_2 \Longleftrightarrow 2CO \qquad \text{Reaction 1}$$
$$CH_4 \Longleftrightarrow C + 2H_2 \qquad \text{Reaction 1}$$
$$C + H_2O \Longleftrightarrow CO + H_2 \qquad \text{Reaction 2}$$
$$2NH_3 \Longleftrightarrow N_2 + 3H_2 \qquad \text{Reaction 3}$$
$$NH_3 \Longleftrightarrow N + 3/2H_2 \qquad \text{Reaction 4}$$
$$1/2\,N_2 \Longleftrightarrow N \qquad \text{Reaction 5}$$
$$HCN \Longleftrightarrow C + N + 1/2H_2 \qquad \text{Reaction 6}$$
$$CO + 2NH_3 \Longleftrightarrow CH_4 + H_2O + N_2 \qquad \text{Reaction 7}$$
$$CO + NH_3 \Longleftrightarrow HCN + H_2O \qquad \text{Reaction 8}$$
$$CO_2 + H_2 \Longleftrightarrow CO + H_2O \qquad \text{Reaction 9}$$
$$CH_4 + H_2O \Longleftrightarrow CO + 3H_2 \qquad \text{Reaction 10}$$
$$CH_4 + CO_2 \Longleftrightarrow 2CO + 2H_2 \qquad \text{Reaction 11}$$
Reactions 1 to 6 play a direct and active part in the production of both carbon and nitrogen. In creating atomic carbon for the diffusion reactions, reactions 1–3 have the greatest significance. Atomic nitrogen is created in reactions 4–6 and is available to the steel for diffusion, together with the carbon. A key point is that, at the process temperature of the carbonitriding procedure, molecular nitrogen will decompose to create active, atomic nitrogen (N) in accordance with reaction 6. In accelerating the penetration of both carbon and nitrogen, part of the process will create very small quantities of prussic acid (hydrocyanic acid) on the steel surface. The remaining direct or indirect reactions are inconsequential.

Atomic hydrogen is emitted and is directed to the surface of the steel and will intensify both the reduction and dissociation of surface oxides, as well as converting the oxygen emitted as a result of the carburising reaction. When using 'real-world' furnace atmospheres, oxygen will always be present, as a result of moisture from the endothermic gas, or from unavoidable furnace leakages.

The source of nitrogen for diffusion into the steel is derived from the introduction of ammonia, together with the hydrocarbon enrichment gas. At the process temperature, ammonia dissociation will occur rapidly, which begins in reaction 4 and ends in the final decomposition described in reaction 5. Atomic nitrogen is produced almost immediately as result of the decomposition of the ammonia, followed by the decomposition of molecular into atomic nitrogen. Note that the volume of ammonia should be between 4% to 8% of the total gas flow into the process furnace.

The size of the N_2 molecule is too large to permit this to diffuse into the austenite matrix of the steel and so nitrogen will not dissolve into the steel as molecular nitrogen (the solubility is limited to 0.025%). It is only the active or atomic nitrogen, resulting from the dissociated ammonia, that will penetrate the steel surface and diffuse into the austenite. The limit of solubility of atomic nitrogen in iron, at a temperature of 600°C, is approximately six percent.

The quantity of dissociated ammonia, which is available for diffusion, is proportional to the un-dissociated ammonia present in the furnace atmosphere. It is not possible to quantify the un-dissociated ammonia on the basis of thermodynamic dependence, resulting from the conditions of equilibrium between ammonia and other products present in the furnace atmosphere. This is because such an equilibrium will only occur in the range of temperatures between 400 to 600°C. Between this range of temperatures, dissociation is almost total and the quantity of un-dissociated ammonia does not exceed 0.1%.

The factors influencing the degree of dissociation of ammonia, which occurs during the carbonitriding process are:

- Process temperature.
- Atmosphere changes per hour within the furnace.
- Circulation and distribution of the process gas within the furnace.
- Furnace size (process chamber volume).
- Furnace heating elements versus a gas heating system.

The surface properties of the carbonitrided layers are essential in determining the concentration of nitrogen in the superficial layer of the steel. This concentration will depend directly on that established during the early reaction stages of the ammonia (at the gas–metal interface) and indirectly on other

influencing factors such as the speed of the reaction. Therefore for the control of the process, the superficial concentration of nitrogen is usually a function of the concentration of ammonia in the atmosphere, for different temperatures.

At even higher temperatures of 850 to 930°C, the amount of ammonia will be increased, as a result of the temperature. This addition of ammonia will, to a small degree, increase the concentration of nitrogen in the surface layer of the steel. If this is allowed to occur, then the potential for the formation of nitride networks is extremely high. Conversely, if the process temperature is reduced, the opposite will occur. Thus, even small additions of ammonia will cause a dramatic increase in the surface layer nitrogen concentration. Great care should be taken with the addition of ammonia, as a source of atomic nitrogen, as this can cause nitride networks to occur within the formed case.

Steels that include nitride forming elements (for example: aluminium, boron or silicon) will react readily with nitrogen. The alloying elements that will react favourably with nitrogen to form stable nitrides.

It should be noted that chromium, when combined with manganese, will display higher concentrations of nitrogen in the surface layers in comparison with steels that do not include these elements. Furnace atmospheres with higher carbon potentials can saturate the steel surface excessively. Consideration must be given not only to the gaseous reactions, but also to suppression, by the nitrogen activity at the steel surface, of the potential for retained austenite formation. Excess carbon will also encourage carbide formation in the surface of the steel, and nitrogen will assist in diminishing the retention of retained austenite, by allowing a lower austenitising temperature to be selected. An added benefit of the nitrogen reaction (particularly with the nitride forming alloying elements), is that there is an increase in the resulting surface hardness, as well as a reduction of the potential for distortion.

ROLE OF NITROGEN IN THE CARBONITRIDING PROCESS

The direct influence of carbon on the diffusivity of nitrogen in solid solution in the steel is comparatively insignificant. However, there are many other very essential influences of carbon on the process, which allow nitrogen to enter the steel. In the process of carbonitriding, a role of nitrogen is to facilitate the solutioning of carbon in iron. Nitrogen will also contribute to a significant increase in the speed of the carbon diffusion process.

Changes of carbon potential in the furnace atmosphere

Ammonia and the products of ammonia dissociation will change the equilibrium conditions of the main carburising reaction, thus continually changing the carbon potential of the furnace process atmosphere. The products of the dissociation of ammonia (nitrogen and hydrogen) are in accord with reaction (4) and this influences the partial pressures of the carburising components of the atmosphere, compared with non-carburising components and has the effect of raising the carbon potential of the furnace atmosphere. In contrast, ammonia will also react with oxides of carbon and will produce water vapour, which will lower the carbon potential of the furnace atmosphere. Thus, the completion of the ammonia dissociation reaction (and hence its ability to change the atmospheric carbon potential) is very important.

Ammonia will influence the dependence between the carbon potential of the endothermic atmosphere (and enrichment gas) and the temperature of the dew point. Seemingly insignificant additions of ammonia to a carburising atmosphere will cause a decrease in the carbon potential of the furnace atmosphere, which also means a reduction of the atmosphere's dew point.

Increasing the diffusion coefficient of carbon in austenite

The diffusion of nitrogen into steel raises the diffusion coefficient of carbon in austenite. This offers the possibility of utilising low process temperatures. A carbonitride layer developed, at a given temperature, can have a thickness that is similar to that of a carburised layer produced at a temperature that is approximately 50°C higher. Creation of the carbonitrided layer will begin below 850°C and the case will begin to form faster, than for carburising at a temperature of 900°C.

The activity of carbon in austenite

Nitrogen will increase the activity of carbon in austenite, as a result of the superficial concentration of carbon in the primary layer from the furnace atmosphere. This provides an additional reason why, in comparison with carburising, the process of carbonitriding can utilise a lower process temperature.

Changes in the equilibrium conditions in the Fe–Fe$_3$C *system*

Changes in the equilibrium conditions in the iron–cementite system are caused by the presence of nitrogen. Nitrogen acts as a γ stabiliser and reduces both the A$_1$ and A$_3$ temperatures. This assists the diffusion of carbon into the steel surface (the carbon solubility in austenite is much higher than that in ferrite) and gives the possibility of applying lower process temperatures for carbonitriding, as well as utilising lower temperatures for hardening.

Response to quenching

The introduction of nitrogen into the surface of the steel improves the ability to quench the steel without damage. Addition of nitrogen delays diffusional decomposition of the austenite and hence allows the use of a reduced cooling rate.

By the utilisation of lower austenitising temperatures, oil can be employed successfully as the quench medium, thus considerably reducing the potential for distortion. Because of nitrogen diffusion into the steel surface, the dimensional stability of the treated part is greatly improved.

Quenching conditions will determine the surface hardness, the type and properties of induced internal stresses and mechanical properties, such as torsional and tensile strength. Because of potential defects related to water quenching, it is generally recommended that carbonitrided steels be quenched in oil. The use of specially blended quench oils, that would facilitate martensitic transformation of the surface, whilst allowing a pearlitic core structure, within a specific range of oil cooling speeds is recommended. However, it is typically necessary to provide exhaust ventilation for gaseous waste products and there is often a concern for the environmental impact related to the use of quench oils.

It has been found that aqueous solutions of polyalkylene glycol (PAG) based quench media will reduce the potential environmental impact and by varying the concentration of the polymer quenchant in water, a wide range of cooling speeds is possible. The general impact of quenchants and cooling rates on the properties of carbonitrided steels will be discussed subsequently.

Reduction of the martensite start temperature

The presence of nitrogen in the carbonitrided layer will reduce the martensite start temperature (M_s), as well as significantly raising the martensite finish (M_f) temperature. Thus, the M_s temperature of the carbonitrided steel will be lower than if the same steel was carburised and will also cause a reduction in the compressive stress through the case.

Reduction of retained austenite

Lowering the martensite start temperature will reduce the amount of residual austenite in the carbonitrided layer. Residual austenite will normally be found when the surface carbon potential is in excess of 0.7% to 0.9%, with concentrations of nitrogen in solution. If the concentration of both carbon and nitrogen is controlled in the case, then the retention of any untransformed austenite will be minimal, thus producing a relatively dimensionally stable case.

Control of carbon and nitrogen within the diffusion layer

The production of available carbon for the process is derived principally from the enrichment gas, which is added to the endothermic gas, or the nitrogen/methanol plus enrichment gas. The objective is to ensure a surface carbon potential (0.7% to 0.9% carbon) around the eutectoid composition. The carbon potential can be controlled by accepted methods, such as: dew point, shim analysis, oxygen probe or CO/CO$_2$ analysis. The nitrogen is normally derived from the ammonia enrichment gas added to the furnace. This is extremely difficult to control, as there is no commercial system that can be used to control accurately the decomposition of ammonia to release nascent nitrogen. Therefore one must rely on the relationship of the volumetric flow of the process gas (carrier gas and enrichment gas) to the ammonia. Generally, the ammonia flow should be between 4% to 8% (by volume) of the total gas flow into the furnace.

THE CARBONITRIDING PROCEDURE

The carbonitriding process very closely resembles the process of gas carburising. The procedure involves the following steps:

- Conditioning of the furnace.
- Loading the work into the furnace.

- The carbonitriding process.
- Quenching the carbonitrided work.

The carbonitriding process times are much shorter than soaking times experienced with the carburising process.

During the heating cycle of the batch, the introduction of the carbonitriding atmosphere into the furnace takes place. It is not necessary to introduce the process gas into the furnace during the heat up cycle. This is because during the heat up of the batch and particularly in the temperature range of 550°C to 700°C, ammonia can cause the formation of nitrides at the steel surface. These nitrides may not be stable at the carbonitriding process temperature and may undergo transformation.

The selection of the carbonitriding process temperature requires careful consideration, with due regard to the atmospheric composition employed, as well as the heating method of the furnace. This is to ensure a well conducted process that is able to produce the required case depth, as well as the appropriate carbon and nitrogen concentrations within the case. When selecting either low carbonitriding process temperatures or long cycle times to produce deep cases, the probability of high surface nitrogen concentrations is extremely high.

It is not usual to select deep carbonitrided cases. Generally the case for carbonitriding has a maximum depth of 500 µm (0.020 in.). Deep case formation will give rise to a high probability of the retention of un-transformed austenite (retained austenite). If ammonia is introduced into the furnace, for example during the last one-third of the process cycle, then the risk of high surface nitrogen concentrations is reduced almost to the point of elimination. On completion of holding of the workload in the furnace atmosphere, having allowed sufficient time at the process temperature to form the desired case, the load is quenched from the appropriate austenitising temperature. Care must be taken when selecting the austenitising temperature, due to the potential risk of retained austenite and of course the potential for the occurrence of distortion.

HEAT TREATMENT AFTER CARBONITRIDING

Once the process of carbonitriding is completed, this is usually followed by a cooling procedure, down to the hardening temperature. A light tempering process at 180–200°C usually follows this. This is intended to temper the martensitic case and reduce the potential for case/surface cracking.

The cool-down procedure is selected to accomplish the formation of the structures that are needed to produce the properties required by the engineering design for the core and surface of the steel. The steel can be:

- Cooled within the furnace down to the case austenitising temperature in a controlled manner, followed by quenching.
- Cooled down to, perhaps, 500°C, removed from the furnace and cooled externally, followed by reheating to the austenitising temperature and then by a quenching procedure which will harden the carbonitrided case.

Examples of heat treatments after carbonitriding may be found in Figure 29.24.

THE INFLUENCE OF STRUCTURAL FACTORS ON THE PROPERTIES OF CARBONITRIDED LAYERS

Table 29.26 provides information on the relationship between structural factors and the properties of carbonitrided materials.[62]

Table 29.26 The influence of structural factors on the properties of carbonitrided layer.[77,106–108]

STEELS USED IN CARBONITRIDING PROCESSES

Some steels used internationally for carbonitriding may be found in Table 29.27.
Treatment	Carbonitrided surface	Core
1. Pot quenching (direct quenching).	Dissolved carbides, retained austenite.	Increased hardness.
2. Pot quenching with isothermal holding.	Treatment with single diffusion of carbon and nitrogen, excess of carbides or carbonitrides decays, reduced content of retained austenite, minimum of deformation.	Increased hardness.

Figure 29.24   *Heat treatment after carbonitriding* (*not drawn to exact scale*)

Table 29.26 THE INFLUENCE OF STRUCTURAL FACTORS ON THE PROPERTIES OF CARBONITRIED LAYER[77,106–108]

	Properties				
Structural factor	*Hardness H*	*Fatigue strength σ_D*	*Contact fatigue strength*	*Resistance to cracking*	*Wear resistance*
Thickness of case t_c	The hardness of case generally remains within the range 700–900 HV.	Optimum fatigue strength when: $t_c/t_p \sim 0.7$ ($t_p =$ thickness of plastick zone).	Contact fatigue strength is maximised when: $t_c \sim 2t_z$ ($t_z =$ thickness of maximum stress zone).	Resistance to cracking is reduced as the thickness of the layer is increased.	Thickness limits wear resistance.
UTS of core	—	Optimum fatigue strength when the UTS is 1.3 to 1.5 GPa, with a carbon content in the core of 0.2 to 0.25%.	Optimum contact fatigue strength when the UTS is 850 to 1 080 MPa.	Resistance to cracking drops if the strength of the core is increased.	—
Retained austenite γ_R	If γ_R increases, the hardness diminishes.	Fatigue strength is enhanced by 25 to 60% γ_R.	Contact fatigue strength is enhanced by γ_R up to 70%.	—	—
Choice of carbonitriding process	Little effect on hardness.	—	Small influence on contact fatigue strength.	—	Increased wear resistance
Internal oxygenation	Hardness is reduced.	—	Small of harmful influence on contact fatigue strength.	—	Harmful influence on wear resistance.
Pearlite or bainite	Hardness is reduced.	Fatigue strength falls if the thickness of the layer of pearlite or bainite is increased.	—	—	Harmful influence on wear resistance.
Porosity	Hardness is reduced.	Harmful.	—	—	—

29.3   Heat treatment of aluminium alloys

In this section, a brief review of aluminium alloy physical metallurgy, as affected by heat treating, is provided. Defects arising from heat treating operations are also discussed. The importance of selecting the proper quenchant, and quenching parameters are explained.

29.3.1   Introduction to aluminium heat treating

Aluminium in many forms has been used in aircraft since their very beginning. This is because aluminium alloys can be heat-treated to relatively high strengths, while maintaining low weight. These alloys are easy to bend and machine, and the cost of the material is relatively low. Because of these advantages, aluminium is the most common material used in aerospace today. It is used in the manufacture of advanced commercial aircraft such as the Boeing 777, Airbus 380, and military aircraft such as the Boeing UCAV or F/A-18 E/F.

Typically, the aluminium alloys used in aerospace structures are the heat treatable grades, such as 2XXX, 6XXX and 7XXX. 7XXX alloy grades such as 7075, 7040 and 7050 predominate in aerospace structures. Some of the Al–Li alloys such as 2090 and 8090 have also found application. These alloys are used commonly because they are easily available and readily formed and heat-treated to yield high strength, corrosion resistant components.

However, the use of aluminium is not limited to the aerospace industry. It is used extensively in, for example, sporting equipment and in the automotive industry.

The aluminium alloys most commonly used are 7XXX wrought products. The thickness of parts used ranges from 0.6 mm to 250 mm. Aluminium alloy 7075 and 7050 extrusions are used extensively for stringers and other structural requirements. Some extrusions of 2024 and 2014 are also used. Sheet, both clad and non-clad, of 2024, 7475 and 7075 is used for wing and fuselage skins. Sheet is also formed and built-up to produce bulkheads and other structural requirements. For heavy loading, large forgings of 7050 and 7040 are used commonly, particularly in military aircraft.

Recently, there has been much interest in the use of heat treated 7050 and 7040 plate to minimise the cost of forgings. In this case, the plate (heat treated at the aluminium mill) is supplied to the airframe manufacturer. There the plate is heavily machined to fabricate large ribs and bulkheads. The advantage of this is that it avoids heat-treating small parts and may serve to improve distortion and residual stress control. Unfortunately, there is a significant property variation through the thickness of thick plate. This variation has been studied in detail and the microstructure development in thick sections has been researched extensively.[108a]

Primarily, because of affordability, castings have also been used. However, the use of castings has been limited because of design factors and their limited ductility. Typically casting alloys such as A356 and A357 are used for casting. Applications of castings are simple, non-flight critical components, such as door handles and avionics cabinets.

Heat-treating of aluminium requires stringent controls. To achieve repeatable results, and to provide a quality product, the airframe manufacturers, suppliers and heat-treaters have developed a series of specifications. The most widely used specification is AMS-2770 'Heat Treatment of Aluminum Parts'.[109] This specification details solution treating times, temperatures, quenchants and ageing practices. It also defines the required documentation for heat treat lot traceability. Furthermore, this specification establishes the quality assurance provisions needed to ensure that a quality product is provided to the airframe manufacturer.

29.3.2 A brief description of aluminium physical metallurgy

There are four aluminium alloy types that dominate the heat treatable alloys used in industry today. These are: Al–Cu, Al–Cu–Mg, Al–Mg–Si and Al–Zn–Mg–Cu. A brief explanation of the precipitation sequence, for each alloy type follows.

29.3.2.1 Al–Cu *alloys*

The aluminium–copper system has been reviewed in detail.[110] The equilibrium phase diagram[111] contains an eutectic, at 548°C and approximately 32% copper, involving the face centred cubic Al solid solution phase (α) in equilibrium with $CuAl_2$ (θ). The extent of solid solubility at the aluminium rich end is approximately 5.7% copper. Commercial alloys of this type are 2219, 2011 and 2025.

The precipitation sequence was originally established by Guinier[112,113] and Preston.[114,115] Hornbogen further examined the precipitation in Al–Cu and confirmed the results of Guinier and Preston.[116] The precipitation sequence, on ageing after rapid quenching, has been accepted as being Guinier–Preston zones (GPZ) in the form of plates parallel $\{001\}_{Al}$, transforming to the coherent precipitate θ'', followed by semi-coherent θ'' plates parallel $\{001\}_{Al}$. The final equilibrium precipitate is $\theta(Cu_2Al)$. Silcock *et al.*,[117] examined this progression of precipitates and showed multiple stages in precipitation, evidenced by changes in hardness and Laue reflections.

29.3.2.2 Al–Cu–Mg *alloys*

Aluminium–copper–magnesium alloys were the first precipitation hardenable alloys discovered.[118] The first precipitation hardenable alloy was a precursor to alloy 2017 (4% Cu, 0.6% Mg and 0.7% Mn). A very popular alloy in this group is 2024.

The addition of magnesium greatly accelerates precipitation reactions. In general, the precipitation sequence, starting from a supersaturated solid-solution (SSSS), is:

$$SSSS \longrightarrow GP\ zones \longrightarrow S'(Al_2CuMg) \longrightarrow S(Al_2CuMg)$$
The GP zones in this system are generally considered to be collections of Cu and Mg atoms collected as disks on the $\{110\}_{Al}$ planes. S$'$ is incoherent and can be observed directly in the transmission electron microscope (TEM). S$'$ precipitates heterogeneously on dislocations. These precipitates appear as laths on the $\{210\}_{Al}$, oriented in the <001> direction.[119] Since S$'$ precipitates on dislocations, cold working after quenching increases the number density of S$'$ and produces a fine distribution of precipitates in the matrix.

29.3.2.3 Al–Mg–Si *alloys*

The aluminium–magnesium–silicon alloy system forms the basis for the 6XXX series aluminium alloys. In this heat treatable alloy system, magnesium is generally in the range of 0.6–1.2% Mg and silicon is in the range of 0.4–1.3% Si. The sequence of precipitation is the formation of GP zones, followed by metastable β' (Mg_2Si), followed by the equilibrium β (Mg_2Si). The GP zones in this case, are needles oriented in the <001> direction, with β' and β showing similar orientations.

29.3.2.4 Al–Zn–Mg–Cu *alloys*

This aluminium–zinc–magnesium–copper series of alloys is probably the most popular and readily used. These alloys are used extensively in the aerospace industry because they have excellent corrosion resistance, fracture toughness and strength, compared with the other age hardenable aluminium

alloys. In 7XXX Al–Zn–Mg–Cu alloys, several phases have been identified that occur in Al–Zn–Mg–Cu alloys as a function of precipitation sequence. Four precipitation sequences have been identified. These are shown schematically below:

$$\alpha_{ssss} \Rightarrow S$$
$$\alpha_{ssss} \Rightarrow T' \Rightarrow T$$
$$\alpha_{ssss} \Rightarrow VRC \Rightarrow GPZ \Rightarrow \eta' \Rightarrow \eta$$
$$\alpha_{ssss} \Rightarrow \eta$$
In the first precipitation sequence, the S phase, Al_2CuMg, is precipitated directly from the supersaturated α solid solution (α_{ssss}). The S phase is reported to be orthorhombic,[120] with a space group of Cmcm, and 16 atoms per unit cell. The lattice parameters are:[121] a = 401 pm, b = 925 pm, and c = 715 pm. This phase has been identified[122] as a coarse intermetallic that is insoluble in typical Al–Zn–Mg–Cu alloys at 465°C and as a fine lath precipitate in Al–4.5%Zn–2.7%Cu–2.2%Mg–0.2%Zr alloys. No orientation relationships to the matrix have been identified in the literature.

In the second precipitation sequence, an intermediate phase T′ occurs in the decomposition of the supersaturated solid solution. Bernole and Graf first identified this phase.[123] Auld and McCousland[124] suggested that the structure was hexagonal with the reported lattice parameters a = 1.39 nm and c = 2.75 nm. It was further suggested that the orientation of the hexagonal cell to the aluminium matrix is:

$$(0001)_{T'} // (111)_{Al} \quad (10\bar{1}0)_{T'} // (11\bar{2})_{Al}$$

Further on, in the second precipitation sequence, the equilibrium T phase forms. This phase was reported[125] to be cubic, space group Im3, with 162 atoms in the unit cell. It was indicated that the lattice parameter varies from 1.41 to 1.47 nm, with this variation being due to compositional variations. Bergman *et al.*[126] have proposed that the chemical formula $Mg_{32}(Al,Zn)_{49}$ is appropriate. The T phase was found to be incoherent with the aluminium matrix. This phase has been rarely reported in substantial quantities, even though commercial heat treatments up to 150°C lie in the $Al + MgZn_2 + Mg_{32}(Al,Zn)_{49}$ phase field. In general, the T phase only precipitates above 200°C.[128]

In the third sequence of precipitation, the supersaturated solid solution decomposes to form vacancy-rich clusters, Guinier–Preston zones, η' and then η. Guinier–Preston zones have been inferred in Al–Zn–Mg alloys, based on small increases in electrical conductivity and an increase in hardness during the initial stages of ageing.[134]

The η' phase is an intermediate step towards the precipitation of the equilibrium phase η ($MgZn_2$). Direct evidence of η' is rare, and difficult to obtain. It has recently been accepted that the η' phase is hexagonal, however, the reported lattice parameters vary widely.

29.3.3   Defects associated with heat treatment

During the production of a part, defects can occur. These can come from operations before heat treatment, such as midline porosity or inclusions that are formed during casting the ingot. Further defects can form during homogenisation of the ingot, such as segregation, the formation of hard intermetallics and other second phase particles.

Defects associated with the heat treatment of aluminium can occur during solution treatment, quenching or ageing. Solution treatment defects include oxidation, incipient melting and underheating. Defects that occur during quenching are typically distortion of the part or inadequate properties caused by a slow quench, resulting in precipitation during quenching and inadequate supersaturation. Defects that can occur during ageing include growth or shrinkage of the part. Problems can also arise from an inadequate response, by the material, to the ageing treatment. Heat-treatment-related defects are discussed in more detail below, in the sections dealing with the relevant process step.

29.3.4   Solution treatment

Aluminium alloys are classified as either heat treatable or not heat treatable, depending on whether the alloy responds to precipitation hardening. In the heat treatable alloy systems, such as 7XXX,

Table 29.28   SOLUTION TREATMENT TEMPERATURE RANGE AND
EUTECTIC MELTING TEMPERATURE FOR 2XXX ALLOYS

Alloy	*Solution treatment temperature range* (°C)	*Eutectic melting temperature* (°C)
2014	496–507	510
2017	496–507	513
2024	488–507	502

6XXX and 2XXX, the alloying elements show greater solubility at elevated temperatures than at room temperature. This is illustrated for the Al–Cu phase diagram (see Chapter 11).[127]

The Al–Cu phase diagram shows that holding a 4.5% Cu alloy at 515 to 550° will cause all the copper to go into solution completely. The temperature used to achieve complete solutioning is known typically as the 'solution heat treating temperature' or 'solution treatment temperature'. If the alloy is cooled slowly, then the equilibrium structure of α (saturated solid solution of Cu in Al) + $CuAl_2$ will form. The $CuAl_2$ that forms is large, coarse and incoherent. However, if the alloy is cooled rapidly, there will be inadequate time for the $CuAl_2$ to precipitate. Hence, in the rapidly cooled alloy, all the solute is held in a supersaturated condition. Controlled precipitation of the solute, as finely dispersed particles, at room temperature (natural ageing) or at elevated temperatures (artificial ageing) is used to develop the optimised mechanical and corrosion properties of these alloys.

Solution treatment involves heating the aluminium alloy to a temperature slightly below the eutectic melting temperature. Solution treatment develops the maximum amount of solute into solid solution. This requires heating the material close to the eutectic temperature and holding at temperature long enough to allow close to complete solid solutioning. After solution treatment, the material is quenched to maintain the solute in supersaturated solid solution.

Because the solution treatment temperature is so close to the eutectic melting temperature, temperature control is critical. This is especially true for 2XXX series alloys. In this alloy group, the eutectic melting temperature is only a few degrees centigrade above the maximum recommended solution treatment temperature (Table 29.28).

29.3.4.1   *Oxidation*

If parts are exposed to temperature for too long a time, what is commonly referred to in the industry as 'high-temperature oxidation' could become a problem. Note: the term high-temperature oxidation is really a misnomer, in the context of the heat-treatment of aluminium alloys. Instead, in the present case, the culprit is actually moisture present in the air, during solution treatment. This moisture is a source of hydrogen, which diffuses into the base metal. Voids form at inclusions or other discontinuities. The hydrogen gas gathers and forms a surface blister on the part. In general, 7XXX alloys are the most susceptible (particularly 7050), followed by the 2XXX alloys. Extrusions are the most prone to blistering, followed by forgings.

Eliminating the moisture will minimise the problem of surface blistering. This is accomplished by the sequencing of doors over quench tanks and thoroughly drying and cleaning furnace loads prior to solution treatment. It is also important to make sure that the load racks used for solution treatment are dry. However, it is not always possible to eliminate high humidity in the air, in order to prevent surface blistering. Often the ambient relative humidity is high, so that other measures may have to be taken.

Ammonium fluoroborate is typically used to prevent blistering on 7XXX extrusions and forgings. An amount equivalent to 5 g per m^3 of workload space is usually employed to prevent surface blistering. This is applied as a powder, in a shallow pan, hanging from the furnace load rack. This material is very corrosive and requires operators to wear the appropriate personal protective safety equipment. Because the material is corrosive at temperature, it is recommended that the inside panels in the furnace be manufactured from stainless steel. The use of stainless steel panels will reduce corrosion and hence maintenance.

Anodising parts prior to solution treatment is an alternative to ammonium fluoroborate. This is generally practical for larger extrusions and forgings, where the cost of anodising is small compared with the cost of the part. However, for small parts, the additional cost does not generally justify the possible benefit of anodising prior to solution treatment.

29.3.4.2   *Eutectic melting*

Non-equilibrium conditions can occur because of localised solute concentrations. Because of the increased concentration of solute, the eutectic temperature could be decreased, causing localised melting. This is often called *incipient melting*. When this occurs, significant decreases in properties result. Properties most affected include toughness and tensile properties (both strength and ductility).

Local melting can also occur if the material is heated too quickly. This is particularly true of 2XXX alloys. In this alloy system, there are local concentrations of Al_2Cu. At slow heating rates, the Al_2Cu dissolves slowly into the matrix. At high heating rates, there is inadequate time for the Al_2Cu to dissolve. Local concentrations cause the local eutectic temperature to drop, resulting in localised melting. If inadequate time is allowed for this metastable liquid to dissolve into the matrix, then in general, there is no decrement in properties.

Based on the equilibrium solidus temperature, 7XXX series aluminium alloys should be safe from eutectic melting. However, these alloys can exhibit eutectic melting under certain circumstances. In the 7XXX series alloys, there are two soluble phases, $MgZn_2$ and Al_2CuMg. Al_2CuMg is very slow to dissolve during solution treatment. Local concentrations of Al_2CuMg can cause non-equilibrium melting, between the temperatures of 485 and 490°C (905 to 910°F) and this is a problem, since the work may be brought to this temperature range, or a higher temperature.[128] Homogenisation practice of the ingot is the primary source of S phase in these alloys. Because of the hazards of eutectic melting, it is imperative that the 7XXX alloys be homogenised.

29.3.4.3   *Under-heating*

Under-heating during solution treatment can cause problems, by not allowing enough solute to go into solid solution. This means that less solute is available during subsequent precipitation hardening reactions. As an illustration of this, Figure 29.25 shows the effect of solution-treating temperature on the yield strength and ultimate tensile strength. As the temperature is increased for both alloys shown in the figure, the tensile strength is also increased. For 2024-T4, it can be seen that there is a change in slope and a rapid rise in final properties as the solutionising temperature is increased past about 488°C.

29.3.4.4   *Furnaces for solution treatment*

Furnaces used for the solution treatment of aluminium alloys are typically of two types. Either 'drop-bottom' furnaces or salt bath furnaces are used. Both are batch type operations. There are several continuous types of aluminium furnaces, but these are typically limited to smaller parts.
Figure 29.25   *Tensile strength as a function of solution-treating temperature for 6061 and 2024 (after Hatch)*[128]

Solution treating and quenching of these alloys is typically accomplished in large high-temperature ovens. In some applications, the furnace is supported above the quench tank. The quench tank moves under the furnace on rails. Sometimes there is more than one quench tank, with each tank containing a different quenchant.

Drop bottom furnaces are typically arranged with a moveable quench tank underneath. Often, there is more than one quench tank, one for water and the other for polymer quenchants. These quench tanks move back and forth as desired, and the selected quench tank is positioned under the furnace. The door on the bottom of the furnace opens and the workload is immersed into the quenchant. Sometimes, because the quench tank is so large, it is impractical to move the tank. Therefore, the furnace is moved in a similar fashion to a gantry furnace.

29.3.5 Quenching

In this section, the effects of quenching on the structure and properties of aluminium alloys are discussed. Further detail on quenching media may be found in the Appendix (Section 29.3.7).

The key consideration during quenching is to prevent precipitation, without damaging the part. The problem of undesired precipitation during quenching can be understood in terms of the kinetics of nucleation and growth, during diffusional phase transformations.[128] As with other diffusional phase transformations, the kinetics of precipitation occurring during quenching are dependent on the degree of solute supersaturation, versus the rate of solute diffusion, both of which are functions of temperature. The degree of supersaturation increases with undercooling and hence with decreasing temperature. Hence the driving force for nucleation increases as the temperature decreases. Conversely, solute diffusion coefficients, and hence the rate of diffusion-controlled growth of precipitates, increase with increasing temperature. When either the solute supersaturation or diffusivity is low, the overall rate of precipitation is low. At intermediate temperatures, the amount of supersaturation is relatively high, as is the rate of diffusion. Therefore the overall rate of precipitation is greatest at intermediate temperatures. This is shown schematically in Figure 29.26. The amount of time spent in this critical temperature range is governed by the quench rate.

Precipitation occurring during quenching reduces the amount of subsequent hardening possible. This occurs because solute is precipitated from solution during quenching, is unavailable for any further precipitation reactions. Precipitation during quenching results in lower as-aged tensile strength, yield strength, ductility and fracture toughness.

Quantifying quenching and the cooling effect of different quenchants, has been studied extensively.[129–132] The first systematic attempt to correlate properties to the quench rate in Al–Zn–Mg–Cu alloys was performed by Fink and Wiley[133] for thin, 1.6 mm (0.064″) sheet. A time-temperature-tensile property curve was created and was probably the first instance of a TTT-type diagram for aluminium alloys. It was determined that the critical temperature range for 75S is 400°C to 290°C. This is similar to the critical temperature range found for Al–Zn–Mg–Cu alloys.[134]
Figure 29.26 *Schematic showing the interrelationship between the amount of solute supersaturation and diffusion rate on the amount of heterogeneous precipitation occurring during quenching*

At quench rates exceeding $450°C\,s^{-1}$, it was determined that maximum strength and corrosion resistance were obtained. At intermediate quench rates, from 450 down to $100°C\,s^{-1}$, the strength obtained was lowered (using the same ageing treatment), but the corrosion resistance was unaffected. Between 100 and $20°C\,s^{-1}$, the strength decreased rapidly, and the corrosion resistance was at a minimum. At quench rates below $20°C\,s^{-1}$, the strength decreased rapidly, but the corrosion resistance improved. However, for a given quenching medium, the cooling rate through the critical temperature range was invariant no matter the solution treatment temperature.

One method that quantifies the quench path and the material kinetic properties is called the 'quench factor' and was originally described by Evancho and Staley.[135] This method is based on the integration of the area between the time-temperature-property curve and the quench path. Wierszykkowski[136] provided an alternative explanation of the underlying principles of the quench factor. However, his discussion is more generally applied to the thermal path prior to isothermal transformation. The procedures for developing the quench factor have been well documented.[137] This procedure could be used to predict tensile properties,[143] hardness[144] and conductivity.[138] It was found that the quench factor could not be used to predict elongation because of its strong dependence on grain size[138]. This method tends to overestimate the loss of toughness.[142] The quench factor method also can be used to determine the critical quench rate for property degradation.[145]

29.3.5.1 *Quench rate effects*

The objective of quenching is to preserve the solid solution formed during solution-treating. This is accomplished by cooling rapidly to room temperature. This rapid cooling maintains the vacancy concentration necessary to enable the low temperature diffusion required for GP zone formation. Solute that precipitates, at either the grain boundaries, or dispersoids, is lost and cannot be utilised for further strengthening. Hence, the best properties (with respect to both strength and corrosion resistance) are usually achieved by employing the highest possible quench rate.

As an illustration of quench rate effects in a 7050 alloy, a Jominy end quench bar was fabricated from extruded 7050, and quenched using the Jominy apparatus.[108a] Quench rates ranging from in excess of $1\,000°C\,s^{-1}$ to 1–$2°C\,s^{-1}$ were obtained. This bar was sectioned and examined at specific locations along the quenched bar, using a TEM. Distinct differences in the microstructure were observed. At fast quench rates, the GP zones are small, and exhibit strain fields around the zones. There is little evidence of precipitation at the grain boundaries. As the quench rate is decreased, the strain fields are still present, however they are not as intense. There is also evidence of precipitation on the grain boundaries, although these precipitates are small. Some precipitation also occurs within the grains. Again, these precipitates are small. As the quench rate is further decreased, larger and coarser precipitates are evident. These precipitates occur at the grain boundaries and in the interior of the grains. The lack of a strain field around the precipitates indicates that the precipitates are incoherent with the matrix. The solute contained in the coarse precipitates at the grain boundaries and in the interior of the grain are unrecoverable, and will not participate in any strengthening of the alloy. Further, the presence of the precipitates at the grain boundaries can serve as localised galvanic cells, providing a preferred path for intergranular and stress-corrosion-cracking.

29.3.5.2 *Warpage and distortion*

Of all the possible 'defects' occurring during the heat treatment of aluminium, distortion during quenching is the most common. It is probably responsible for most of the non-value-added work (straightening) and costs associated with aluminium heat-treating.

Distortion during quenching is caused by differential cooling, and differential thermal strains developed during quenching. These thermal strains could be developed centre-to-surface, or surface-to-surface. This differential cooling can be caused by large quench rates, so that the centre is cooled much slower than the surface (non-Newtonian cooling) or by non-uniform heat transfer across the surface of the part.

Aluminium alloys are more prone to quenching distortion than steels. This is because solution treatment temperatures are so close to the liquidus temperature in the former case. Aluminium alloys exhibit less strength and greater plasticity than steels at the solution treatment temperature (or austenitising temperature for steels). Furthermore, much higher quench rates are necessary in aluminium alloys, than in steels, to prevent premature precipitation from occurring during quenching and to maintain supersaturation of the solute.

In steels, there is a phase transformation from austenite to martensite, on quenching. This causes around a 3% volume change, during quenching. There is no analogous phase transformation in

aluminium alloys that can cause cracking or distortion. However, the coefficient of linear expansion of aluminium is approximately twice that of steel (2.38×10^{-5} K^{-1} compared with 1.12×10^{-5} K^{-1}). This causes much greater changes in length or volume as a function of temperature, and increases the probability that distortion will occur.

Proper racking of the parts is critical. The parts should be fully supported, with the loads spread out over a large area, since the creep strength of aluminium is poor. Parts should be wired loosely to prevent the parts from hitting each other during solution treatment. If wired too tightly, the wire could cut the parts. The use of pure aluminium wire minimises this problem.

Because of the poor strength of the solution-treated aluminium parts, distortion of the parts can occur as they enter the quenchant. As a general rule, parts should enter the quenchant aerodynamically to avoid distortion of the part, before it even enters the quenchant. The parts should enter the quenchant smoothly—they should not 'slap' the quenchant.

Racking a part so that it enters the quenchant smoothly also offers the benefit that it is more likely to have uniform heat transfer across the part. Distortion is more likely to occur because of horizontal changes in heat transfer than by vertical differences in heat transfer.

29.3.5.3 *Grain boundary precipitation*

Grain boundary precipitation and the formation of a precipitate free zone (PFZ), are the result of solute coming out of solution during quenching. With a perfect quench, all solute would be held in supersaturated solid solution and no precipitation would occur during quenching. However, a perfect quench is rare with real parts of the types used typically in contemporary practice. Since there is little likelihood of a perfect quench, some precipitation almost invariably occurs. The degree of precipitation depends on the alloy and the quench rate.

As already discussed, the rate of precipitation during quenching is based on two competing factors: supersaturation and diffusion. As temperature is decreased during quenching, the amount of supersaturation increases, providing increased driving force for precipitation. In contrast, at the beginning of quenching, the temperature is high, increasing the rate of diffusion. The Avrami precipitation kinetics for continuous cooling can be described by:[135]

$$\zeta = 1 - \exp(k\tau)^n \tag{1}$$

where ζ is the fraction transformed, k is a constant and τ is defined as:

$$\tau = \int \frac{dt}{C_t} \tag{2}$$

where τ is the quench factor, t is the time (s) and C_t is the critical time (s). The collection of the C_t points for continuous cooling, also known as the C-curve, is analogous to the time-temperature-transformation curve for isothermal transformation. These equations can be used to predict the volume fraction that has precipitated, and how that precipitation will affect the properties.

To avoid excessive precipitation during quenching, three requirements must be met. First, the transfer time from the solution treatment furnace into the quench tank must be minimised. Second, the properties of the quenchant must be selected to enable a quench that is fast enough to ensure that proper supersaturation is achieved, so that the desired properties can be obtained during subsequent ageing. Lastly, the quench tank must have adequate thermal inertia so that the quenchant does not heat excessively, causing an interrupted quench. In addition, the quenching system must extract heat uniformly to minimise property variations.

The quench delay time, or the transfer time from the furnace to the quench tank, is defined differently for air furnaces and salt baths. For air furnaces, the quench delay time is defined as the time interval, from when the furnace door first begins to open, until the last corner of the workload is immersed into the quench tank. For salt baths, the quench delay time is defined as the time interval from when the first corner of the workbasket is exposed, to the time at which the last corner of the workload is immersed into the quench tank. In general, this time interval is independent of the alloy, but depends on the solution treatment temperature, the velocity of movement and the emmisivity of the workload. Table 29.29 shows typical allowable quench delay times for various thicknesses.

The specification for the maximum allowable quench delay time is based on the assumed amount of cooling of the workload, before it enters the quenchant. In general, the maximum allowable quench delay times can be exceeded if it can be demonstrated that the part temperatures do not fall below approximately 413°C before immersion. An exception to this is for AA2219, where the part temperatures can not fall below 482°C before immersion.

Table 29.29 TYPICAL MAXIMUM QUENCH DELAY TIMES

Minimum thickness		Maximum time (s)
mm	inch	
Up to 0.41	Up to 0.016	5
Over 0.41–0.79	Over 0.016–0.031	7
Over 0.79–2.29	Over 0.031–0.090	10
Over 2.29	Over 0.090	15

It is difficult to measure directly and control the temperature drop during transfer of the workload from the solution treating furnace to the quench tank. However, the quench delay time is easily controlled using only a stopwatch. This is augmented with the results from routine tensile testing and intergranular corrosion testing.

29.3.6 Ageing (natural and artificial)

29.3.6.1 *Natural ageing*

Some heat treatable alloys, especially 2XXX alloys, harden appreciably at room temperature to produce the useful tempers T3 and T4. These alloys, when naturally aged to the T3 or T4 tempers, exhibit high ratios of ultimate tensile strength/yield strength and also have excellent fatigue and fracture toughness properties.

Natural ageing, and the resulting increase in properties, occurs by the rapid formation of GP (Guinier–Preston) zones from the supersaturated solid solution, by means of solute diffusion involving quenched-in vacancies. Strength increases rapidly, with properties becoming stable after approximately 4–5 days. The T3 and T4 tempers are based on natural ageing for 4 days. For 2XXX alloys, improvements in properties after 4–5 days are relatively minor, and become stable after one week.

The Al–Zn–Mg–Cu and Al–Mg–Cu alloys (7XXX and 6XXX), harden by the same mechanism of GP zone formation. However, the properties resulting from natural ageing are less stable. These alloys still exhibit significant changes in properties, even after many years.

The natural ageing characteristics vary from alloy to alloy. The most notable differences are the initial incubation time for changes in properties to be observed, and the subsequent rate of change in properties. Ageing effects are suppressed with lower than ambient temperatures. In many alloys, such as 7XXX alloys, natural ageing can be nearly completely suppressed by holding at $-40°C$.

Because of the very ductile and formable nature of as-quenched alloys, retarding natural ageing, increases scheduling flexibility for forming and straightening operations. It also allows for uniformity of properties during the forming process. This contributes to a quality part. However, refrigeration at the temperatures employed normally, does not completely suppress natural ageing. Some precipitation still occurs. Table 29.30 shows typical temperature and time limits for refrigeration.

29.3.6.2 *Artificial ageing*

After quenching, most aerospace aluminium alloys are aged artificially. This is a complex process and requires an understanding of vacancies, and the interaction of precipitation and metastable phases. In general, the sequence of precipitation occurs by clustering of vacancies, formation of GP zones, nucleation of a coherent precipitate, precipitation of an incoherent precipitate and finally the coarsening of the precipitates.

Precipitation hardening is the mechanism where the hardness, yield strength and ultimate strength dramatically increase with time at a constant temperature (the ageing temperature) after rapidly cooling from a much higher temperature (the solution treatment temperature). This rapid cooling or quenching results in a supersaturated solid solution and provides the driving force for precipitation on ageing. The age hardening phenomenon was first discovered by Wilm,[118] who found that the hardness of aluminium alloys with small quantities of copper, magnesium, silicon, and iron, increased with time, after quenching from a temperature just below the melting temperature.

Table 29.30   TYPICAL TIME AND TEMPERATURE LIMITS FOR REFRIGERATED PARTS STORED IN THE AS-QUENCHED (AQ) CONDITION

Alloy	Maximum delay time after quenching (min)	Maximum storage time for retention of the AQ condition (days)		
		−12°C (10°F) Max.	−18°C (0°F) Max.	−23°C (−10°F) Max.
2014 2024 2219	15	1	30	90
6061 7075	30	7	30	90

Precipitation hardening (ageing) involves heating the alloyed aluminium to a temperature in the 95 to 230°C (200–450°F) range. In this range, the supersaturated solid solution, created by quenching from the solution treatment temperature, begins to decompose. Initially there is a clustering of the solute atoms. Once sufficient solute atoms have diffused to these initial clusters, coherent precipitates form. Because the clusters of solute atoms have a lattice parameter mismatch with the aluminium matrix, a strain field surrounds the solute clusters. As more solute diffuses to the clusters, eventually the matrix can no longer accommodate the matrix mismatch. At this point, a semi-coherent precipitate forms.

Finally, after the semi-coherent precipitate grows to a large enough size, the matrix can no longer support the crystallographic mismatch, and the equilibrium phase forms as incoherent precipitates.

Heating the quenched material in the range of 95–205°C accelerates precipitation in heat treatable alloys. This acceleration is completely not due to changes in reaction rate. As was shown above, structural changes occur that are dependent on time and temperature. In general, the increase in yield strength that occurs during artificial ageing increases faster than the ultimate tensile strength. This means that the alloys lose ductility and toughness. T6 properties are higher than T4 properties, but ductility is reduced. Overageing decreases the tensile strength, and increases the resistance to stress-corrosion-cracking. It also enhances the resistance to fatigue crack growth and imparts dimensional stability to the part.

Precipitation hardening curves have been developed for all the most common alloys. Figure 29.27 shows ageing curves for 2024 and 6061. Both alloys show evidence of reversion of GP zones, as indicated by initial reductions in hardness. This reduction in hardness is caused by the re-solutioning of small GP zones that are below the critical size required for stability. Similar ageing curves have been developed for 7075 and casting alloys.

The ageing curves for different alloys vary; however, generally the higher the ageing temperature, the shorter the time required to attain maximum properties. When high ageing temperatures are used, properties are reached very rapidly. For this reason, ageing temperatures are usually lower to assure that the entire load is brought to the required ageing temperature without risk of reduced properties caused by over-ageing of the fastest heated components.

29.3.7   Appendix: Quenchants

In section 29.3.5 the quenching process step was discussed. In this section, the nature of interactions between the hot part and the quenching medium are discussed and used to explain the choice of quenchants for industrial heat treatment.

For any quenchant, there are typically three phases that occur while the part cools: the vapour phase; nucleate boiling and finally convection. Each of these stages has very specific characteristics and heat transfer mechanisms.

In the vapour phase, a stable gas film of superheated quenchant surrounds the part. The stability of this vapour film depends on several factors, including surface roughness, the boiling temperature of the quenchant and viscosity of the quenchant. Heat transfer is very slow through this film, as heat transfer occurs primarily by radiation and conduction. Because of the relatively low temperatures involved in aluminium alloy solution treatment, radiation heat transfer through the film is negligible. Conduction is also negligible because of the poor conductive heat transfer characteristics of gases.
2024

6061

Figure 29.27   *Ageing curves for 2024 and 6061*

As the part cools, the stability of the vapour film also decreases, until the collapse of the vapour film occurs. At this point, nucleate boiling occurs. This transition between stable film boiling, and nucleate boiling is called the 'Ledenfrost temperature'.

Nucleate boiling is the fastest regime of cooling during quenching. This is where the vapour stage starts to collapse and all liquid in contact with the component surface erupts into bubbles as boiling occurs. The high heat extraction rates are due to the carrying away of heat from the hot surface and the transferring of it further into the liquid quenchant, which allows cooled liquid to replace it at the surface. In many quenchants, additives have been included to enhance the maximum cooling rates obtained with a given fluid. The boiling stage stops when the temperature of the component's surface reaches a temperature below the boiling point of the liquid. For distortion prone components, high boiling temperature oils or liquid salts could be used, if cooling in these media is fast enough to harden the material, but both of these quenchants see relatively little use in induction hardening.

The final stage of quenching is the convection stage. This occurs when the component has reached a temperature below that of the quenchant's boiling point. Heat is removed by convection and is controlled by the quenchant's specific heat and thermal conductivity, and the temperature differential between the component's temperature and that of the quenchant. The convection stage is usually the slowest of the three quenching stages. Typically, it is this stage where most distortion occurs.
Figure 29.28 *Cooling curve of distilled water showing extended stable vapour phase*

Obtaining the desired properties with low distortion is usually a balancing act. Often, optimal properties are obtained at the expense of high residual stresses or excessive distortion. Conversely, low distortion or residual stresses are usually obtained with a sacrifice in properties. Therefore, the optimum quench rate is one where properties are just met. As a general rule, this usually provides the minimum distortion.

There are several types of quenchants used for heat treating aluminium. The most common are cold water, hot water and polymer quenchants.

29.3.7.1 *Cold water quenching*

Water is the most common of all quenchant materials. It is easy and inexpensive to obtain, and is readily disposed of, unless severely contaminated. In general, as the temperature of the water is raised, the stability of the vapour phase increases and the onset of nucleate boiling in a stagnant fluid is suppressed. Hence, both the maximum and overall rates of cooling are decreased.

Cold water quenching is the most severe of commonly used quenchants. In an early study using cooling curves,[146] it was shown that quenching into still water caused rapid heat transfer. This study found that heat transfer at the surface of the part was very turbulent at the metal/water interface. The same investigation also showed that there was a marked difference between hard water and distilled water. Distilled water produced an extensive vapour blanket that extended to very low temperatures (Figure 29.28).

29.3.7.2 *Hot water quenching*

The cooling rate produced by water quenching is independent of material properties, such as thermal conductivity and specific heat. Instead, the cooling rate is primarily dependent on water temperature and agitation.[147] Water temperature is the largest primary variable controlling the cooling rate. As already discussed, with increasing water temperature, the cooling rate decreases. The maximum cooling rate also decreases, as the water temperature is increased. In addition, the temperature of maximum cooling decreases with increasing water quenchant temperature. The length of time and stability of the vapour barrier increases, with increasing water temperature. This is shown in Table 29.31.

Often, the application of cold water quenchants causes excessive distortion, residual stresses or cracking. Elevated temperatures up to approximately 80°C (180°F) are sometimes used. However, the extended vapour phase that results tends to cause the properties of the workpiece to be compromised, while doing nothing to reduce distortion. In this application, the uniformity of agitation is critical.

Table 29.31 EFFECT OF WATER TEMPERATURE ON COOLING RATES[148]

Water temperature (°C)	Maximum cooling rate (°C s^{-1})	Temperature corresponding with maximum cooling rate (°C)	Cooling rate (°C s^{-1}) at workpiece temperature		
			704°C	343°C	232°C
40	153	535	60	97	51
50	137	542	32	94	51
60	115	482	20	87	46
70	99	448	17	84	47
80	79	369	15	77	47
90	48	270	12	26	42

Agitation must be able to reach all portions of the part to be effective. Otherwise, vapour can collect and serve as insulation. This will result in soft spots with inadequate properties.

Quenching into water at <50–60°C often produces non-uniform quenching. This non-uniformity manifests itself as spotty hardness, distortion and cracking. This non-uniformity is caused by relatively unstable vapour blanket formation. Because of this difficulty, it was necessary to identify an alternative to water quenching. Polyalkylene glycol quenchants (PAG) were developed to provide a quench rate in between that of water and oil. By control of agitation, temperature and concentration, quench rates similar to water and thick oil can be achieved.

29.3.7.3 *Polymer quenching*

Polyalkylene glycol polymer quenchants are used in the aerospace industry to control and minimise the distortion occurring during the quenching of aluminium. Typically these quenchants are governed by AMS 3025, and are either Type I or Type II. Type I quenchants are single polyalkylene glycol polymers, while Type II quenchants are multiple molecular weight polyalkylene glycol polymers. Each offers different benefits. Because of the higher molecular weight of the Type II PAG quenchants, lower concentrations can be used. However, Type I polymers have a lower cloud point temperature, which can cause higher drag-out, if parts are removed from the quenchant before they reach the quenchant temperature, typically 25–40°C (80–100°F). Typical concentrations used for Type I polymer quenchants are shown in Table 29.32. A more extensive listing of recommended concentrations is provided in AMS 2770 (Wrought products and forgings) and AMS 2771 (castings).

Polyalkylene glycols exhibit inverse solubility in water. They are completely soluble in water at room temperature, but insoluble at elevated temperatures. The inverse solubility temperature can range from 60°C to 90°C depending on the molecular weight of the polymer, and the structure of the polymer. This phenomenon of inverse solubility modifies the conventional three-stage quenching mechanism[149] and provides great flexibility to control the cooling rate.

When a component is first immersed, the solution in the immediate vicinity of the metal surface is heated to above the inverse solubility temperature. The polymer becomes insoluble and a uniform polymer-rich film encapsulates the surface of the part. The stability and longevity of this polymer film is dependent on the temperature, concentration and amount of agitation present. The stable polymer-rich film eventually collapses uniformly, and cool quenchant comes into contact with the hot metal surface. Nucleate boiling results, with high heat extraction rates.

As the period of active boiling subsides, cooling occurs by conduction and convection into the quenchant. When the surface temperatures fall below the inversion temperatures, the polymer dissolves, forming a homogeneous solution again.

The cooling rate of these polymers can be readily varied to suit the specific application by changing the concentration, quenchant temperature, and the amount of agitation. Typically, for most applications, the agitation is usually fixed, while the concentration is changed.

The concentration of the polymer influences the thickness of the polymer film that is deposited on the surface of the part during quenching. As the concentration increases, the maximum rate of cooling, and the cooling rate in the convection phase decrease.

Agitation has an important effect on the quenching characteristics of the polymer quenchant. It ensures uniform temperature distribution within the quench tank and it also affects the quench rate. As the severity of agitation increases, the lifetime of the polymer-rich phase decreases and eventually disappears, and the maximum rate of cooling increases. Agitation has comparatively little effect on the cooling rate during the convection stage.

Table 29.32   TYPICAL CONCENTRATION LIMITS FOR QUENCHING IN PAG

Alloy	Form	Maximum thickness		Concentration (vol. %)
		inches	mm	
2024	Sheet	0.040	1.02	34 Max.
		0.063	1.60	28 Max.
		0.080	2.03	16 Max.

30 Metal cutting and forming

30.1 Introduction and cross-references

The noted British mathematician R. Hill once described the state of metal cutting and forming operations with the statement that 'it is notorious that the extant theory of the mechanics of machining do not agree well with experiment'.[1] As this has largely continued to be the case, this chapter makes no attempt to review those theories. Rather, a short summary of the principal processes is provided along with a detailed list of reference recommendations. Professionals with an interest in the theory of metal cutting are referred to several of the many texts in this area.[2–5] Metal forming experts are referred to the excellent text by Altan *et al.*,[6] although numerous texts exist in this area e.g. [7–10]. For a comprehensive manufacturing approach to the processes with many accompanying illustrations, the reader is referred to the text by DeGarmo *et al.*,[11] or the text by Stephenson *et al.*[12] These texts provide detailed, comprehensive illustrations of many of the processes discussed below with comprehensive supporting details.

The processes discussed in this chapter represent a very brief survey of metal cutting operations, grinding, deburring, metal forming, machinability, lubricants/coolants, and emerging non-traditional machining techniques. Although occupational safety guidelines that apply to these operations are incorporated as they are discussed, a short, concise reference section on the occupational safety standards that may apply is provided for the professional engineer to refer to as he/she reviews and selects the appropriate processes. Related material on lubricants, superplasticity and diffusion bonding (used commonly in conjunction with superplastic forming) may be found respectively in Chapters 24, 36 and 33.

30.2 Metal cutting operations

30.2.1 Turning

In turning, a cutting tool is fed into the rotating workpiece to generate a cylindrical or conical surface that is concentric with the axis of rotation. Traditionally, this has been done using a lathe, which is one of the oldest and most versatile of the conventional machine tools. A very large number of lathes have been developed over the years and they are well documented in the literature.[13,14]

30.2.1.1 *Hard turning*

A special case of turning is hard turning, in which heat-treated metals are machined using very hard tools. This produces very fine finishes and tolerances and avoids the growing United States National Institute for Occupational Safety and Health (NIOSH)/industry concerns with metal working fluids.[15–18]

30.2.2 Boring

The boring operation is equivalent to turning, but is performed exclusively on internal surfaces. It is used for roughing (sometimes referred to as 'hogging'), semi-finishing, or finishing of castings or drilled holes. Finish boring is particularly noted for its ability to achieve dimensional and surface

finish tolerances. Specialised versions of the boring machine include vertical and horizontal as well as jig borers.[11]

30.2.3   Drilling

Drilling is the standard process for producing holes and as such, it is the most common metal cutting process. The drill has a complex geometry, and the process is complex, often being the key bottleneck process in high volume manufacturing. Critical holes are often drilled in two or more passes to promote chip removal and dimensional accuracy, each tool penetrating to only a fraction of the final depth. Often, boring or reaming operations will follow drilling. There are a great many types of highly specialised drilling tool designs.

30.2.3.1   *Conventional drilling*

Most people are familiar with conventional drilling methods. Process machines include upright machines (drill presses), radial machines, and specialised single cycle automatics amongst other variations of the basic machines.[19,20]

30.2.3.2   *Deep hole drilling*

A deep hole is one with a depth-to-diameter ratio of more than 5:1. Special machines are often required to drill these deep holes with adequate accuracy and to ensure proper chip removal. Various lubricants and coolants are frequently used in these processes and are a special concern in the emerging area of metal working fluid hazards defined by NIOSH.[17] Three commonly used deep hole drilling methods in use are solid drilling, trepanning, and counter-boring.[19–21]

30.2.3.3   *Microdrilling*

Microdrilling is the machining of small diameter holes (typically less than 0.5 mm) with a depth-to-diameter ratio greater than 10.[22] The small diameter of the holes precludes the use of coolants due to the lack of coolant channels. This requires frequent tool withdrawal in a process known as 'pecking', which increases the cycle time of the process.

30.2.4   Reaming

Reaming is a specialised process used to enlarge a hole and/or improve its roundness and surface finish. Although reaming is superficially similar to boring, there are notable differences in the design of the tool, making it a separate classification.[11,20] No special machines are required. The same machine that was used in drilling the hole can be used to ream the hole after a tool exchange.

30.2.5   Milling

During milling operations, material is removed from the workpiece by a rotating cutter with multiple teeth. In general, the workpiece is fed into the rotating (but stationary) cutter. The material (metal) removal rate is quite high compared to other machining operations and the surface finish can be very good. The cutter's teeth will be intermittently engaging the workpiece, so the cutting is interrupted, frequently causing chatter and vibration problems for the process.

30.2.5.1   *Face milling*

Face milling generates a surface normal to the axis of rotation. It is generally used for wide flat surfaces. The peripheral portions of the teeth do most of the metal cutting.[11]

30.2.5.2 *End milling*

This is a specific type of face milling operation which is used for milling pockets, facing, profiling and slotting operations.[11]

30.2.5.3 *Peripheral (or plain) milling*

Peripheral milling generates a surface parallel to the axis of rotation. Both flat and formed surfaces can be produced by this method, with the cross section of the resulting surface corresponding to the axial contour of the cutter. The process is sometime referred to as 'slab' milling.[11]

30.2.5.4 *Up-milling and down-milling*

The terms up-milling and down-milling can be applied to all milling procedures. Up milling is the traditional way to mill, and is often called 'conventional milling'. The cutter rotates against the direction of feed rate of the workpiece. In climb, or down milling, the cutter rotation is in the same direction as the feed rate. Although the cutting tool is identical, the method of chip formation is entirely different. In addition, the cutting forces in climb are different from down milling, since the climb milling process undergoes extensive interrupted cutting when entering the work piece, creating large impact loading, cyclic heating and cyclic forces not seen in other cutting operations.[11]

30.2.5.5 *Planing and shaping*

Although commonly used in woodworking, planing and shaping are not as commonly used as a metal cutting process. They are single point cutting processes and have largely been displaced by high speed milling operations. In a planing operation, the workpiece reciprocates while the tool is fed across the workpiece to provide the relative motion. In shaping, the tool reciprocates across the workpiece. Generally, only small or medium size parts are made by shaping. Broaching tools offer a more economical choice over planing and shaping machines.

30.2.5.6 *Broaching*

Broaching resembles sawing since a tool is moved (drawn) across the workpiece.[23,24] However, broaching uses a series of tool edges set at increasing heights. As the tool is drawn over the work surface, the next (longer) tooth of the broach removes successively deeper cuts from the workpiece. A wide variety of finishes (rough to very fine) are thus possible in a single operation, along with a large variety of shapes. Rapid exchange of broach tools allows the broach to be one of the most economical and versatile tools in industry.

30.2.5.7 *Tapping and threading*

Many mechanical assemblies attempt to take advantage of either internal or external screw threads. Also threads may be produced by grinding operations, the most common means are tapping and threading operations.[11,25]

Tapping

When a pre-existing hole exists, tapping is generally used to form the internal threads. A hardened, specially formed threading tool is fed into a hole drilled in a previous operation by one of the drilling processes described earlier.

Thread turning

Used since the earliest lathes,[26] thread turning, usually with a single point tool, remains one of the most widely used methods for producing internal and external threads. A skilled technician may use this technique as a quick way to produce threaded surfaces on conventional or computer numerical control (CNC) machines.

Thread milling

Thread milling, typically done in a machine commonly referred to as a 'screw machine', uses milling cutters to rapidly produce both internal and external threaded surfaces in large quantities. This is now an old technology with many manufacturers of these relatively inexpensive machines.[27,28]

Die threading

This simple process, which may be done manually, forms the threads by using a hard die on softer materials.

Thread rolling

This is an external cold forming process[6] for producing threads. The die tool extrudes the metal from the part surface to form the threads.

30.3   Abrasive machining processes

Abrasive machining is unquestionably the oldest of the basic machining processes,[29–32] with many texts written on the subject. Basically, chips are formed by very small cutting edges that are integral parts of abrasive machining processes, usually man-made. The formed chips may be extremely small, mandating the use of eye protection at all times.

30.3.1   Surface grinding

In this process, the workpiece is typically moved past the grinding surface by either reciprocating or rotating it perpendicular to the grinding surface while it is fed laterally into the grinding surface.[33] This method competes directly with planing and milling operations that require much greater cutting forces.

30.3.2   Cylindrical grinding

These machines often resemble highly specialised machine lathes, since they are equipped with many of the same functional parts (headstock, tailstock, etc). They remove material from external cylindrical surfaces by rotating both the workpiece and the grinding surface in opposite directions. It is typically used for parts requiring a fine surface finish.[32]

30.3.3   Centreless grinding

This process is similar to cylindrical grinding, but the workpiece is allowed to 'float'[32] between the rollers of the grinding surfaces. The workpiece is allowed to find its own centre. Centreless grinding is used when it is not possible to place centering holes in the part or when extreme precision is required in the cylindricity of the part.

30.3.4   Plunge grinding

This is a specialised form of cylindrical grinding in which the wheel is moved continuously into the workpiece rather than traversing. It may be used to part material using modern composite grinding wheels in lieu of more traditional band-saw technology.

30.3.5   Creep feed grinding

In this specialised process,[31] a surface or cylindrical grinding wheel removes a full depth of cut in a single pass on the workpiece at a very slow feed rate. It is commonly used with brittle materials such as ceramics and for materials for which the extent of plastic deformation during machining is critical, such as nickel-base superalloys.

30.3.6   Honing

Honing[34] uses fine abrasive stones to remove very small amounts of metal. It is often the final machining process, removing common errors left by boring or machining, or to remove the tool marks left by other grinding techniques. The honing may be external, or internal, manual or automated. It is limited only by the imagination of the individual designing the honing process.

30.3.7   Microsising

This specialised honing technique uses modern super-abrasives[31] to improve the accuracy of internal cylindrical surfaces. A pre-set, barrel-shaped tool or a highly specialised expandable tool with abrasive stones around its periphery is used. The tool, the workpiece, or both, may rotate. It provides excellent control of the bore.

30.3.8   Belt grinding

As the ability of materials engineers to attach grinding abrasives to flexible belts has increased, the use of belt grinding in metal forming has expanded. It may now be use in place of many of the other grinding processes. It is generally viewed as more efficient than other techniques of grinding.[35]

30.3.9   Disc grinding

This is a face grinding method in which all or most of the flat face of a grinding wheel contacts the workpiece. The wide surface area, which this geometry allows, generates surfaces with low flatness errors, provided that the backing plate is itself quite flat and the grinding surface is regular in thickness.

30.4   Deburring

Burrs are undesired projections of material beyond the edge(s) of the workpiece, which are usually due to plastic deformation during machining and or metal forming. Many deburring methods are widely used. These include barrel tumbling, centrifugal barrel tumbling, vibratory deburring, water jet and abrasive jet deburring, sanding, liquid honing and many others.[36–45] There are many conferences each year to address this important manufacturing topic.

30.5   Metal forming operations

30.5.1   Introduction

In metal forming, an initially simple part, usually a metal billet or sheet blank, is plastically deformed between tools (or dies) to obtain the desired final configuration. Thus, a simple initial geometry is transformed into a more complex one, whereby the tools 'store' the desired geometry and impart pressure on the deforming material through the tool/material interface. Metal forming processes usually produce little or no scrap and generate the final part geometry in a very short time, usually in one or a few strokes of a press or hammer. They are generally considered to offer the greatest savings in both energy and material. Additionally, for a given weight, parts produced by metal forming exhibit better mechanical and metallurgical properties and reliability than do those manufactured by casting or machining.[6] Generally, metal forming is viewed as having two major subdivisions, the massive forming operations and the sheet metal forming processes. Table 30.1 provides a summary listing of these operations.

30.5.2   Massive forming operations

In 'massive' forming operations, the input material is in billet, rod or slab form, and a large increase in the surface to volume ratio occurs in the formed part. Sheet metal operations do not undergo this

Table 30.1   SUMMARY LISTING OF METAL FORMING OPERATIONS

For much more detailed explanations, with excellent diagrams, refer to the metal forming text by Altan *et al.*,[6] or the manufacturing text by Degarmo *et al.*,[11] or many of the other cited references.

Typical classifications of the forming processes			
Massive forming		*Sheet metal forming*	
Extrusion	*Rolling*	*Bending*	*Deep recessing*
Nonlubricated hot extrusion	Sheet rolling	Brake bending	Spinning
Lubricated direct hot extrusion	Shape rolling	Roll bending	Roller flanging
Hydrostatic extrusion	Tube rolling		Deep drawing
	Ring rolling	*Contouring sheets*	Rubber pad forming
Forging	Rotary tube piercing	Stretch forming	Marform process
Coining	Gear rolling	Androforming	Rubber diaphragm
Closed die with flash	Roll forging	Age forming	hydroforming
Closed die w/o flash	Cross rolling	Creep forming	Superplastic forming
Forward extrusion forging	Surface rolling	Die-quench forming	
Backward extrusion forging	Shear forming	Vacuum forming	*Shallow recessing*
Hobbing	Tube reducing	Bulging	Dimpling
Nosing		Superplastic forming	Electromagnetic forming
Isothermal forging	*Drawing*		Explosive forming
Electro upsetting	Drawing		Joggling
Open-die forging	Drawing with rolls		
Orbital forging	Ironing		
P/M forging	Tube sinking		
Radial forging			
Upsetting			
Swaging			

large, massive change in surface to volume ratio. Processes which fall under the massive forming processes have the following features:

- The workpiece undergoes large plastic deformation, resulting in a marked change in shape and/or cross section.
- The portion of workpiece that undergoes permanent deformation is much larger in general than the portion undergoing elastic deformation. Elastic recovery after deformation is essentially negligible.

Examples of massive forming processes are extrusion, forging, rolling and drawing.

30.5.2.1   *Extrusion*

In the extrusion process, metal is compressed and forced to flow through a suitably shaped die to form a product with reduced but constant cross section. It may be performed either hot or cold, although hot extrusion is commonly employed to reduce the forces required, eliminate cold-working effects and reduce directional properties. Basically, the extrusion process is like squeezing toothpaste out of a tube. Extrusion types include nonlubricated hot extrusion, lubricated direct hot extrusion and hydrostatic extrusion.[46,47]

30.5.2.2   *Forging*

Forging is the term applied to a family of processes where the deformation is induced by local compressive forces. It is generally regarded as the oldest metal working process (e.g. the village blacksmith). The equipment can be manual or power hammers, presses, or special forging machines. While the deformation can be done in the hot, cold, warm or isothermal mode, the term *forging* usually implies hot forging done above the recrystallisation temperature. A metal may be *drawn out* to increase its length while decreasing its cross section, *upset* to decrease the length and increase the cross section, or *squeezed* in closed impression dies to produce multidirectional flow. Common forging processes include closed die forging with flash, closed die forging without flash, coining,

electro-upsetting, forward extrusion forging, backward extrusion forging, hobbing, isothermal forging, nosing, open die forging, orbital forging, powder metal (P/M) forging, radial forging, upsetting and swaging.[6,47–49]

30.5.2.3 *Rolling*

Rolling is often the first process that is used to convert material into a finished product. Fundamentally, in the basic rolling process, the material being rolled is passed between two rollers rolling in opposite directions. It may be done hot or cold, although most materials undergo both processes during their life cycle. During hot-rolling, thick starting stock can be rolled into blooms, billets, or slabs. The initial shape may be obtained directly from a continuous casting process as input to the rolling process. A bloom has a square or rectangular cross section, with a thickness greater than six inches ($\sim$152 mm) and a width no greater than twice that thickness. A billet is usually smaller than a bloom with a square or circular cross section. A slab is a rectangular solid where the width is greater than twice the thickness. Slabs are typically further rolled to produce plate, sheet and strip. It is at this point that cold rolling becomes practical with the reduced dimensions of the plates, sheets and strips. Types of cold and hot rolling include sheet rolling, shape rolling, tube rolling, ring rolling, rotary tube piercing, gear rolling, roll forging, cross rolling, surface rolling, shear forming (or flow turning) and tube reducing.[8,10,11,50–52]

30.5.2.4 *Drawing*

Drawing is a plastic deformation process in which a flat sheet or plate is formed into a recessed, three-dimensional part with a depth more than several times the thickness of the metal. As a punch descends into a mating die (or the die moves upward over a mating punch), the metal assumes the desired configuration. Hot drawing is used to form relatively thick walled parts of simple geometries, usually cylindrical, with considerable thinning of the material as it passes through the dies. In contrast, cold working uses relatively thin metal, changes the thickness very little or not at all, and produces a wide variety of shapes. Generally, drawing is classified as drawing, drawing with rolls, ironing and tube sinking.[8,47,51]

30.5.3 Sheet-metal forming operations

In sheet forming operations, a relatively thin sheet blank is plastically deformed into a three dimensional object without any significant changes in sheet thickness and surface characteristics. Characteristics of sheet-metal forming include:

- Workpiece is a sheet or a part fabricated from a sheet.
- Deformation usually causes significant changes in shape, but not cross section, of the sheet.
- The magnitudes of plastic and recoverable elastic deformations are comparable. Springback, during elastic recovery, may be very significant as a control issue in the manufacturing process.

Examples of processes, which fall under the category of sheet forming processes, include bending and straight flanging, surface contouring of a sheet, linear contouring, deep recessing and flanging, and shallow recessing. The large number of techniques within these categories includes: bulging, joggling, dimpling, marforming, vacuum forming, and many other processes.[6,10,47,53–58]

30.5.4 Superplasticity

Some alloys, under proper conditions, can undergo extraordinary tensile deformation (up to 300%) without fracturing. This has led to a specialised form of sheet metal forming referred to as 'superplastic forming' which is normally combined with some type of diffusion bonding process to form complex aircraft frames and shapes for example. A range of materials can exhibit superplasticity including some aluminium, titanium and nickel alloys, certain steels and even a few ceramics.[59–67]

Table 30.1 provides a summary listing of the many metal-forming processes. For the most complete description, refer to the references cited in the paragraphs above.

30.6   Machinability and formability of materials

Machinability and formability have nearly as many meanings as there are processes and materials.[47,68–86] Malleability, workability, and formability all refer to a material's suitability for plastic deformation processing. Each material's formability must be evaluated for specific combinations of material, process and process parameters. Machinability generally refers to the ease with which a material can be machined to an acceptable surface finish.

30.6.1   Definitions

The three principal definitions of machinability are entirely different from each other.

30.6.1.1   *Machinability as a material property*

Machinability can be defined as the ease with which the material is machined in terms of specific energy, specific horsepower, or shear stress. In general, the larger the shear stress or specific power values, the more difficult the material is to machine and form, requiring greater forces and lower speeds. In this definition, the material is the key.[11]

30.6.1.2   *Machinability as a factor in tool life*

An important economic measure of a materials machinability is defined by the relative cutting speed for a given tool life of the tool cutting some material, compared to a standard material cut with the same tool material. Thus tool-life curves may be used to express the machinability ratings. For example, the steel industry has established the B1112 steel as the comparative standard, using an expected tool life of 60 minutes at a cutting speed of 100 sfpm ($\sim$0.15 m^2 s^{-1}). Thus, if another steel X has a rating of 70% of B1112, you adjust the cutting speed to 70% to achieve a 1-hour tool life. Each metal association (e.g. the Copper Metal Working Association) defines these comparative ratings for the various alloys for which they have authority as the standard setter.

30.6.1.3   *Machinability in terms of the cutting speed*

Machinability may be defined in terms of the maximum speed at which a tool can provide satisfactory performance for a specified time under specified conditions in specified machines (e.g. ASTM Standard E-618-81: 'Evaluating machining performance of ferrous metals using an automatic screw/bar machine').

30.6.1.4   *Other factors, criteria, tests and indices*

Other factors that are sometimes used to characterise machinability include tool wear rates, chip form, achievable surface finish, achievable tolerance, functional or surface integrity, cutting temperature, and mechanical properties (e.g. hardness) of the material being machined.

30.6.2   Formability

The Metals Handbook[19] defines formability as the relative ease with which a metal can be shaped through plastic deformation, and uses it as a synonym for workability of the material. This simplistic definition opens the door to the entire library of plastic deformation theories, none of which are perfect, when applied to forming operations (e.g. Chow[87]). Many represent the best compromise, based on needs of the end user who is forming the material.[77–87] Over the years, many formal tests, specified by ASTM, ISO, Euronorm *et al.*, have been developed which a manufacturer may be required to provide documentation for in the engineering specifications (e.g. [88, 89]). The most common tests usually develop some type of flow curve (tensile, compression etc), although impact tests, fracture tests, fatigue tests, hardness and corrosion testing are also frequently required. One of the most widely specified tests is the uniaxial compression test, or upset test. In the test, a right

cylindrical specimen is compressed between flat, parallel dies. From this, flow stress values are derived for use in diagramming flow curves.[83]

30.7   Coolants and lubricants (see also Chapter 24)

A significant fraction of metal cutting and forming operations are performed wet, using what the United States National Institute of Occupational Safety and Health classifies as Metal Working Fluids (MWFs). Closely allied with the definitions of machinability and formability, their use permits the use of increased speeds and feed rates, while reducing wear and friction. In machining, the fluid is often critical in the removal of the formed chips. The application of coolants and lubricants represent a significant portion of the part manufacturing cost, and an increasing cost of the health insurance costs in the manufacturing sector. Cutting fluids may be applied in a liquid, gaseous or mixed liquid-gaseous form.[90–93] There are significant occupational risks associated with each type, requiring an informed trade-off in benefit versus risk.

30.7.1   Liquid metal working fluids

Cutting liquid fluids are classified into four types: oil based, soluble oils, semi-synthetics, and synthetics. The last three are generally referred to as water-based coolants. Water-based coolants provide the best cooling action, while oil based fluids provide the best lubrication effects. Many of the hydrocarbon based metal working fluids have been proven to be a Type B carcinogen, whereas there is a growing awareness of the biological hazards associated with the water-based metal working fluids. Most types have been shown to be a cause of dermatitis.

30.7.1.1   *Oil based fluids*

Oil based fluids include straight mineral oils as well as fatty oils and compound oils. They reduce friction in the cutting zone and are generally most effective in grinding, where they are best able to improve the surface finish.[94] NIOSH has recommended airborne limits for their usage,[17] based on dermatitis and thoracic cancer concerns.

30.7.1.2   *Soluble or emulsifiable oils*

These are special types of mineral oils diluted in water at a typical concentration of 20:1, with emulsifying agents added to form stable dispersions. They are generally regarded as superior to oil based metal working fluids at higher cutting speeds because of the added cooling effect of water. However, the additives, particularly those with chlorinated paraffin additives and carboxylates, increase the risks identified by NIOSH.[17,95]

30.7.1.3   *Semi-synthetics*

These are surface-active water based cutting fluids that consist of fine colloidal dispersions of organic and inorganic materials (oil and chemicals) in water. In addition to the biological concerns of NIOSH, these cutting fluids frequently leave a residue on the machined surface and foam excessively.[96] Disposal of the waste material is carefully regulated because of the use of chemical additives.

30.7.1.4   *Synthetic cutting fluids*

These are water-based fluids consisting of chemical lubricating agents, wetting additives, disinfectants and stabilisers. They are oil free, but contain alkanolamines and organic esters, for which NIOSH has identified exposure levels.[96] They are excellent coolants because of the large percentage of water, which encourages biologic growth, requiring additives to limit such growth. Their disadvantages include reduced lubricity due to the absence of petroleum products, a tendency to leave hard crystalline deposits, high alkalinity, a tendency to foam, and disposal problems.[12]

30.7.2   Gaseous fluids and gaseous-liquid mixtures

Types of gaseous fluids include air, Freon, helium, and nitrogen, with air being the most common. High-pressure air can be used to eject chips if proper machine guarding techniques are used. Noise generation is a significant concern with high velocity and/or pressure air systems, frequently exceeding the permissible noise exposure levels.[12]

30.8   Non-traditional machining techniques

Most of the technology discussed in this chapter existed prior to the end of World War II, although it continues to dominate the manufacturing world at the start of the 21st century. These techniques remain the most cost effective way to produce most manufactured goods. However, with the drive towards electronics and miniaturisation, new technologies have emerged which are 'non-traditional' in the sense that they have not been 'on-the-scene' as long as the other processes. The six processes to alter material in non-traditional machining are electricity, water, new abrasives, chemicals, ionised gas, and light.

30.8.1   Electrical Discharge Machining (EDM)

Wire EDM uses a travelling wire electrode that physically passes through the workpiece. The wire is monitored precisely by a CNC system. Like any other machining tool, wire EDM removes metal; but wire EDM removes metal with electricity by means of spark erosion. Rapid DC electrical pulses are generated between the wire electrode and the workpiece, using a dielectric shield between the two of deionised pure water. When sufficient voltage is applied, the fluid ionises and a controlled spark erodes a small section of the workpiece, causing it to melt and vaporise. High air turnover rates in the workspace are required to prevent accumulation of metal fumes, with periodic monitoring by a certified industrial hygienist.[97,98] Extremely complicated shapes can be cut economically, automatically, and precisely, even in materials as hard as carbide. A specialised type of EDM referred to as ram EDM machining (or sometimes as sinker EDM, die sinker, vertical EDM and plunge EDM) may be employed to produce blind cavities in materials.[99]

30.8.2   Fast Hole EDM drilling

Although it is possible to drill holes with conventional EDM machines such as described in the preceding paragraph, highly specialised EDM machines have been developed that are capable of drilling holes at speeds up to two inches per minute ($\sim$850 μm s^{-1}). Basically, a servo system maintains a gap between the tip of the electrode and the workpiece. If the electrode touches the workpiece, a short occurs and the servo resets the gap. This 'Fast Hole' EDM drilling technique is used for putting holes in turbine blades, fuel injectors, cutting tool coolant channels, hardened punch ejector holes, plastic mould vent holes, wire EDM starter holes, and other complex operations that require very exact hole placement and sizing.[99]

30.8.3   Waterjet and abrasive waterjet machining

Manufacturers are increasingly turning to waterjet and abrasive waterjet machining in their quest for productivity and quality. Extremely powerful abrasive waterjets are capable of cutting through 3-inch ($\sim$76 mm) tool steel at a rate of 2 inches per minute ($\sim$850 μm s^{-1}), 10-inch ($\sim$254 mm) reinforced concrete at more than 1 inch per minute, and 1-inch ($\sim$25 mm) plate glass at 2 feet per minute ($\sim$10 mm s^{-1}). Pure water, or water mixed with an abrasive is supplied at high pressure through a sapphire, ruby or diamond orifice cutting head which periodically requires replacement. Some ceramics have been developed which are capable of acting as cutting heads.[99–101] When manufacturers order metal stock, there is a high probability that it was resized for delivery using waterjet technology.

30.8.4   Plasma cutting

Plasma cutting systems use a highly conductive gas to cut electrically conductive materials. The interior of a plasma-cutting torch normally consists of a consumable nozzle, an electrode, and either gas or water to provide cooling. Electric arcs are generated inside the nozzle, which ionises the

coolant and produces an electrically conductive plasma arc. A pressurised gas flowing through the nozzle creates a pilot arc. As the heated plasma arc strikes the workpiece, the arc vaporises the metal. The flowing gas forces out the molten metal and pierces the workpiece. After piercing, the motion machine begins to advance the torch in the pre-programmed directions for the cut.[99]

30.8.5 Photochemical machining

Photochemical machining (PCM), which is also known as photoetching, photolithography, and photochemical milling, is a process that etches out parts by means of chemicals. Protected areas are masked, and chemicals are then used to dissolve the unmasked areas. Parts are typically designed in a computer-aided design (CAD) system, and then projected with a precision camera system onto the work surface. The metal, which has been coated with a photosensitive material, is then chemically processed using a corrosive solution. Where the photo resistant material has been exposed, the metal is etched away. It can produce elaborate, stress free parts, eliminates hard tooling and provides rapid turn-around (just in time ordering). It always leaves a bevelled edge though, and is therefore not suitable for processes that require straight, cornered lines.[102]

30.8.6 Electrochemical machining

Electrochemical machining (ECM) is one of the least used non-traditional methods despite a high, stress free metal removal rate because it requires a high level of craftsmanship in allowing for the flow effects of the electrolyte. The process is used for various automotive and aircraft components, gun barrel rifling, steam turbine casings, and for deburring. With electrochemical machining, a pressurised conductive salt solution, the electrolyte, flows around the workpiece as an electrical–chemical reaction de-plates material from the workpiece. It is the opposite of the classic plating process. When plating, metal is applied with the use of electrical current. ECM removes metal with electric current. Since it is done chemically, material hardness and toughness have no effect.[103–106]

30.8.7 Ultrasonic machining

Ultrasonic machining is a highly specialised process used to machine detailed and complex parts, especially in graphite materials. The process can also be used for polishing and machining glass, carbide and ceramics. A metal forming tool, the 'sonotrode' is fabricated to the desired pattern. Then the sonotrode is mounted in a recessed opening in the ultrasonic machine and the target is lowered from above into the recessed sonotrode, with an abrasive slurry mixture being injected between them. The sonotrode vibrates at speeds in excess of 20 000 cycles per second (20 kHz), causing the abrasive particles to erode the target and produce a mirror image of the form tool. Very delicate details are possible for objects (such as coinage dies) that may be sized to these configurations.[107,108]

30.8.8 Lasers

Lasers are everywhere in modern society, from the checkout stand to the manufacturing floor. With rapid advances in laser technology (and falling prices), laser cutting is becoming the first choice for many manufacturers. Typical cutting speeds range from 1 to 1 000 inches per minute ($\sim$400 μm s^{-1} to $\sim$400 mm s^{-1}). They have high accuracy, speed and minimum workpiece distortion. They can economically produce round holes, square cut-outs, radii, tapers, and undercuts to any imaginable shape, without expensive tooling costs as with turret or power presses. Generally, a desired shape is programmed on a CAD system, post-processed with a computer-aided manufacturing (CAM) system, which converts it into a CNC language, and downloaded into the cutting laser machine. The laser physically vaporises the material which is carried away by a combination purge and exhaust system. Although tooling and lubricants/coolants are eliminated, control of potentially dangerous fumes is an ever-present concern with these systems. In addition to the fumes from the material being cut, which may vary widely, lasers are a high voltage threat and pose a threat to human eyes. With increasing strength and efficiency, lasers will continue to increase their use in manufacturing, requiring more operator training to avoid exposure.[109–113]

30.8.8.1 *Lasers in rapid prototyping and freeforming*

Lasers are being used more and more frequently to develop rapid prototypes, which can then be analyzed quickly for potential design/failure problems. In stereolithography, laser equipment translates

CAD designs into solid objects through a combination of laser, photochemistry and software technologies. A computer-driven laser solidifies a vat of liquid resin, layer by layer, into a three-dimensional epoxy prototype part. In another method, a selective laser sintering station [SLS] uses a plastic powder to create prototype parts. The powder is melted, layer-by-layer, by a computer-directed heat laser. Additional powder is deposited on top of each solidified layer and again sintered. SLS allows for great diversity in material selection, including nylon, glass filled nylon, SOMOS [a rubber like compound] and Trueform [used in investment casting]. One company has invented a technique, laminated object manufacturing, which builds parts by laminating and laser trimming the material delivered in sheet form. Each layer arrives, is glued in place, then trimmed by the laser. The workpiece moves down away from the laser and work surface just before delivery of the next layer, permitting a rapid build-up of the desired part from an initial CAD drawing. These techniques are frequently referred to as formless manufacture, since the parts do not use traditional machining or mould fabrication techniques.[110,114–126]

30.9   Occupational safety issues

In the area of metalworking, which includes both metal cutting and forming, three major occupational safety concerns exist. These include machine guarding, workers exposure to hazardous materials, and excessive exposure to noise level. Safety requirements are frequently a hidden cost in operations.

30.9.1   Machine guarding

Rotating machinery operating at high voltage may represent a significant crushing, nipping or shock hazard to personnel. Most countries have established occupational safety standards detailing minimum protection requirements, which include machine guards, eye protection and operating procedures.[127–131]

30.9.2   Hazardous materials

Workers are generally entitled by law to know the physical dangers of the materials around which they work.[132–142] Professionals should consider these life cycle costs in their selection of manufacturing processes.

30.9.3   Noise exposure

A general rule of thumb amongst occupational safety professionals is that 'if you must raise your voice to be heard, you are probably in a high noise area' (>85 db in the United States). There are strict medical protocols and legally required programs, depending upon the measured level and local government which should be reviewed for their applicability.[143,144]

30.9.4   Ergonomics

There are many complex ergonomic issues, including tool hand vibration, whole body vibration, lifting of loads, tool positioning and others, which the engineer selecting a major manufacturing tool or system must consider.[145–159] Relatively simple and inexpensive ideas, incorporated during the tool selection process, may provide a large, long-term return on investment.

The many occupational safety issues mentioned in this chapter and above would fill the professional's library very quickly. One of the less expensive, smallest (back pocket), yet most comprehensive references is a spiral bound book produced by the American Conference of Governmental Industrial Hygienists.[160] The title is somewhat misleading, since it addresses nearly every occupational issue of interest to the modern managing engineer.

31 Corrosion

31.1 Introduction

It is generally accepted that ten unique types of corrosion exist. Unfortunately, identification of a specific type of corrosion mechanism often occurs only in forensic analysis after a component fails. Design considerations must account for corrosion through the use of corrosion resistant materials, or by increasing the bulk of a material with a known corrosion characteristic to account for loss during its service life. Actuarial science and economics govern this choice in the design phase, but corrosion failures often arise in service operations not anticipated in the design phase. There are numerous remedies in existence to counteract specific corrosion mechanisms and increase the service life of specific components. The goal of this chapter is to summarise each of the individual corrosion mechanisms and describe tests to identify a material's susceptibility to a specific corrosion mechanism.

31.2 Types of corrosion

Corrosion mechanisms can be divided into two categories: (1) general or uniform corrosion and (2) non-uniform or localised forms of corrosion. Though uniform corrosion accounts for the majority of metal consumed (raw tonnage), localised corrosion is much more insidious because it is difficult to detect and its rates are often larger by several orders of magnitude. Due to these accelerated rates, breach of the material and subsequent failure are rapid and most often only detected by post-mortem failure analysis.

31.3 Uniform corrosion

Uniform corrosion is recognised universally as the most prevalent of all forms of corrosion, but the least damaging in terms of number of failures. Like all forms of corrosion, uniform corrosion is the result of electrochemical reactions occurring at the surface of a metal. Uniform corrosion prevails when there are no preferential sites on the surface that are more favoured for attack than others: thus all sites are equivalent and uniform dissolution takes place. Atmospheric corrosion is probably the most visible form of uniform corrosion.

There are two aspects of uniform corrosion that need to be considered more carefully, *corrosion susceptibility* and *corrosion rate*. Corrosion susceptibility is the tendency of a particular material to corrode and is a function of thermodynamics, specifically the potential energy that is required to oxidise and reduce species present in a corrosion cell. The most quoted example used to demonstrate corrosion is rust formation on iron metal. Rust, the orange-red coloured powder found commonly at the surface of iron, is the hydrated complex $Fe_2O_3 \cdot H_2O$. It is formed by the anodic oxidation of iron, $Fe\,(s) = Fe^{+2}\,(aq) + 2e^-$, and the cathodic reduction of oxygen, $O_2(g) + 4H^+\,(aq) + 4e^- = 2H_2O$ (l). The standard potential versus a normal hydrogen electrode (NHE) for the oxidation of Fe is $-0.44\,V$. The potential for the reduction of O_2 is $1.229\,V$ vs. NHE. The corrosion cell thus possesses a potential of $1.669\,V$ vs. NHE. Since V > 0, the overall process will proceed. The susceptibility of a material determines if it will corrode, while the second parameter, corrosion rate, determines how much a material will corrode in a given time interval.

The *corrosion rate* is the single most important measure for a corrosion engineer, especially for uniformly corroding systems. In these systems, the corrosion rate is measured primarily by

monitoring mass loss or by using electrochemical techniques. Relevant ASTM test standards include:

- G 1–90 Standard Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens
- G 31–72 Standard Practice for Laboratory Immersion Corrosion Testing of Metals
- G 50–76 Standard Practice for Conducting Atmospheric Corrosion Tests on Metals

The mass loss corrosion rate is calculated as follows:

$$\text{Corrosion Rate} = (K \times W)/(A \times T \times \rho)$$

where K is a constant, 8.76×10^4 (in mm/year), W is the mass lost in grams, A is the specimen area in cm^2, T is the time of exposure in hours, and ρ is the density of the material in grams per cm^3. Mass loss measurements have the advantage of high accuracy, as long as the specimen and exposure medium are truly representative of the service conditions. A disadvantage is that the time required to determine a significant mass loss is usually quite long. Electrochemical methods overcome the problem of excessive test periods.

Electrochemical techniques are preferred to mass loss determinations because they (1) are accomplished in shorter periods, (2) measure corrosion rates in real-time, and (3) provide more information about the corrosion rate—time relationship. There are several electrochemical tests that can be performed to provide information about corrosion processes. In addition to the test specimen and electrolyte solution, all electrochemical tests require a potentiostat/galvanostat, a test flask, a calibrated reference electrode, and suitable counter electrodes. These techniques range from potentiostatic and potentiodynamic measurements to more complex impedance measurements. There are disadvantages in using electrochemical techniques, however, electrochemical techniques thermodynamically destabilise a test environment in order to measure a response. This destabilisation, or perturbation from the equilibrium condition, may drive a system to extremes that are not truly representative of the service environment. Therefore, it is important to reasonably modify standard test procedures to more accurately reflect actual service conditions. ASTM standard test procedures for electrochemical techniques include:

- G 5–94 Standard Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarisation Measurements
- G 59–97 Standard Test Method for Conducting Potentiodynamic Polarisation Resistance Measurements
- G 102–89 Standard Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements

31.3.1   Galvanic corrosion

A galvanic cell is formed when two dissimilar metals are electrically connected while both are immersed in an electrolyte solution. The less noble of the two materials will corrode preferentially with respect to the other. In order to predict galvanic activity, it is useful to consider where each metal lies, relative to the other, in a galvanic series. A galvanic series provides rest potentials of various metals in a specific environment. Figure 31.1 displays a generic galvanic series of metals and alloys in order from the most active to the least active (most noble). While it is tempting to believe that greater relative separation among metals within the galvanic series will yield more aggressive corrosion, in reality this must be more carefully addressed by considering the coupling within mixed potential theory.

Mixed potential theory is best demonstrated by an example Evans Diagram of two metals. Figure 31.2 shows a galvanic couple between an active metal, M, and a more noble metal, N, in a dilute corrosion solution. According to mixed potential theory, the coupled potential, E_{couple}, is determined at the point where the sum anodic current (total oxidation) is equivalent to the sum cathodic current (total reduction). In the case where N is truly inert, e.g. platinum, only the active side of the couple need be considered. At E_{couple} the anodic dissolution rate for M, the anode in the couple, increases from $I_{corr,M}$ to $I_{couple,M}$, and that for N, the cathode decreases from $I_{corr,N}$ to $I_{couple,N}$.

Electrochemical analysis is frequently chosen as a method to measure galvanic corrosion processes. One of the simplest methods employs a zero-resistance ammeter (ZRA) connected in series with an external wire attached to each of the dissimilar metals. The ZRA is a sensitive instrument that allows direct measurement of current flowing between the two materials. Additionally, galvanic series determinations can be used in materials selection to weed out materials with a propensity for galvanic corrosion. These are implemented by individually placing the materials of interest into a simulated service environment and monitoring their electrochemical potential over time. The material with the more electronegative potential will become the anode and experience accelerated degradation when
Figure 31.1   *Galvanic series of select pure metals and alloys in seawater*

placed in a galvanic couple. Galvanic corrosion can also be examined by overlaying polarisation curves for each metal. ASTM test standards for assessing galvanic corrosion include the following:

- G 71–81 Standard Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes
- G 149–97 Standard Practice for Conducting the Washer Test for Atmospheric Galvanic Corrosion

31.3.2   Erosion, cavitation, and fretting corrosion

The common link between erosion, cavitation, and fretting attack is that each is potentially damaging to the surface films that protect materials. Erosion originates from either solid particles or liquid droplets impinging on the surface of a material. The amount of damage depends upon the impingement angle, the velocity of the particle or droplet, the size of the particle or droplet, and the type of material being affected. Solid particles impacting ductile materials at low impingement angles produce greater damage than more normal angles. The opposite is true for brittle materials. In ductile materials, solid particles impinge on the surface and create a crater. In brittle materials, the energy of the impacting particle is focused and creates a microcrack. Loss of material occurs when these cracks coalesce and material chips away. Erosion-corrosion tests are quite simplistic and generally involve directing a jet of gas-entrained particles or liquid at the surface of a material and monitoring the weight loss over some time interval.

Cavitation is a phenomenon closely connected with fluid dynamics and the formation and collapse of gas bubbles near the surfaces of materials. One of the most common examples is the cavitation
Figure 31.2   *Evans diagram of generic mixed potential galvanic couple between active material* M *and less active metal* N

of ship propellers. The collapse of the bubble near the propeller tip is sufficiently rapid and violent that it physically shocks the material surface and results in pitting. Cavitation results from highly localised pressure discontinuities that lead to a massive instability in the bubble interface. In cavitation corrosion tests, a specimen coupon is vibrated while immersed in a liquid to induce cavities at its surface, then the weight loss is monitored as a function of both velocity and exposure time.

Fretting corrosion is a tribological effect of two surfaces in contact and in relative motion to one another. There are a number of factors that control fretting: the number of cycles, the load normal to each surface, the amplitude of translational motion, the frequency of motion, and the temperature of the system. Fretting corrosion tests involve bringing two surfaces in contact under a known load and contact geometry, moving one surface relative to the other under an oscillation with small amplitude. The weight loss is measured as a function of time. ASTM test standards that apply to cavitation and erosion include the following:

- G 32–03 Standard Test Method for Cavitation Erosion Using Vibratory Apparatus
- G 134–95 Standard Test Method for Erosion of Solid Materials by a Cavitation Liquid Jet

31.4   Localised forms of corrosion

Localised corrosion refers to any type of material dissolution that is heterogeneous, i.e. there are preferential sites with accelerated degradation relative to surrounding areas. Localised forms of corrosion are commonly much more aggressive than uniform corrosion, because the dissolution flux is concentrated in a much smaller area. Many distinct individual mechanisms of localised corrosion have been identified. In contrast with uniform corrosion, localised corrosion is more probabilistic, more aggressive, and less predictable.

31.4.1   Crevice corrosion

The term crevice corrosion refers to enhanced dissolution in discrete areas of a material that are physically occluded, or shadowed. The mechanism that drives this enhanced dissolution is inhibition of electrolyte diffusion by a lack of linear transport paths, usually resulting from the presence of a physical barrier such as a crevice. This situation is often associated with deposits on a surface

and at fabricated joints. The crevice corrosion mechanism is broken down into four stages: (1) deoxygenation, (2) increasing localised concentration of acids and salts, (3) depassivation, and (4) propagation of the crevice.

Crevice corrosion is a direct result of impeded mass transport at an occluded site on a material surface. Convection between the solution trapped within the occluded area and the bulk medium is slow, so the dissolved oxygen in the occluded region is rapidly consumed. A local galvanic cell evolves from the differential between the less oxygenated crevice region (anode) and the surrounding bulk oxygenated surface (cathode). This differential aeration cell may also serve to attract aggressive anions such as Cl^-.

A relatively simple test for crevice corrosion involves the use of a crevice former, such as trifluoroethylene (TFE) blocks, held tightly against the surface of the material of interest. The test specimen is immersed in a ferric chloride ($FeCl_3$) solution for 72 hours. After the test period, the area beneath the TFE blocks is examined for indications of crevice corrosion. Another method relies upon the determination of critical temperatures to rank alloys. The most common method for this is electrochemical critical temperature (ECT) testing. In ECT tests for crevice corrosion specimens are typically rectangular coupons with a hole machined in their center. A threaded support runs through the hole and crevice formers—Delrin round nuts with machined flat steps—are fastened tightly to each face of the specimen. With the proper combination of heat and applied potential, localised corrosion will initiate and result in a rapid increase of measured current density at the specimen. The temperature at which this takes place is referred to as the electrochemical critical crevice corrosion temperature (ECCT).

Table 31.1 provides a listing of degrees of crevice corrosion resistance of some common materials. ASTM test standard relating to crevice corrosion include the following:

- G 48–00 Standard Test Methods for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by Use of Ferric Chloride Solution
- G 78–01 Standard Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments.

31.4.2 Dealloying corrosion

Dealloying is the selective dissolution of one or more components of a solid solution alloy. Dealloying is known to occur in a wide range of conditions and is characterised by the formation of a

Table 31.1   RESISTANCE TO CREVICE CORROSION

Metal	Very resistant $\longrightarrow$	Moderate corrosion $\longrightarrow$			Severe corrosion

Fe–Cr Alloys	High temperature oxidising conditions	Cr
Ni–Mo Alloys	High temperature oxygen	Mo

porous microstructure resembling a sponge. It is common to observe a high degree of interconnectivity between these pores with islands of the more noble metals remaining intact. Often alloys that undergo dealloying are also susceptible to stress corrosion cracking (SCC). The porous microstructure that forms during dealloying often localises at pre-existing crack tips, which when subjected to a stress, promotes ductile fracture within the corroded region and may propagate into the unaffected surrounding material. There are a number of mechanistic models for dealloying corrosion. They are the bulk diffusion model, the vacancy diffusion model, the surface diffusion model, the dissolution and reprecipitation model, the oxide formation model, and the percolation model. On the basis of measured corrosion rates, the surface diffusion model seems the most plausible.

The most common example of dealloying corrosion is the dezincification of brass. Selective dissolution of zinc in brass (Cu–Zn alloys) occurs in extended exposures to chloride containing solutions. The $\alpha + \beta$ two-phase alloys are most susceptible with significant attack occurring in the zinc concentrated β phase. Dezincification results in a porous, highly weakened layer of copper and a copper oxide corrosion product. At room temperature dezincification occurs in slightly acidic water or acid chlorides and is more uniform throughout the β phase. The effect at higher temperatures is more locally pronounced with very high penetration rates. Dezincification can be prevented by controlling the purity of process streams, by limiting the amount of zinc, or by substituting it with more corrosion resistant components. Table 31.2 lists some environments leading to dealloying corrosion.

31.4.3   Environmental cracking—stress corrosion cracking and corrosion fatigue cracking

Environmental cracking is a general term that is utilised to describe localised corrosion mechanisms that couple the simultaneous actions of mechanical stress (typically static and tensile) and a chemically reactive environment. Isolated, each of these actions is of little consequence to a material, but in their combined form they often lead to unpredictable catastrophic failures. Three distinct subset mechanisms of environmental cracking are stress corrosion cracking (SCC), corrosion fatigue cracking (CFC), and hydrogen induced cracking (HIC). HIC will be highlighted within its own section (31.4.4)

SCC is the brittle failure of a material in a corrosive environment at relatively low tensile stress. Four conditions need to be present to activate SCC. These include a corrosive environment, a susceptible material, the electrochemical state of a system relative to its surroundings, and a tensile stress. Pure metals are more resistant, but they are not immune. SCC can occur in either transgranular or intergranular fashion, with the crack following a path normal to the tensile stress. In transgranular failure, the cracks usually propagate through grains with a particular crystallographic misorientation, whereas in intergranular corrosion cracks simply follow grain boundaries with no regard to misorientation.

Alloy chemistry has a considerable effect on SCC, particularly with respect to passivity and metallurgical condition. From an electrochemical perspective, the chemical composition and microstructural condition are very important in determining its stability. Heterogeneities associated with microstructure and second phases with varying susceptibility to cracking can produce very different electrochemical properties. In addition to the metallurgical parameters related to electrochemical character, both grain size and yield strength can strongly affect SCC behaviour.

The physical, chemical, and mechanical characteristics of the service environment all affect SCC. Physical characteristics such as temperature and nuclear irradiation can affect the susceptibility and magnitude of SCC. A given alloy system is usually sensitive to SCC in very specific chemical

environments—these range from supercritical sulphuric acid (in the case of the hydrogen-producing sulphur-iodide thermochemical cycle), via natural marine seawater, to steam. Mechanical stress is the major variable that separates SCC from other localised forms of corrosion. A tensile stress is required for SCC to occur.

It is generally accepted that SCC occurs via three stages: initiation, growth, and failure. The time duration of each of these stages is dependent on the fracture toughness of the material, the geometry and surface condition of the specimen, and the loading condition. ASTM standards related to characterisation and measurement of SCC include the following:

- B 858–01 Standard Test Method for Ammonia Vapour Test for Determining Susceptibility to Stress Corrosion Cracking in Copper Alloys
- G 30–97 Standard Practice for Making and Using U-Bend Stress-Corrosion Test Specimens
- G 38–01 Standard Practice for Making and Using C-Ring Stress-Corrosion Test Specimens
- G 123–00 Standard Test Method for Evaluating Stress-Corrosion Cracking of Stainless Alloys with Different Nickel Content in Boiling Acidified Sodium Chloride Solution
- G 168–00 Standard Practice for Making and Using Precracked Double Beam Stress Corrosion Specimens

Corrosion fatigue cracking (CFC) is a cumulative effect arising from load cycling in an aggressive environment. It originates from the interaction of irreversible cyclic plastic deformation with localised electrochemical reactions. CFC damage typically accumulates with increasing number of loading cycles (N) and in four stages: (1) cyclic plastic deformation; (2) initiation of microcracks; (3) crack growth and coalescence; and (4) macrocrack propagation. Hydrogen typically plays an important role in CFC. Atomic hydrogen adsorbs to crack surfaces as a result of the electrochemical reduction of hydrogen or water, and mass transport carries the hydrogen to the crack tip where it can act to locally embrittle the metal or acidify the environment, leading to enhanced crack propagation.

Passive film rupture is another CFC mechanism. In passive film rupture, a fissure in the protective film is followed by anodic dissolution at the surface initiation site of crack tip. Localised plastic straining arising from mechanical cycling aids passive film rupture. CFC growth in this mechanism depends upon anodic charge passed per load cycle. Other CFC mechanisms have been proposed based upon interactions between dislocations and localised electrochemical environments present at initiation sites and crack tip surfaces.

31.4.4 Hydrogen damage

Hydrogen atoms readily diffuse in metal lattices and can pose a serious threat to mechanical strength and ductility. Hydrogen can be made available to the metal surface from a variety of sources, including the electrochemical reduction of hydrogen or water:

$$2\,H^+ + 2e \;\longrightarrow\; H_2$$

or

$$2\,H_2O + 2e \;\longrightarrow\; H_2 + 2\,OH^-$$
These reactions are often present during corrosion, but may also occur during cleaning procedures and cathodic protection. Hydrogen may also enter the lattice during heat treatment, welding and various post-fabrication processes. Another ready source of hydrogen is steam, as either a by-product of welding, or in a service environment such as piping.

There are many types of mechanical damage and failures associated with the presence of hydrogen in metals. At room temperature, hydrogen in steel may lead to a decrease in ductility (embrittlement), blistering, and cracking that occurs at lower loads than measured in the absence of hydrogen. At higher temperatures, hydrogen is known to decarburise steel by forming methane bubbles that trap and coalesce, exerting significant internal pressure within the lattice.

Testing for hydrogen damage can take on many forms. Methods such as tritium radiography can be employed to determine hydrogen concentrations in a lattice, and mechanical testing can report changes in ductility or greater propensity to cracking. ASTM test standards related to hydrogen embrittlement include the following:

- F 519–97 Standard Test Method for Mechanical Hydrogen Embrittlement Evaluation of Plating Processes and Service Environments
- F 1459–93 Standard Test Method for Determination of the Susceptibility of Metallic Materials to Gaseous Hydrogen Embrittlement

- F 1624–00 Standard Test Method for Measurement of Hydrogen Embrittlement Threshold in Steel by the Incremental Step Loading Technique
- F 2078–01 Standard Terminology Relating to Hydrogen Embrittlement Testing
- G 142–98 Standard Test Method for Determination of Susceptibility of Metals to Embrittlement in Hydrogen Containing Environments at High Pressure, High Temperature, or Both

31.4.5   Intergranular corrosion

Intergranular corrosion (IGC) is strongly associated with the properties and microstructure of a metal. A well-known example of IGC is the sensitisation of austenitic 18Cr—8Ni stainless steels. In the temperature range of 538–927°C, insoluble chromium carbides, $Cr_{23}C_6$, precipitate at the grain boundaries. This precipitate is a product of the reaction between chromium and the carbon diffusing along the grain boundaries. Below 538°C, the carbon remains relatively immobile, and above 927°C the chromium carbides are soluble. Formation of chromium-rich precipitates quickly depletes chromium from a region immediately adjacent to the grain boundary. This reduces the alloy's ability to generate chromium oxide protective films and leads to an increased susceptibility for localised attack in the grain boundary region.

Welding is a common source of localised heating that can sensitise a material. IGC is often observed within the heat affected zone after welding a material susceptible to heat sensitisation. Figure 31.3 illustrates IGC coincident to a weld bead. Note that the sensitisation band occurs on each side of the weld, parallel to its axis of propagation. The displacement and width of the IGC regions is dependent upon the thermal conductivity of the material and the duration that it resides in the critical sensitisation temperature range.

Knifeline attack is a highly localised form of IGC that has been observed in titanium and niobium doped austenitic stainless steels, Types 321 and 327, respectively. The region of attack is typically only a couple of grain diameters from the weld bead. Knifeline attack results from dissolution of titanium or niobium carbides at high temperatures, >1230°C, followed by rapid cooling.

IGC usually requires a strongly oxidising condition. Limiting the use of sensitised materials to weakly corrosive environments will help insure their stability. Likewise it is possible to control oxidation by injecting reducing gases such as H_2, or by operating at lower acidity. Metallurgical techniques are more common for preventing IGC. Typically, those employed are: a) decreasing the level of carbon loading; b) solution annealing; and c) stabilisation using titanium or niobium.
Figure 31.3   *Illustration of IGC region and heat affected zone coincident with a weld*

IGC testing is accomplished by determining the susceptibility of a material to heat sensitisation, then exposing the material to a strongly oxidising environment. Most involve an exposure to sulphuric acid, nitric acid, oxalic acid, or a solution of sulphuric acid and copper sulphate. ASTM standards relating to IGC include the following:

- A 262–02 Standard Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels
- A 763–93 Standard Practices for Detecting Susceptibility to Intergranular Attack in Ferritic Stainless Steels
- G 28–02 Standard Test Methods of Detecting Susceptibility to Intergranular Corrosion in Wrought, Nickel-Rich, Chromium-Bearing Alloys
- G 108–94 Standard Test Methods of Detecting Susceptibility to Intergranular Corrosion in Wrought, Nickel-Rich, Chromium-Bearing Alloys
- G 110–92 Standard Practice for Evaluating Intergranular Corrosion Resistance of Heat Treatable Aluminium Alloys by Immersion in Sodium Chloride + Hydrogen Peroxide Solution

31.4.6 Pitting corrosion

Pitting corrosion is one of the most studied areas of corrosion science. One motivation for studying pitting is its lack of predictability. In general pitting, requires that a material initially be passive in its environment. For pitting to initiate, there must be process that leads to the breakdown of this passivity. Often, this process involves either a structural or chemical heterogeneity in the passive film at the surface of the material or within the solution medium. Following the initial breakdown in passivity, the pit grows, then it potentially repassivates.

There are a variety of valid mechanistic theories that consider the initial breakdown of passivity. In the penetration mechanism, aggressive anions transfer through the passive layer to the metal-oxide interface. The film breaking mechanism relies on ruptures in the passive film. This rupture is caused by sudden changes in the electrode potential that cause excessive stresses in the surface film. The adsorption mechanism starts with the formation of surface complexes that lead to enhance transport between the metal-oxide interface and the electrolyte.

During pit growth, accumulation of corrosion products enhances the precipitation of a salt film. When the salt film forms, the pit growth rate slows down and the pit morphology becomes hemispherical. The general requirement for pit stability is the ability to transport aggressive ions that accumulate about the pit. If the transport of aggressive anions out of pits is efficient then there is a strong probability that the corrosion pit will repassivate. Accumulation of aggressive anions prevents formation of a passive layer at the active pit surface.

Coupon testing can be utilised to quantify pitting corrosion. Typically this involves measured, cleaned, and weighed coupons immersed into the medium of interest. After some determined exposure time, the coupons are removed, examined for surface corrosion, then cleaned and weighed to determine any loss. The major disadvantage in using this method is that the exposure times required to measure an appreciable change are rather long.

Electrochemical techniques offer greater utility because one is able to utilise a solution representative of the service environment and that the testing period is relatively short. The most common electrochemical test is cyclic polarisation. The specimen is anodically polarised from its corrosion potential, E_{corr}, to a potential where the onset of localised corrosion is indicated by a large increase in the measured applied current. The onset point is referred to as the breakdown potential, E_{BD}. The polarisation is then reversed (cathodic direction) to determine the point at which the current returns to background. This point is referred to as the repassivation potential, E_{RP}, the potential where pits repassivate. An analogue to cyclic polarisation is critical pitting temperature determination. Instead of polarising the specimen, the temperature of the system is increased to the point where an increase in current is measured.

Electrochemical noise (ECN) measurements are gaining popularity as a non-destructive, real-time monitoring technique. In electrochemical noise measurements, variations in potential and current transients are recorded for two identical specimen electrodes in a system of interest. Large amplitude peaks in the measured signals are indicators of local activity and corrective action can be taken to insure the stability of the system.

ASTM test standards related to pitting corrosion include the following:

- G 46–94 Standard Guide for Examination and Evaluation of Pitting Corrosion
- G 48–00 Standard Test Methods for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by Use of Ferric Chloride Solution

- G 150–99 Standard Test Methods for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by Use of Ferric Chloride Solution

31.5   Biocorrosion

Biocorrosion, or microbiologically influenced corrosion (MIC), refers to generally corrosion affected by the excretions and activities of microbes in biofilms on metals and alloys. Microbes are capable of altering corrosion processes by changing the chemical environment at a metal surface and thereby influencing electrochemical events occurring there. Microbiologically mediated processes can alter both rates and types of electrochemical reactions and produce a broad range of outcomes, from severe localised corrosion to significant reductions in corrosion rate.[1] Pitting, crevice corrosion, differential aeration cells, metal concentration cells, selective dealloying, accelerated erosion, and enhanced galvanic corrosion can result from biocorrosion. Single-cell organisms such as bacteria, fungi, and yeast have all been shown to influence corrosion processes. Micro organisms are generally ubiquitous and can be attracted to both anodic[2] and cathodic[3] sites making spatial relationships between micro organisms and corrosion products insufficient, on their own, to be interpreted as biocorrosion. Accurate interpretation of biocorrosion generally requires a combination of surface analytical, microbiological, and electrochemical techniques.

Cells attach to wet surfaces and produce a biofilm consisting of a matrix of polymeric substances and a diverse population of cells in microcolonies, as shown schematically in Figure 31.4[4,5]. Biofilm formation consists of a sequence of steps that begin with adsorption of macromolecules (proteins, polysaccharides, and humic acids) and smaller molecules (fatty acids, lipids) at the metal surface. The adsorbed molecules form conditioning films that alter the physical and chemical characteristics of the water-surface interface, including such properties as hydrophobicity and electrical charge. This conditioning of the surface allows for the additional adsorption of microbial cells from the bulk liquid. The adsorbed micro organisms then initiate production of adhesive substances (predominantly exopolysaccharides[6]), collectively known as extracellular polymeric substances (EPS). These substances provide the biopolymer matrix (slime) that holds bacteria together and permits the formation of microcolonies and ultimately a mature biofilm. EPS are also implicated in the increased resistance of biofilm cells to biocides and other antimicrobial compounds.[6]

The most detrimental biocorrosion takes place in the presence of microbial consortia where many species of micro organisms are present within the structure of the biofilm. Participants in biocorrosion include sulphate-reducing bacteria (SRB), metal-oxidising and metal-reducing bacteria,
Figure 31.4   *Possible microbial reactions within a mixed-species biofilm.* (*Courtesy of Dr. Brenda Little, Naval Research Laboratory*)

acid-producing and slime-producing bacteria, hydrogen-consuming and hydrogen-producing bacteria, and metal-depositing bacteria, plus other forms of aerobic and anaerobic micro organisms (see Figure 31.4). Among these types, SRB are the best understood in terms of their role in biocorrosion.[1]

SRB consist of a diverse group of anaerobic bacterial species found in both natural and industrial environments that vary in their ability to accelerate corrosion[7]. In the absence of oxygen, SRB use sulphate as the terminal electron acceptor during respiration and produce hydrogen sulphide. When the respiration rate of aerobic bacteria within a biofilm is greater than the oxygen diffusion rate, the metal/biofilm interface can become anaerobic and provide a niche environment for SRB. The corrosion rate of iron and copper alloys in the presence of hydrogen sulphide is accelerated by the formation of iron sulphide minerals that stimulate the cathodic reaction. Typically, the distribution of the sulphides produced is not uniform and, therefore, leads to localised pitting of the metal surface.

Some microbes utilise a combination of manganese oxidation and reduction reactions to facilitate cell growth and metabolism of organic carbon. Microbial deposition of manganese oxide on stainless and mild steel can significantly alter the corrosion potential (E_{corr}) resulting in an increased corrosion rate.[8–10] Iron-oxidising bacteria produce tubercles of iron oxides and hydroxides creating regions of relatively low oxygen concentration within the tubercle that can induce localised corrosion events. Other bacterial strains promote corrosion of iron alloys through metal reduction reactions that lead to the dissolution of protective oxide/hydroxide films on the metal surface. Passive layers are either removed or replaced by less stable films that are ineffective against further corrosion.[11]

Fungi as well as bacteria can produce a wide variety of either inorganic or organic acids (e.g. acetic, formic, lactic, succinic) as by-products of metabolism that are capable of initiating or accelerating corrosion.[12,13] Mineral acids produced by bacteria can be very corrosive. In addition, a growing body of research points to EPS/metal-ion interactions as a source of biocorrosion.[14,15] These and other microbially-mediated reactions within a biofilm are shown schematically in Figure 31.4.

Laboratory experiments[16–21] and field tests in service water[22] have demonstrated a reduction in corrosion in the presence of certain aerobic bacteria. One theory for this phenomenon is the mitigation of corrosive agents. For example, reduction of oxygen by aerobic bacteria in a biofilm[17,20] has been proposed. In this process, oxygen diffusing through a biofilm from the electrolyte is prevented from reaching the metal surface by microbial respiration. This deaeration should reduce corrosion rates as long as the concentration of oxygen is roughly uniform. Otherwise, aeration cells could develop that would result in enhanced localised corrosion. Although bacterial respiration of oxygen probably assists the observed reduction in corrosion, it is unlikely that this mechanism alone produces the substantial decreases in corrosion rate that have been observed. Furthermore, E_{corr} is often ennobled in the presence of protective aerobic bacteria.[17,22] However, simple depletion of oxygen should push E_{corr} in the opposite direction. Thus, it appears that a microbiological process other than oxygen depletion, such as the excretion of a metabolic product, is inhibiting the corrosion. Although this inhibition is not entirely understood, it has been shown that live bacteria are required in the biofilm to maintain the observed corrosion inhibition. For example, corrosion rates rise substantially, and E_{corr} becomes more negative, to levels typical of abiotic conditions when an antibiotic is introduced that kills the bacteria in the biofilm.[21]

Whether or not corrosion takes place, and at what rate, typically depends on a complex set of both abiotic and biotic environmental conditions. Consequently, serious difficulties generally arise when interpreting data from any single type of corrosion measurement or observation. Thus, it is important to incorporate a number of investigative techniques in any study involving biocorrosion. Three broad categories of techniques used to detect and monitor biocorrosion are: 1) surface inspection, 2) microbial sampling and identification, and 3) corrosion rate determination using mass loss and electrochemical measurements.[1] Surface inspection ranging in resolution from macroscopic visual, Fourier transform infrared spectroscopy (FTIR), scanning electron microscopy (SEM), to atomic force microscopy (AFM) have been found to be useful. Microbial sampling can be made from either the liquid or biofilm on the metal surface. However, it is generally agreed that biofilm sampling is more representative of the microbial population that influences corrosion processes. Identification of bacteria ranges from relatively indiscriminant techniques such as microbial activity or biomass measurements, to species-specific techniques that employ DNA sequence comparisons or gene probes. Field kits have also been developed that detect certain types of corrosion promoting bacteria such as SRB.[1] Useful electrochemical techniques include those that are non-destructive (such as redox and open circuit potential measurement, electrochemical noise analysis, linear polarisation resistance, and electrochemical impedance spectroscopy), as well as those that are destructive (such as polarisation curve and pitting scan methods).

Several approaches for preventing biocorrosion have been tried with limited success. For example, cathodic protection has been found to retard the growth of aerobic bacteria but also favour the growth of deleterious anaerobic species. Pitting has been observed in stainless steel under a biofilm containing SRB even at high cathodic potentials.[23] The success of biocides for controlling biocorrosion

has also been quite limited, primarily because the bacteria in biofilms are protected by the EPS that seem to mitigate biocide efficiency or act as a barrier.[1] Biocides are also relatively expensive, often dangerous to work with, and present a potential environmental hazard if used in large quantities. Antifouling paints that contain biocides have also been developed.[24] While these coatings can be effective when fresh biocide is continually exposed by rapid flow (e.g. ship hull), they tend not to perform well in the presence of moderate flow rate or stagnant media. Another recommendation for preventing biocorrosion is to keep the industrial system extremely clean to avoid the formation of a biofilm altogether. Although this may seem like an effective measure, it can be extremely costly to maintain over long periods and may not prevent the short-term colonisation of metal surfaces that lead to biocorrosion. If this approach is taken, it must be implemented from the design of the system onward, including hydrostatic testing prior to service. Finally, it should be noted that a novel method of controlling biocorrosion has been proposed which involves the use of protective strains of bacteria.[25] Some of these strains seem to be capable of secreting both antimicrobial and corrosion inhibiting compounds. This probiotic approach, called corrosion control using regenerative biofilms (CCURB), has been successfully implemented so far in both laboratory experiments and field tests resulting in two-fold or greater reductions in corrosion rate.

32 Electroplating and metal finishing

The processes and solutions described in this section are intended to give a general guide to surface finishing procedures. To operate these systems on an industrial scale would normally require recourse to one of the Chemical Supply Houses which retail properietary solutions. This particularly applies to electroplating baths containing brighteners.

32.1 Polishing compositions

The following abrasive powders are used for polishing metal.

ALOXITE

Aluminium oxide made by fusing bauxite. Used for cutting down in the same way as emery.

ALUMINA

Certain grades of alumina are used for polishing stainless steel and chromium. The material is generally used in the form of a composition in which the powder is mixed with stearines or other fats.

EMERY POWDER

Used principally in cutting down and for preliminary operations. It is applied to the mop by means of an adhesive, usually glue. Emery powder is an impure aluminium oxide containing about 50–60% Al_2O_3, 30–40% magnetite and small amounts of ferric oxide, silica, chromium, etc. Emery powder should never be used on magnesium or aluminium components because of the adverse effect on corrosion resistance.

TRIPOLI

A calcined diatomaceous earth used for polishing brass, steel and aluminium. It is used generally in the intermediate stages, and is usually compounded with stearines and paraffin wax to make a polishing composition which can be used directly on a mop.

CROCUS POWDER

A polishing composition consisting essentially of ferric oxide, of coarser grade than rouge, used for polishing iron and steel, and also, tin. Usually compounded with stearine and used with a mop or fibre brush.

ROUGE

A high-grade ferric oxide supplied in various degrees of fineness. It can be used in the form of a paste directly on to a soft mop or can be made into a composition with stearine. It is used essentially for finishing to obtain a very high polish on gold, silver, brass, aluminium, etc.

BLACK ROUGE

This consists of black oxide of iron and is sometimes used for finishing operations.

GREEN ROUGE

Chromic oxide used for polishing chromium and stainless steel and can be used either in the form of a composition mixed with stearine or as a paste applied directly to the mop.

VIENNA LIME

Used for making the white finish for polishing nickel, etc. It consists of a calcined dolomite and contains about 60% calcium oxide and 40% magnesia.

CARBORUNDUM

Silicon carbide used for low tensile strength materials, e.g. brass, copper, aluminium, etc. and also brittle metals, such as hard alloys and cast irons.

32.2   Cleaning and pickling processes

VAPOUR DEGREASING

Used to remove excess oil and grease. Components are suspended in a solvent vapour, such as tri- or tetrachloroethylene.
   Note: Both vapours are toxic and care should be taken to ensure efficient condensation or extraction of vapours.

EMULSION CLEANING

An emulsion cleaner suitable for most metals can be prepared by diluting the mixture given below with a mixture of equal parts of white spirit and solvent naphtha.

Pine oil	62 g
Oleic acid	10.8 g
Triethanolamine	7.2 g
Ethylene glycol–monobutyl ether	20 g

This is used at room temperature and should be followed by thorough swilling.

Table 32.1   ALKALINE CLEANING SOLUTIONS

Metal to be cleaned	Composition of solution		Temperature		Remarks
		oz gal^{-1}	g l^{-1}	°F	°C	
All common metals other than aluminium and zinc, but including magnesium	Sodium hydroxide (NaOH)	6	37.5	180–200	80–90	For heavy duty
	Sodium carbonate (Na$_2$CO$_3$)	4	25.0			
	Tribasic sodium phosphate (Na$_3$PO$_4$.12H$_2$O)	1	6.2			
	Wetting agent	$\frac{1}{4}$	1.5			

Table 32.1 ALKALINE CLEANING SOLUTIONS—*continued*

Metal to be cleaned	Composition of solution			Temperature		Remarks
		oz gal^{-1}	g l^{-1}	°F	°C	
	Sodium hydroxide	2	12.5	180–200	80–90	For medium duty
	Sodium carbonate	4	25.0			
	Tribasic sodium phosphate	2	12.5			
	Sodium metasilicate (Na$_2$SiO$_3$.5H$_2$O)	2	12.5			
	Wetting agent	$\frac{1}{8}$	0.75			
	Tribasic sodium phosphate	4	25.0	180–200	80–90	For light duty
	Sodium metasilicate	4	25.0			
	Wetting agent	$\frac{1}{8}$	0.75			
Aluminium and zinc	Tribasic sodium phosphate	2	12.5	180–200	80–90	—
	Sodium metasilicate	4	25.0			
	Wetting agent	$\frac{1}{8}$	0.75			
Most common metals	Sodium carbonate	2	12.5	180–200	80–90	Electrolytic cleaner, 6 V Current density 100/A ft^{-2} (10/A dm^{-2})
	Tribasic sodium phosphate	4	25.0			
	Wetting agent	$\frac{1}{4}$	1.5			Article to be cleaned may be made cathode or anode or both alternately
Most common metals	Sodium carbonate	6	37.5	Room	Room	May be used electrolytically
	Sodium hydroxide	1	6.25			
	Tribasic sodium phosphate	2	12.5			
	Sodium cyanide (NaCN)	2	12.5			
	Sodium metasilicate	1	6.25			
	Wetting agent	$\frac{1}{8}$	0.75			

Table 32.2 PICKLING SOLUTIONS

Metal to be pickled	Composition of solution			Temperature		Remarks
		oz gal^{-1}	g l^{-1}	°F	°C	
Aluminium (wrought)	*For etching* Sodium hydroxide (NaOH)	8	56	104–176	40–80	Articles dipped until they gas freely, then swilled, and dipped in nitric acid 1 part by vol. to 1 of water (room temperature)
Aluminium (cast and wrought)	Nitric acid, s.g. 1.42	1 gal	11	Room	Room	Articles first cleaned in solvent degreaser. Use polythene or PVC tanks
	Hydrofluoric acid (52%)	1 gal	11			
	Water	8 gal	81			
	Bright dip Chromic acid	0.84 oz	5.2 g	195	90	Immerse for $1\frac{1}{2}$ min. Solution has limited life. AR chemicals and deionised or distilled water should be used
	Ammonium bifluoride	0.72 oz	4.5 g			
	Cane syrup	0.68 oz	4.2 g			
	Copper nitrate	0.04 oz	0.25 g			
	Nitric acid (s.g. 1.4)	4.8 oz	30 ml			
	Water (distilled) to	1 gal	11			
Aluminium and other non-ferrous metals	*Bright dip* Phosphoric acid (s.g. 1.69)	8.4 gal	9.41	195	90	Immerse for several min. Agitate work and solution. Good ventilation necessary. Addition of acetic acid useful with some alloys
	Nitric acid (s.g. 1.37)	0.6 gal	0.61			

Table 32.2   PICKLING SOLUTIONS—*continued*

Metal to be pickled	Composition of solution	oz gal^{-1}	g l^{-1}	Temperature °F	°C	Remarks
Copper and copper alloys	*To remove scale* Sulphuric acid* Water	1 gal 4 gal	11 41	150–170	65–75	After pickling articles can be dipped in sodium cyanide: 4 oz gal^{-1} (25 g l^{-1}) to remove tarnish
	Or Sulphuric acid* Sodium dichromate (Na$_2$Cr$_2$O$_7$.2H$_2$O) Water	1 gal 12 oz 4 gal	11 75 g 41	70–175	20–75	This solution leaves a slight passive film which helps to prevent tarnish
	Bright dip Sulphuric acid* Nitric acid Water Hydrochloric acid	2 gal 1 gal 1 gal 0.5 oz	21 11 11 25 ml	Room	Room	If any scale first dip in spent bright dip. Remove stains by dipping in sodium cyanide 4 oz gal^{-1} (25 g l^{-1})
	Matt dip Sulphuric acid* Nitric acid (s.g. 1.42) Zinc oxide (ZnO)	1 gal 1 gal 2 lb	11 11 200 g	160–180	70–80	If the finish is too fine add nitric acid. If too coarse add sulphuric acid
	Semi-matt dip Sodium dichromate Sulphuric acid* Water	3 oz 18 oz 1 gal	19 g 114 g 11	Room	Room	
Iron and steel	*Slow pickle to loosen heavy scale* Sulphuric acid* Glue	2% 0.25%	— —	Room	Room	Leave for several hours or overnight
	To remove scale Sulphuric acid*	10%	—	120–180	50–80	Or hydrochloric acid 10–20%
	Bright dip Oxalic acid crystals Hydrogen peroxide (100 vol.) Sulphuric acid (10%) Water to	4 oz 2 oz 0.02 oz 1 gal	25 g 13 g 0.1 g 11	Room	Room	This solution has so far only been used on an experimental basis
	Anode etching Sulphuric acid* Water	1 gal 2 gal	11 21	Not above 75	Not above 25	Current density: 200 A ft^{-2} (20 A dm^{-2})
	For polished work Sulphuric acid*	—	—	Not above 75	Not above 25	Density must not fall below 1.61 g cm^{-3} or work will be etched
Magnesium and magnesium alloys	*General cleaner* Chromic acid	16–32	100–200	Up to b.p.	Up to b.p.	For removal of oxide films, corrosion products, etc. Should not be used on oily or painted material

(*continued*)

Table 32.2 PICKLING SOLUTIONS—*continued*

Metal to be pickled	Composition of solution			Temperature		Remarks
		oz gal^{-1}	g l^{-1}	°F	°C	
	Sulphuric acid pickle					
	Sulphuric acid*	3%	—	Room	Room	Should be used on rough castings or heavy sheet only. Removes approx. 0.002 in. in 20–30 s
	Nitro–sulphuric pickle					
	Nitric acid	8%	—	Room	Room	
	Sulphuric acid*	2%	—			
	Bright pickle for wrought products					
	Chromic acid	23	150	Room	Room	Lustrous appearance. Involves metal removal
	Sodium nitrate	4	25			
	Calcium or magnesium fluoride	$\frac{1}{8}$	$\frac{3}{4}$			
	Bright pickle for castings					
	Chromic acid	$37\frac{1}{2}$	235	Room	Room	
	Concentrated nitric acid (70%)	$3\frac{1}{4}$	20			
	Hydrofluoric acid (50%)	1	6.2			
	Acetic acid	8 approx.	50 approx.	Room	Room	Special purpose pickles
	Citric acid	8 approx.	50 approx.	Room	Room	Special purpose pickles
Stainless steel	*To loosen scale*					
	Sulphuric acid*	13–30	80–180	130–160	60–70	Use prior to scale removal treatment, for heavy scales
	Hydrochloric acid (s.g. 1.16)	6–20	40–120			
	To remove scale					
	Nitric acid (s.g. 1.4)	32	200	130–150	55–65	
	Hydrofluoric acid (52% HF)	6	40			
	Or					
	Sulphuric acid*	10	60	Room	Room	
	Hydrofluoric acid	10	60			
	Chromic acid (CrO$_3$)	10	60			
	Bright pickle					
	Hydrochloric acid (s.g. 1.16)	40	250	140–160	60–70	
	Nitric acid (s.g. 1.4)	3	22			
	White matt finish					
	Ferric sulphate [Fe$_2$(SO$_4$)$_3$]	13	80	160–180	70–80	5–15 min
	Hydrofluoric acid (52% HF)	6	40			
Zinc and zinc alloys	*Bright dip*					
	Chromic acid (CrO$_3$)	40	250	Room	Room	5–30 s. If yellow film persists after rinsing dip in sulphuric acid: 1 fl oz per gal (6 ml l^{-1}) and rinse again
	Sodium sulphate (Na$_2$SO$_4$)	3	19			

* Sulphuric acid, pure comcl. grade, s.g. 1.84.

Note: It is almost universal practice to use an inhibitor in the pickling bath. This ensures dissolution of the scale with practically no attack on the metal. Inhibitors are usually of the long chain amine type and often proprietary materials. Examples are Galvene and Stannine made by ICI.

32.3   Anodising and plating processes

Table 32.3   ANODISING PROCESSES FOR ALUMINIUM

Good ventilation above the bath and agitation of the bath is advisable in all cases.

Composition of solution			Temperature		Current density amp ft^{-2} (A dm^{-2})	Time and voltage	Cathodes	Vat	Hangers	Remarks
	oz gal^{-1}	g l^{-1}	°F	°C						
Chromic acid (CrO$_3$), chloride content must not exceed 0.2 g l^{-1}, sulphate less than 0.5 g l^{-1} (After Bengough-Stuart)	5–16	30–100	103–108	38–42	Current controlled by voltage. Average 3–4 (0.3–0.4) d.c.	[†]1–10 min 0–40 V increased in steps of 5 V 5–35 min Maintain at 40 V 3–5 min Increase gradually to 50 V 4–5 min Maintain at 50 V	Tank or stainless steel	Steel (exhausted)	Pure aluminium or titanium	Slight agitation is required This process cannot be used with alloys containing more than 5% copper
Sulphuric acid (s.g. 1.84)	32	200	60–75	15–24	10–20 (1–2) d.c.	12–18 V 20–40 min	Aluminium or lead plates (tank if lead lined)	Lead lined steel	Pure aluminium or titanium	The current must not exceed 0.2 A l^{-1} of electrolyte
Hard anodising Hardas process Sulphuric acid	32	200	23–41	−5–+5	25–400 (2.5–40) d.c.	40–120 V	Lead	Lead lined steel	Aluminium or titanium	Agitation required. Gives coating 1–3 thou. thick
Eloxal GX process Oxalic acid (COOH)$_2$.2H$_2$O	12.8	80	70	20	10–20 (1–2) d.c.	50 V 30–60 min	Vat lining	Lead lined steel	Aluminium or titanium	Oxalic acid processes are more expensive than sulphuric acid anodizing; but coatings are thicker and are coloured.
Eloxal WX process Oxalic acid	12.8	80	75–95	25–35	20–30 (2–3) a.c.	20–60 V 40–60 min	Vat lining	Lead lined steel	Aluminium or titanium	
Integral colour Anodising Kalcolor process Sulphuric acid Sulphosalicylic acid	0.8 16	5 100	72	22	30 (3) d.c.	25–60 V 20–45 min	Lead	Lead lined steel	Aluminium or titanium	Aluminium level in solution must be maintained between 1.5 and 3 g l^{-1}

[†] Period according to degree of protection. Complete cycle normally 40 min.

Table 32.4   ANODISING PROCESSES FOR MAGNESIUM ALLOYS

Composition of solution			Temperature		Current density A ft^{-2} (A dm^{-2})	Time and voltage	Cathodes	Vat	Hangers	Remarks
	oz gal^{-1}	g l^{-1}	°F	°C						
HAE process										
Potassium hydroxide	19.2	120	<95	<35	12–15 (1.2–1.5)	90 min at 85 V approx. a.c. preferred	Mg alloy for a.c. Mg or steel if d.c. used	Mild steel or rubber lined	Mg alloy	Matt hard, brittle corrosion resistant, dark brown 25–50 µm thick, abrasion resistant
Aluminium	1.7	10.4								
Potassium fluoride	5.5	34								
Trisodium phosphate	5.5	34								
Potassium manganate	3.2	20								
Dow 17 process										
Ammonium bifluoride	39	232	160–180	70–85	5–50 (0.5–5)	10–100 min up to 110 V a.c. or d.c.	Mg alloy for a.c. Mg or steel for d.c.	Mild steel or rubber lined	Mg alloy	Matt dark green, corrosion resistant, 25 µm thick approx., abrasion resistant
Sodium dichromate	16	100								
Phosphoric acid 85% H$_3$PO$_4$	14	88								
Cr 22 process										
Chromic acid	4	25	165–205	75–95	15 (1.5)	12 min 380 V a.c.	—	Mild steel	Mg alloy	Matt dark green, corrosion resistant, 25 µm thick approx.
Hydrofluoric acid (50%)	4	25								
Phosphoric acid H$_3$PO$_4$ (85%)	13.5	84								
Ammonia solution	25–30	160–180								
MEL process *Fluoride anodise*										
Ammonium bifluoride	16	100	<86	<30	5–100 (0.5–10)	30 min 120 V a.c. preferred	Mg alloy for a.c. Mg or steel for d.c.	Rubber lined	Mg alloy	Principally a cleaning process to improve corrosive resistance by dissolving or ejecting cathodic particles from the surface

32.4   Electroplating process

Table 32.5   PLATING PROCESS

Metal	Type and composition	oz gal^{-1}	g l^{-1}	Temperature °F	Temperature °C	Current density A ft^{-3}	Current density A dm^{-2}	Current efficiency %	Voltage	pH	Anodes	Vat	Remarks
Aluminium	Aluminium chloride	65	400	60–140	15–60	20	2	100	—	—	Aluminium	Glass sealed	Operation must be in an atmosphere of nitrogen and the work introduced through a lock. Connections must not spark
	Lithium aluminium hydride	2	13										
	Diethyl ether	Solvent											
Antimony	Antimony oxide (Sb$_2$O$_3$)	7	45	130	55	25	2.5	—	—	3.6	Antimony or carbon	Hard rubber or rubber lined	—
	Potassium citrate	20	130										
	Citric acid	24	150

32.5   Plating processes for magnesium alloys

DOW PROCESS (H. K. DELONG)

This process depends on the formation of a zinc immersion coat in a bath of the following composition:

Component	Concentration	
	oz gal^{-1}	g l^{-1}
Tetrasodium pyrophosphate	16	120
Zinc sulphate	5.3	40
Potassium fluoride	1.0	7

The treatment time is 3–5 min at a temperature of 175–185°F (80–85°C) with mild agitation. The pH of the bath should be 10–10.4.

The steps of the complete process are:

1. Solvent or vapour degreasing.
2. Hot caustic soda clean or cathodic cleaning in alkaline cleaner.
3. Pickle $\frac{1}{4}$–$1\frac{1}{2}$ min in 1% hydrochloric acid and rinse.
4. Zinc immersion bath as above without drying off from the rinse.
5. Cold rinse and immediately apply copper strike as under.

Component	Concentration	
	oz gal^{-1}	g l^{-1}
Copper cyanide	4.2	26
Potassium cyanide	7.4	46
Potassium carbonate	2.4	15
Potassium hydroxide	1.2	7.5
Potassium fluoride	4.8	30
Free cyanide	1.2	7.5
pH	12.8–13.2	—
Temperature	140°F (60°C)	—

CONDITIONS

30–40 A ft^{-2} (3–4 A dm^{-2}) for $\frac{1}{2}$–1 min, reducing to 15–20 A ft^{-2} (1.5–2 A dm^{-2}) for 5 min or longer.

If required, the copper thickness from the above strike can be built up in the usual alkaline or proprietary bright plating baths. Following the above steps, further plating may be carried out in conventional electroplating baths.

ELECTROLESS PLATING ON MAGNESIUM

Deposits of a compound of nickel and phosphorus can be obtained on magnesium alloy components by direct immersion in baths of suitable compositions. Details of the process may be obtained from the inventors, The Dow Chemical Co. Inc., Midland, Michigan, USA.

'GAS PLATING' OF MAGNESIUM (VAPOUR PLATING)

Deposits of various metals on magnesium components (as on other metals) can be produced by heating the article in an atmosphere of a carbonyl or hydride of the metal in question.

32.6 Electroplating process parameters

Table 32.6 AVERAGE CURRENT EFFICIENCIES OF PLATING SOLUTIONS

The figures given below are approximate

	%
Cadmium (oxide)	85–95
Chromium	12–16
Copper (acid)	95–99
Copper (cyanide)	30–60
Copper (Rochelle)	40–65
Gold	70–85
Indium (cyanide)	30–50
Indium (sulphate)	70–90
Iron	90–95
Lead	90–100
Nickel	94–98
Silver	100
Tin (acid)	90–95
Tin (stannate)	70–85
Rhodium	35–40
Zinc (acid)	97–99
Zinc (cyanide)	85–90

Thickness of metal deposited per hour is given in mils (1 mil = 0.001 in.) by

$$\frac{CD \times W \times CE}{237 \times \Delta}$$

where

$CD =$ current density in A ft^{-2}
$W\ =$ g A^{-1} h (Table 32.7)
$CE =$ current efficiency (Table 32.6)
$\Delta\ =$ density of metal deposited

Table 32.7 THEORETICAL RELATIONS OF METAL AND CURRENT

Metal	Metal deposited		Current required	
	g A^{-1} h	oz A^{-1} h	A h lb^{-1}	A h kg^{-1}
Aluminium	0.335	0.011 8	1 356	2 989

Zinc	1.220	0.043 0	372	820

32.7   Miscellaneous coating processes

(1) AUTOCATALYTIC PLATING

Autocatalytic plating is a form of electroless plating in which metal is deposited via a chemical reduction process (as opposed to immersion plating in which thin coatings are formed by electrochemical displacement of the coating metal).

Processes exist for the autocatalytic deposition of a large number of metals, particularly nickel, gold, silver and copper. Basically, the solutions contain a salt of the metal to be deposited and a suitable reducing agent (most commonly hypophosphite, but also hydrazine and boranes etc.). When a metal substrate, which is catalytic to the solution, is introduced into the bath, it becomes covered with a layer of the coating metal which is itself catalytic and thus the process can continue. This mechanism results in an extremely even distribution of deposit on the substrate, i.e. these solutions have a high 'throwing power'.

The most widely used autocatalytic process is nickel–phosphorus; a typical acid bath is as follows:

nickel chloride	4.8 oz gal^{-1}	(30 g l^{-1})
sodium hypophosphite	1.6 oz gal^{-1}	(10 g l^{-1})
sodium glycollate	8.0 oz gal^{-1}	(50 g l^{-1})

The solution is operated at temperatures between 75 and 100°C, at pH 4–6, giving deposition rates up to 0.6 thou. per hour (15 μm h^{-1}). The deposit is an alloy of nickel and phosphorus, containing about 7–10% phosphorus. A useful property of this material is that it can be hardened (typically by heat treating for 1 hour at 400°C) so as to increase the as-deposited hardness from 400 HV to almost 1 000 HV. Thus, autocatalytic nickel coatings find engineering applications, often as a replacement for hard chromium electrodeposits.

(2) COMPOSITE COATINGS

Composite coatings can be electroplated or electroless plated deposits into which a uniform distribution of a second phase material is dispersed. The incorporated material can be hard, ceramic particles for increased wear resistance, as in the Tribomet process carried out by BAJ Ltd. Alternatively, PTFE particles can be used to increase surface lubricity as in the Niflor process from Norman Hay Engineered Surfaces Ltd.

(3) ELECTROSTATIC AND ELECTROPHORETIC METHODS OF PAINT APPLICATION

These are methods which have been developed for the economic application of paint to articles of complicated shapes (and often skeleton structure) in large numbers.

When an article like a metal chair is sprayed by a conventional spray gun procedure, much of the spray overshoots the surfaces and is wasted. In the electrostatic method a very high electrical potential is developed between the gun and the article being painted. The droplets of paint assume a charge of opposite sign to the workpiece and are attracted to it. This ensures more uniform coverage, less overspray, and thus greater economy in operation.

Electrophoresis has been utilised in a somewhat similar way. When a direct current is applied to an aqueous emulsion, large dispersed molecules and even oily particles are caused to move towards one of the electrodes. In the electrophoretic process a paint is provided as an aqueous emulsion and current is applied in such a manner that the globules of paint move towards and attach themselves to the object to be painted. The process can be made automatic and continuous and results in very uniform build-up even on points and sharp edges. It is only suitable for large-scale operations but is very economical in paint.

(4) COATING WITH CERAMIC MATERIALS

Just as metals can be sprayed, certain refractory oxides and silicates and the like can be applied by flame gun. Coating thickness and uniformity can be controlled by suitable means and hard, dense coatings can be built up. The coatings resemble biscuit-ware rather than a vitreous glaze, that is, they are absorbent: their chief use is to provide abrasion resistance and to delay heat transfer.

(5) MECHANICAL PLATING

Mechanical plating is a method of plating which utilises mechanical energy to deposit metal coatings on to metal parts. Parts, glass beads, water, chemicals and metal powder are tumbled together in a barrel at around room temperature to obtain the desired coating.

The process is used primarily to provide ferrous-based parts with sacrificial coatings of zinc, cadmium, and co-deposits with tin. Parts treated by this method are most often fasteners, springs, clips and sintered iron components which are typically handled in bulk.

Parts which have been degreased, descaled, and copper-flashed are tumbled in rubber-lined barrels with water, glass bead impact media, promoter chemicals, and a finely divided powder of the metal to be plated. The promoter chemical serves to clean the metal powder and controls the size of the metal powder agglomerates that are formed. The mechanical energy generated from the barrel's rotation is transmitted through the glass impact media and causes the clean metal powder to be cold welded to the clean metal parts, thereby providing an adherent, metallic coating.

Due to the absence of an impressed current during coating, the process does not produce hydrogen diffusion into the steel substrate. Thus, a post-electroplating bake, in order to preclude hydrogen embrittlement of high strength steel components, is not required for mechanically plated deposits.

32.8   Plating formulae for non-conducting surfaces

(1) METAL POWDERS

The article to be treated may be coated with a metal powder. The best powder for this purpose is a finely ground copper, which is generally sold under the commercial title of bronze powder. This may be applied by mixing it with a cellulose lacquer to which has been added five parts by volume of thinner and spraying it on the object concerned. Alternatively, the object may first be sprayed with lacquer and before it is quite dry may be brushed over with the bronze powder using a soft camel-hair brush. After this treatment the article can be struck over in an acid copper solution.

Waxes (for gramophone records, etc.) may be coated directly by brushing with bronze powder and a soft brush. After brushing with bronze powder they may be treated in the following manner to improve the conductivity and reduce the time of covering in the plating bath:

1. Brush with a soft brush and a 50% mixture of methylated spirit and distilled water.
2. Immerse in a solution containing $30 \, \text{g} \, \text{l}^{-1}$ of sodium cyanide and $6 \, \text{g} \, \text{l}^{-1}$ of silver nitrate.
3. Make up two solutions as follows: (a) Pyrogallic acid $7 \, \text{g} \, \text{l}^{-1}$, citric acid $4 \, \text{g} \, \text{l}^{-1}$ and (b) silver nitrate, $40 \, \text{g} \, \text{l}^{-1}$. Take four parts of solution (a) and one part of solution (b) and mix together and immerse article in this solution for about 10 min.
4. Swill and place in plating bath.

(2) SILVER REDUCTION

A number of articles can be treated by directly reducing silver on the surface. This process is particularly applicable to plastics and glass. Any process which will form a good silver mirror may be used, but the following will be found satisfactory for most purposes.

1. The surface of the article must be very thoroughly cleaned and completely free from grease. Glass and porcelain may be cleaned by using concentrated acid and alkali alternately. Plastics may be treated by brushing or barrelling with a mixture of Vienna lime and pumice, by treating with a suitable solvent or by immersing in a solution of chromic acid.
2. Priming. After cleaning the article is immersed in a 10% stannous chloride solution. Alternately, the solution may be swabbed on to the surface with cotton wool. The article is then thoroughly swilled.
3. The article is then silvered by immersing in a silvering solution, the formula for which is given below. The silvering operation generally takes about 20 min and the temperature must be carefully controlled during this period; usually about 21°C will be found the most satisfactory. The solution should be slightly agitated during the process.
4. The articles are thoroughly swilled and struck over in a copper tartrate bath. After being coated over with copper any desired plating can be made upon it.

The silvering solution is prepared from the following:

> Solution (a) 100 g l^{-1} Rochelle salt.
> Solution (b) 10 g l^{-1} silver nitrate.
> Solution (c) 200 cm^3 per litre ammonia (sp. gr. 0.880).

Take 100 cm^3 of solution (b) and add solution (c) carefully a little at a time until the precipitate which first forms just redissolves. If too much is added and the solution becomes quite clear, add a few drops of solution (b) until a very faint turbidity is produced. Then add 20 cm^3 of solution (a), thoroughly mix and use immediately.

[N.B. The brown precipitate formed by adding ammonia to silver nitrate is explosive if allowed to dry. Care should be taken therefore to see that this does not happen.]

(3) 'VACUUM METALLISING'

This process is carried out at less than 0.000 7 mmHg pressure and can only be applied to objects which are stable under these conditions. The metal to be deposited is heated until it evaporates and there are several ways in which this is achieved. The vapour recondenses on the first cool surface it encounters, and can be made to form a thick dense coating. The 'throwing power' is very poor since the evaporated metal travels in straight lines and steps must be taken to rotate or manipulate objects exposed to it in order to achieve uniform coating. By controlling the temperature of the work piece the crystal structure of the deposit can be varied.

32.9   Methods of stripping electroplated coatings

CADMIUM OR TIN FROM STEEL

Coatings may be stripped from steel by immersing the article in a solution containing 1 gal (4.5 litres) of hydrochloride acid, 2 oz (57 g) of antimony trioxide and $\frac{1}{2}$ pint (280 ml) of water. After stripping and rinsing the article will probably require wiping to remove smuts.

CHROMIUM

Chromium may be stripped from non-ferrous metals by dissolving it in dilute hydrochloric acid. From steel it is best stripped by making it the anode in a solution of sodium hydroxide. If the base metal is zinc or zinc base diecastings, it is best to strip the chromium by making it the anode in sodium carbonate solution as this will not attack the exposed zinc. The conditions of operation are not critical.

COPPER FROM STEEL

Copper can be stripped from steel by immersing in a solution containing 5 lb gal^{-1} (500 g l^{-1}) of chromic acid and 8 oz gal^{-1} (50 g l^{-1}) of sulphuric acid. This solution will work at room temperature but strips the copper very quickly if heated.

Alternatively, the article can be made anodic (2–6 V) in a solution containing 14 oz gal^{-1} (90 g l^{-1}) sodium cyanide and 2.4 oz gal^{-1} (15 g l^{-1}) sodium hydroxide.

COPPER FROM ZINC AND ZINC BASE DIECASTINGS

Copper may be stripped from these materials by immersing in a solution prepared by dissolving 18 g of sulphur and 250 g of sodium sulphide ($Na_2S.9H_2O$) in a litre of solution. The solution works very rapidly if warmed. The sludge formed on the surface of the object will require removing from time to time by brushing or immersion in a 120 g l^{-1} sodium cyanide solution.

COPPER, NICKEL, ETC., FROM MAGNESIUM

Most metal deposits can be removed from plated magnesium by submitting the component to the fluoride anodising process. Alternating current is used in a bath of 10% ammonium bifluoride, in which the plating gradually dissolves without affecting the magnesium. About 4–10 V are used until most of the plating has disappeared. Finally, the voltage is raised to 120 V to complete the process and cleanse the magnesium from remaining traces of foreign metal. Magnesium hangers must be used with firm connections. The bath should be operated cold. Direct current may be used if the work piece is made the anode using mild steel or magnesium cathodes.

LEAD FROM STEEL, COPPER AND BRASS

Immersion of article in a solution of 95 vol. % glacial acetic acid, 5 vol. % hydrogen peroxide (30 wt %). Dilute solutions may be used although this can lead to pitting of steel.

NICKEL FROM COPPER AND BRASS

Nickel may be stripped from copper by an anodic treatment in either 60 vol. % sulphuric acid or $15 \, g \, l^{-1}$ hydrochloric acid. Care must be taken with the concentration of the acids as this can affect the pitting of the substrates.

NICKEL FROM STEEL

Nickel can be anodically stripped in sulphuric acid, as for nickel from copper. Copper sulphate $(30 \, g \, l^{-1})$ or glycerine $(30 \, g \, l^{-1})$ can be added to reduce pitting of the steel. An immersion process involves the use of fuming nitric acid (85–95% HNO_3, sp. gr. 1.50) from which water is excluded.

SILVER FROM BRASS

Silver may be stripped from brass by immersing the object in a mixture of 1 vol. conc. nitric acid and 19 vols. conc. sulphuric acid heated to 175°F (80°C). The silver is dissolved in a few minutes. The articles should be immediately removed and swilled.

ZINC FROM STEEL

The reagent used for stripping cadmium may be used. Alternatively zinc may be stripped from steel in either warm dilute hydrochloric or sulphuric acid, or 10–15% ammonium nitrate solution, or hot sodium hydroxide solution.

32.10   Conversion coating processes

(1) PHOSPHATING

Phosphating solutions are used to produce corrosion-resistant coatings on ferrous metals and also zinc, cadmium and aluminium. Probably the most important application for these coatings is to act as bases for subsequent painting operations.

Basically, phosphate solutions comprise metal phosphates dissolved in carefully balanced solutions of phosphoric acid. When a clean metal surface is dipped into the solution, the free acid present reacts with the metal, liberating hydrogen and causing the pH of the solution, adjacent to the metal, to rise. This unbalances the solution, resulting in the precipitation of metal phosphates which form a film, chemically bonded to the substrate.

Due to the complexity of modern phosphate solutions, these processes are normally proprietary, examples of which are listed in section 32.11.

There are four main types of phosphate solution: iron, zinc, heavy zinc and manganese, and these produce increasing weights of coating from 30–90 mg ft^{-2} for iron phosphate solutions to 1 000–4 000 mg ft^{-2} for manganese phosphate solutions.

(2) CHROMATING

Chromating solutions contain hexavalent chromium ions and a mineral acid and are used to increase the corrosion resistance of metals, in particular zinc, cadmium, aluminium and magnesium, by forming a surface layer containing chromium compounds.

The process is usually performed by immersion, although spraying or brushing processes are also used. A wide variety of proprietary solutions are available which produce coatings of different thicknesses. These coatings are often distinguishable by their colour which can vary from clear, to blue, to iridescent yellow and finally to black.

(3) COLOURING OF METALS

The following solutions and operating conditions will produce coloured conversion coatings, as detailed:

(i) Copper and Brass
Black

Copper carbonate	1 lb (454 g)
Ammonia	2 pt (950 ml)
Water	5 pt (2.4 l)

The copper carbonate and ammonia are mixed before adding the water. The solution is operated at 175°F (80°C).

The blue black colour may be fixed by dipping in $2\frac{1}{2}$% sodium hydroxide solution.

Green

Water	1 gal (USA)	(3.8 l)
Sodium thiosulphate	8 oz	(227 g)
Nickel ammonium sulphate	8 oz	(227 g)
or Ferric nitrate	1 oz	(28 g)
Temperature	160°F	(71°C)

Brown

Potassium chlorate	$5\frac{1}{2}$ oz	(154 g)
Nickel sulphate	$2\frac{3}{4}$ oz	(77 g)
Copper sulphate	24 oz	(680 g)
Water	1 gal (USA)	(3.8 l)
Temperature	195–212°F	(90–100°C)

(ii) Iron and steel
Black

Sodium hydroxide	8 lb	(3.6 kg)
Sodium nitrate	$1\frac{1}{2}$ oz	(42 g)
Sodium dichromate	$1\frac{1}{2}$ oz.	(42 g)
Water	1 gal.	(3.8 l)
Temperature	295°F	(146°C)

Blue

Ferric chloride	2 oz	(56 g)
Mercuric nitrate	2 oz	(56 g)
Hydrochloric acid	2 oz	(56 g)
Alcohol	8 oz	(227 g)
Water	8 oz	(227 g)

Room temperature. Parts are immersed for 20 minutes, removed and allowed to stand in air for 12 hours. Repeat and then boil in water for 1 hour. Dry, scratch-brush and oil.

Brown

Copper sulphate	3 oz gal^{-1}	(20 g l^{-1})
Mercuric chloride	0.8 oz gal^{-1}	(5 g l^{-1})
Ferric chloride	5 oz gal^{-1}	(30 g l^{-1})
Nitric acid	25 oz gal^{-1}	(150 g l^{-1})
Alcohol	93 fl oz gal^{-1}	(700 ml l^{-1})

Dip in solution, place in hot box at 175°F (80°C) for 30 minutes, stand in steam box at 150°F (65°C) until coated in red rust, immerse in boiling water to form black oxide, dry and scratch brush. Repeat this operation three times before oiling with linseed oil.

(iii) Stainless steel
Black

Sulphuric acid	180 parts	
Water	200 parts	
Potassium dichromate	50 parts	
Temperature	210°F (99°C)	

(iv) Zinc
Black

Ammonium molybdate	4 oz gal^{-1}	(24 g l^{-1})
Ammonia	6 fl oz gal^{-1}	(45 ml l^{-1})

Heat solution to obtain a deep black. Rinse in cold and then hot water; allow to dry and harden.

(v) Aluminium
Black

Potassium permanganate	1.6 oz gal^{-1}	(10 g l^{-1})
Nitric acid	0.5 fl oz gal^{-1}	(4 ml l^{-1})
Copper nitrate	4 oz gal^{-1}	(25 g l^{-1})

Operate at 70°F (24°C) for 10 minutes.
Blue

Ferric chloride	60 oz gal^{-1}	(360 g l^{-1})
Potassium ferricyanide	60 oz gal^{-1}	(360 g l^{-1})
Temperature	150°F	(66°C)

32.11   Glossary of trade names for coating processes

32.11.1   Wet processes

(1) PHOSPHATE PROCESSES

Processes by which a coating of phosphate is produced on the surface of steel or zinc base alloys by treatment in or with a solution of acid phosphates. For rustproofing, the metal must receive a finishing treatment with paint, varnish, lacquer or oil; examples of typical finishing treatments are given under *Parkerising* but it should be understood that firms using or marketing other proprietary phosphate processes may apply different designations or use different media for the necessary finishing treatment.

Bonderising   A proprietary phosphate process applied to steel and zinc, marketed by Ardrox Pyrene Ltd. (similar to Parkerising for steel but produces a thinner and less protective coating; synonymous with Parkerising for zinc alloys).
Coslettising   The original phosphate process for steel, introduced in 1903.
Electro-granodising   A proprietary phosphate process applied to steel, marketed by ICI Ltd. (Paints Division). The chemical action of the solution is assisted by electrolysis.
Granodising   Proprietary phosphate processes applied to steel and zinc marketed by ICI Ltd. (Paints Division).
Lithoform   A proprietary phosphate solution applied to zinc, marketed by ICI Ltd. (Paints Division).
Parkerising   A proprietary phosphate process applied to steel and zinc, marketed by Ardrox Pyrene Ltd. Examples of subsequent finishing treatments are:

P20	Dewatering black finish
P41	Black shellac finish
P75	Oiled finish
P96	Oiled finish
SP55	Mineral oil finish

Walterising   A proprietary phosphate process applied to steel and zinc base alloys, marketed by the Walterisation Co., Ltd.

(2) ALKALINE OXIDATION PROCESSES

Processes by which a black oxide film is formed on steel by treatment in a strongly alkaline solution containing an oxidising agent. For rustproofing, the metal must receive a finishing treatment which is usually carried out with oil.

Black Magic   Blackening processes marketed by M&T Chemicals Ltd.
Blakodising   Black chemical finishes on steel, marketed by Tool Treatments Ltd.
Ebonol   Range of conversion coating processes for both ferrous and non-ferrous metals, marketed by OMI-Imasa (UK) Ltd.
Jetal   An American process marketed by Technic Inc.

(3) CHROMATE PROCESSES

Alocrom   Chromating solutions marketed by ICI Paints Ltd.
Enthox   Chromating solutions marketed by OMI-Imasa (UK) Ltd.
Kenvert   Chromating solutions marketed by the 3M Company Ltd.

(4) ANODIC OXIDATION OF ALUMINIUM AND ITS ALLOYS (ANODISING)

For protection against corrosion and wear, for decoration, for aiding heat emission and for miscellaneous uses based on the absorptive properties of the oxide film when freshly made; used in conjunction with electrolytic 'polishing' for producing reflectors. Processes involving electrolytic treatment in solution, generally of chromic, sulphuric or oxalic acid with the production of a relatively thick film of oxide.

Anobrite   Bright anodising process operated by Anobrite Ltd.
Bengough–Stuart process (chromic acid)   The first anodising process patented in 1923.
Brytal process   A process of producing reflectors introduced by British Alcan Aluminium.
Eloxal   A generic term used in Germany for anodic oxidation.
Phosbrite process   Chemical polish for bright anodising marketed by Albright & Wilson Ltd.

(5) IMMERSION PROCESSES FOR THE TREATMENT OF ALUMINIUM ALLOYS

Alocrom process   A process of priming a thin greenish yellow film in a cold acid solution containing chromates. Marketed by ICI Ltd. (Paints Division).
Alumon   Zincating process marketed by Enthone/Imasa Ltd.
Bondal   Zincating process marketed by W. Canning Ltd.
Decoral   Oxidising process giving electrically conducting coatings capable of being coloured by dyeing. Marketed by Lea Manufacturing Co. Ltd.
MBV process   (Modified Bauer Vogel)   A process of forming a thin oxide film by immersion in an alkaline solution containing chromates.
Pylumin process   A similar process marketed by Ardrox Pyrene Ltd.

(6) NON-ELECTROLYTIC PROCESSES

Enplate   Electroless nickel plating solutions, marketed by Enthone/Imasa Ltd.
Niklad   Electroless nickel plating solutions, marketed by Lea Manufacturing Co. Ltd.
Sylek   Electroless nickel–boron plating solutions, marketed by Imasa Ltd.
Transiflo   Mechanical plating process, marketed by the 3M Company Ltd.

(7) ELECTROPLATING AND ELECTRODEPOSITION PROCESSES

Achrolyte   Tin–cobalt alloy plating process marketed by Udylite/Oxy Metals Ltd.
Alecra 3000   Trivalent chromium plating process marketed by Albright and Wilson Ltd.
Brylanising   Zinc coating of wire by the 'Bethanising' electroplating process of the Bethlehem Steel Co.
Chromonyx   Black chromium plating process, often used for coating solar panels. Marketed by Harshaw Chemicals Ltd.

Fescolising   A term applied by Fescol Ltd., to any electrodeposition process carried out by them (incomplete without mention of the metal referred to, e.g. Fescolising in chromium, etc.). Now carried out by British Metal Treatments Ltd.

Listard process–Van der Horst process   Patented processes of hard chromium plating for protecting the cylinders of internal combustion and other engines from wear. These processes give an oil-retaining surface to the chromium. The processes are operated by British Metal Treatments Ltd.

Niron   Bright nickel–iron plating process, marketed by OMI-Imasa (UK) Ltd.

Rovalising   A term applied by International Corrodeless Ltd., to any protective coating process used or marketed by them. Incomplete without description of the process referred to (e.g. Roval cadmium, etc., *see also* phosphate processes).

Tryposit   A name used by Thomas Try Ltd., to indicate their special process of electrodepositing heavy nickel or hard chromium for engineering purposes.

Zartan   Alloy deposit, used as an alternative to decorative chromium. Marketed by M&T Chemicals Ltd.

32.11.2   Dry processes

(1) THERMAL PROCESSES

The processes described below involve heating of the object to be coated in contact with the coating metal (in the form of powder or as a coating to secure inter-penetration) or with a compound of the coating element. Used for coating steel except where otherwise stated.

Aluminising   A process involving spraying with aluminium and heating to cause alloying.

Bower Barff   A process of coating steel with a black oxide by heating in contact with steam.

Calorising   A process of coating with aluminium, similar to sherardising (*see* below) but using aluminium in place of zinc.

Chromising   A process of coating with chromium involving heating to a high temperature in contact either with a vapour of chromous chloride or with metallic chromium.

Galvanising   A process of coating with zinc by dipping pickled steel into molten zinc (electrogalvanising is sometimes used to mean electroplating with zinc).

Ihrigising   A process of coating with silicon by heating to a high temperature in contact with the vapour of silicon tetrachloride.

Nitriding   A process of forming a hard layer on steel involving heating in a suitable atmosphere (usually ammonia vapour) to form a surface layer rich in nitride.

Sherardising   A process of coating with zinc involving heating in contact with zinc powder in revolving drums (introduced by Sherard Cowper Coles).

(2) METAL SPRAYING PROCESSES

A method of coating consisting of projecting a stream of molten metallic particles at high velocity against the surface to be coated. Mainly for protection against corrosion but also used for restoring the dimensions of undersized parts.

Wire or Schoop process   A process marketed by Metallisation Ltd., and Metallising Equipment Co. Ltd., in which the coating metal in the form of wire is melted and atomised.

Schori or powder process   A process marketed by Schori Metallizing Process Ltd., in which a stream of the powdered coating metal is fed into a flame and blown on to the surface to be coated.

Mellosing or molten metal process   A process in which a molten metal is fed into a jet of heated compressed air which serves to atomise it and to project it against the surface to be coated.

Arc spray process   A process in which the metal feed material is melted by an electric arc and then atomised by a stream of compressed air.

Plasma spray process   A process in which a very high temperature plasma is produced by blowing gas through an electric arc. Metal wire or powder is melted by passage through the plasma and is projected by the gas on to the surface to be coated.

Detonation or D-gun process   Oxygen, acetylene and the material to be plated, are introduced into a detonation chamber where a spark ignites the mixture. A detonation wave travelling at supersonic speed, forces the powdered material heated to $>3\,500°C$, on to the substrate. A special building is required for sound insulation. Very high density coatings of refractory materials like tungsten carbide, can be plated by the process.

33   Welding

33.1   Introduction and cross-reference

Materials joining technologies cover a very wide range of manufacturing processes to assemble products by connecting and uniting component parts. Materials joining processes are generally divided into the following groups: mechanical fastening, adhesive bonding, solid-state welding, brazing and soldering, and fusion welding. Chapters 33 and 34 are concerned only with those processes in which materials are joined through the formation of primary chemical bonds under the combined action of heat and pressure, i.e. welding, brazing and soldering.

In theory, two ideal metallic surfaces that are both perfectly clean and atomically flat will bond together if brought into intimate contact: they will be drawn together spontaneously by the inter-atomic forces until the distance separating them corresponds to the equilibrium interatomic spacing. In practice, surface oxides or other contaminants and surface roughness act to effectively prevent spontaneous bonding. Heat, pressure and/or other engineering measures are therefore required to encourage the formation of a metallurgical joint. There are three major types of materials joining mechanisms: solid-state welding, brazing/soldering, and fusion welding. Solid-state welding is achieved by deformation where no melting occurs; therefore, by definition, solid-state welding occurs at temperatures lower than the melting point of the metals to be joined. Fusion welding and brazing/soldering are achieved by local melting and epitaxial solidification. In brazing/soldering, only the melting of filler metals occurs (in initial stages at least) whereas fusion welding entails transient melting of some base metal in addition to any added filler metal.

A partial list of welding, brazing and soldering processes is given in Table 33.1. Resistance welding, a group of processes utilising localised electric resistance heating, is generally treated separately, although brazing and soldering, as well as the usual fusion welding, are all feasible processing results of local resistance heating. Space limitations preclude the consideration of all welding processes in this chapter, only the major processes being treated, with information on the welding of common materials included in each section.

For techniques related to brazing and soldering, *see* Chapter 34.

33.2   Glossary of welding terms

The 'Glossary of welding terms' is intended to explain the meaning of terms common in welding technology and used throughout this section, and is not necessarily confined to terminology defined in standards. A list of major standards relating to welding is given in Section 33.7.

Arc blow   In arc welding, the deflection of the arc by magnetic forces induced by the welding current or residual magnetism in the workpiece.
Arc welding   A fusion welding process wherein the source of heat is an electric arc.
Argon arc welding   A fusion welding process wherein the source of heat is an electric arc struck between an argon shielded non-consumable tungsten electrode and the work. The filler wire, if required, is added separately.
Atomic hydrogen welding   A fusion welding process wherein hydrogen is dissociated in an arc struck between two tungsten electrodes afterwards recombining to supply the welding heat. The filler wire is added separately.
Autogenous welding   Fusion welding without a filler metal addition, in which the weld metal is provided by melting of the parent material.

Table 33.1   MAJOR WELDING, BRAZING AND SOLDERING PROCESSES

Solid-state group
1. Pressure welding
   a. Cold (pressure) welding
   b. Hot pressure welding
2. Friction welding
   a. Linear friction welding
   b. Radial friction welding
   c. Rotary friction welding
   d. Friction stir welding
3. Ultrasonic welding
4. Explosive welding
5. Diffusion welding

Liquid-state group
1. Fusion welding
   a. Oxyfuel gas welding
   b. Electroslag welding
   c. Thermit welding
   d. Arc welding
      – Manual metal arc welding
      – Metal inert gas welding (MIG)
      – Metal active gas welding (MAG)
      – Tungsten inert gas welding (TIG)
      – Submerged arc welding (SAW)
      – Plasma arc welding
   e. High-energy-density beam welding
      – Laser beam welding
      – Electron beam welding
2. Resistance welding
   a. Resistance spot welding
   b. Resistance seam welding
   c. Projection welding
3. Brazing/soldering
   a. Furnace brazing/soldering
   b. Resistance brazing/soldering
   c. Laser brazing/soldering
   d. Diffusion brazing/soldering
   e. Wave soldering

Backward welding   A fusion welding technique in which the source of heat is directed towards the already deposited weld.
Backing bar   A bar of material used for backing up a joint during welding to control penetration at the root and not contiguous with the weld.
Backing strip   A strip of metal used for backing up a joint during welding and which may or may not be left on after welding.
Backing run   See *Sealing run.*
Backstep welding   Welding in which increments of a run are deposited in a direction opposite to the general direction of welding.
Bead-on-plate weld   A single run of weld metal deposited on an unbroken surface.
Braze welding   A joining process whereby a brazing type of filler is deposited in a prepared joint using a *gas* welding technique.
Bronze welding   A joining process whereby a brazing type of filler is deposited in a prepared joint using an *arc* welding technique.
Butt weld   A weld between two members lying approximately in the same plane and not overlapping.
Carbon arc welding   A fusion welding process wherein the source of heat is an arc struck between the work and a non-consumable carbon electrode. A filler wire may or may not be used. A shielding gas may also be employed.
Carbon dioxide welding   A carbon dioxide shielded metal arc welding process using a continuous consumable bare wire electrode. (See also *MAG*.)
Chain intermittent fillet welding   Two lines of intermittent fillet welding on either side of a joint wherein the fillet welds on one side are opposite those on the other side.
Cold welding   Pressure welding at room temperature.

Constant potential (or voltage) *power source*   A power source, the output voltage/ampere characteristic of which is substantially parallel to the current axis. Ideal for self-adjusting arc welding.

Controlled arc welding   Metal arc welding in which the arc length is kept constant by controlling, from the arc voltage, the rate of feed of the consumable electrode.

Controlled tungsten arc welding   Tungsten arc welding in which the arc length is controlled from the arc voltage.

Cored electrode (or cored wire)   A consumable electrode in tubular form having a core of flux or other materials.

Corner weld   An outside weld between two members approximately at right angles forming an L.

Cover glass   A clear glass, sometimes gelatin coated, used in welders' helmets and hand shields to protect the filter glass from spatter and fumes.

Crater   A depression left in the weld metal at the termination of a run.

Diffusion bonding   See *Diffusion brazing/soldering and diffusion welding*.

Diffusion brazing/soldering   A brazing or soldering process in which a thin layer of liquid forms by melting of a filler metal or formation of an in-situ liquid phase. The liquid film wets the faying surfaces and then solidifies isothermally at the bonding temperature. It is also known as liquid phase diffusion bonding or transient liquid phase (TLP) bonding.

Diffusion welding   A solid-state welding process wherein the component parts are held together under a pressure too low to cause significant macroscopic plastic deformation (localised plastic deformation does occur at asperities on the faying surfaces), generally at an elevated temperature. The resultant atomic diffusion (and other sintering type mechanisms) causes bonding.

Dip transfer   A mode of particle transfer in gas-shielded metal arc welding wherein use is made of controlled short circuits between electrode and pool.

Downhand weld   See *Flat position weld*.

Drooping characteristic power source   A power source, the output voltage of which falls as current demand increases. Necessary for manual metal arc welding and controlled-arc welding.

Edge weld   A weld between the edges of two or more parallel and faying members.

Electrogas welding   A vertical butt welding process using a gas-shielded consumable electrode to deposit metal into a molten pool held in place by moving dams which move upwards as the joint is made.

Electron beam welding   A fusion welding process employing a high voltage focussed electron beam to supply energy.

Electroslag welding   A vertical butt welding process in which the filler metal electrode is melted in a rising bath of conducting slag held in position by moving dams.

Explosive welding   A pressure welding process employing the energy from the controlled explosion of sheet explosive to effect joining.

Face of weld   The exposed surface of a fusion weld on the side from which welding was carried out.

Faying surface   That surface of a member which is in contact with another member to which it is to be joined.

Filler wire   Metal to be added in making a weld, usually in the form of a bare or flux-coated wire.

Fillet weld   A weld of approximately triangular cross-section between two members approximately at right angles to each other.

Filter glass   A dark coloured glass used to cut down the radiation from a fusion welding process to assist vision and protect the eyes of the welding operator.

Flash butt welding   A resistance welding process wherein coalescence is produced by the heat obtained from resistance to the flow of a heavy electric current between two lightly abutting surfaces and by the application of pressure upon attainment of welding temperature.

Flat position weld   A fusion weld in which the weld face is approximately horizontal and uppermost.

Flux cored arc welding (*FCAW*)   An arc welding process that uses an arc between a continuous consumable *cored electrode* and the weld pool.

Forge welding   A group of solid-state welding processes wherein coalescence is produced by applying pressure or blows to material rendered plastic by heating.

Forward welding   A fusion welding technique in which the source of heat is directed ahead of the already deposited weld.

Friction stir welding   A variation of friction welding in which a weld is made between two butting workpieces by the frictional heating and plastic material displacement caused by a high speed rotating tool that is slowly plunged into and then traversed along the joint line.

Friction welding   A hot pressure welding process in which frictional heat is produced by rotating one component of the joint against a stationary mating surface under slight pressure. An upset force is applied when rotation is stopped. Orbital or oscillating movement may be employed rather than rotation. (See also *Friction stir welding*.)

Fusion boundary   The boundary between weld metal and parent metal in a fusion weld.

Fusion welding   All welding processes in which the weld is made by fusion of the parent metal by means of externally applied heat but without hammering or pressure. Filler wire may or may not be added.

Gap   The minimum distance at any cross-section between edges, ends or surfaces to be joined.

Gas metal arc welding (*GMAW*)   An arc welding process employing an arc between a continuous consumable electrode and the weld pool shielded by an externally supplied gas. The usual North American terminology for *MIG* and *MAG* welding.

Gas tungsten arc welding (*GTAW*)   The usual North American terminology for *TIG* welding.

Gas welding   A fusion welding process in which the source of heat is the combustion of gas.

Hammer welding   A forge welding process in which the welding pressure is obtained by means of hammer blows.

Heat affected zone   The parent material alongside a weld which is heated during the welding operation.

High frequency induction welding   A resistance welding process wherein coalescence is produced by the application of pressure to edges heated by the skin effect of high frequency alternating current.

High frequency injection   The superimposing of a high frequency voltage on the alternating current used in argon-arc welding to ensure that the arc will restrike at the beginning of electrode positive half-cycles.

Horizontal vertical welding   A weld made in such a position that the longitudinal axis of the weld is approximately horizontal and the plane of the weld face is approximately vertical.

Inert gas metal arc welding   A group of fusion welding processes in which the source of heat is an electric arc struck between the work and an inert gas shielded, continuous, consumable electrode which acts as filler metal.

Interpass temperature   In a multiple pass weld, the lowest temperature of the deposited weld metal before the next pass is started.

Lap weld   A fillet weld between two overlapping members.

Laser welding   A fusion welding process employing the energy from the excitation of an optical laser.

Leg of a fillet weld   The distance from the root of the joint to the toe of a fillet weld.

MAG (*metal active gas*) *welding*   Gas-shielded metal-arc welding with a consumable wire electrode, shrouded by active or non-inert gas.

Manual metal arc welding   Metal arc welding using a flux-coated wire or rod electrode under manual control.

Metal arc welding   An arc welding process in which the metal electrode forms the filler metal.

MIG (*metal inert gas*) *welding*   See *Inert gas metal arc welding*.

Nugget   The fusion zone of a spot, seam or projection weld.

Overhead position weld   A weld made on a surface lying horizontally or at an angle not more than 45° to the horizontal, the weld being made from the underside of the parts joined. Alternatively a weld carried out on the underside of a joint.

Overlap   Protrusion of weld metal beyond the bond at the toe of the weld.

Penetration   The maximum depth a weld extends from its face into a joint, exclusive of reinforcement. In resistance welding, the distance from the interface to the edge of the weld nugget measured on a cross-section through the centre of the weld and normal to the surface.

Plasma arc   An arc which is constricted mechanically or magnetically to produce a high heat concentration over a small area.

Plug weld   A fusion weld made in a hole formed in one of the parts of a lapped joint to attach the other part.

Positional welding   Welding carried out in all positions other than the normal flat position.

Pressure welding   A process of joining metals in which the surfaces to be joined are brought into close contact by pressure either cold or heated below the melting point.

Projection welding   A resistance welding process in which current and pressure concentration for making a weld is achieved by means of small projections usually raised on one of the workpieces.

Pulsed welding   Arc welding, usually gas shielded, in which one or more welding variables, but most commonly current, are periodically varied between two levels.

Reinforcement   Weld metal in a butt weld lying outside the plane joining the toes of the weld.

Resistance butt welding   A resistance welding process in which the parts to be joined are butted together under pressure while current is allowed to flow until a predetermined temperature is attained and metal at the interface is upset and a weld produced.

Resistance welding   A generic term covering those welding processes in which the welding heat is produced by the electrical resistance of the weldment and interfacial contact resistance during passage of the welding current.

Reverse polarity   In direct current welding, the arrangement of current supply wherein the work is made the negative pole and the electrode the positive pole of the welding circuit. The term is misleading, and it is preferable to refer to polarity.

Roller spot welding   A spot welding process using a machine similar to that used in seam welding. Pressure is applied continuously and current intermittently.

Root   (a) The zone in the preparation for V, U, J and bevel butt welds, in the neighbourhood of and including the gap.

(b) The zone between the prepared edges adjacent to a backing strip in an open square butt weld.

(c) The zone, in parts to be fillet welded, in the neighbourhood of the actual or projected intersection of the fusion faces.

Root face   That portion of the groove face adjacent to the root and normal to the face of the weld.

Root gap   The separation between the members to be joined at the root of a joint.

Run-on and run-off tags   Small pieces of metal tacked to a weldment at the beginning and end of welds to facilitate avoidance of undercutting at free edges and to remove the start and stop positions from the components being welded.

Sealing run   A weld bead laid along the back of a groove weld.

Seam welding   A resistance welding process in which a continuous weld is produced in over-lapped sheets by means of two electrode wheels or between an electrode wheel and an electrode bar. The electrode wheels provide continuous pressure and current flow is intermittent with accurately timed periods.

Self-adjusting arc welding   Metal arc welding in which the consumable electrode is fed into the arc at a constant speed with a high current density, any alteration in arc length being corrected by naturally occurring changes in the burn-off rate.

Series welding   The making of two spot or seam welds or two or more projection welds simultaneously with electrodes forming a series circuit.

Shielded metal arc welding (*SMAW*)   North American terminology for *Manual metal arc welding.*

Size of weld   (a) Butt weld—The joint penetration.

(b) Fillet weld—The leg length of the largest isosceles right-angled triangle which can be inscribed within the fillet weld cross-section.

Spot welding   A resistance welding process in which overlapping parts are welded at one or more spots by means of shaped electrodes which give a high current density at the welding point and maintain mechanical pressure on the weld during and after current flow.

Spray transfer   A transfer mode in gas-shielded metal arc welding, wherein metal transfers from the electrode to the weld pool as a stream of droplets.

Staggered intermittent fillet welding   Two lines of intermittent fillet welding on either side of a joint wherein the fillet welds on one side are staggered relative to the fillet welds on the other side.

Stitch welding   A spot welding process in which the welds overlap.

Straight polarity   In direct current welding, the arrangement of current supply wherein the work is made the positive pole and the electrode the negative pole of the welding circuit. The term is misleading, and it is better to refer to actual polarity.

Stringer bead   A weld bead deposited without appreciable transverse oscillation of the electrode.

Strip cladding   A method of surfacing components by automatic submerged arc or gas-shielded arc welding, using a consumable electrode in the form of a strip rather than wire.

Submerged arc welding   Arc welding in which a bare wire consumable electrode is used, the arc being enveloped in a powdered flux, some of which fuses to form a protective slag covering the weld.

Surge injection   A means of arc re-ignition whereby a timed uni-directional medium voltage surge is applied across the arc gap. Used in a.c. argon-arc welding.

Synergic welding   MIG or MAG welding system in which arc parameters are automatically set and controlled, normally for a specific wire feed speed.

Tack weld   A short weld used in assembly of parts and for preventing distortion during welding.

Thermit welding   A fusion welding process where the heat for fusion is obtained from liquid steel resulting from a thermit reaction, the steel so produced being used as the added metal.

Throat of a fillet weld   (a) Theoretical. The distance from the beginning of the root of the joint perpendicular to the hypotenuse of the largest right-angled triangle that can be inscribed within the fillet weld cross-section.

  (b) Actual. The shortest distance from the root of a fillet weld to its face.

TIG (*tungsten inert gas*) *welding*   Arc welding using a non-consumable tungsten electrode, surrounded by an inert gas shield. (See *Argon arc welding.*)

Toe of weld   The junction between the face of a weld and the parent metal.

Touch welding   A metal arc welding technique employing flux coated electrodes of special type, whereby the tip of the rod is rested on the parent metal during welding.

Undercut   A groove melted into the parent metal at the toe of a weld and left unfilled by weld metal.

Vertical position weld   A weld made in such a position that the longitudinal axis of the weld is approximately vertical.

Weaving   The deposition of a weld bead with transverse oscillation of the electrode.

Weldment   An assembly whose component parts are joined by welding.

Weld metal   That portion of metal which has been molten during welding.

33.3   Resistance welding

There are four main types of resistance welding process: spot welding, projection welding, resistance butt welding and flash butt welding. Seam, stitch and roller spot welding are closely related to spot welding.

Spot welding finds application in the lap joining of sheet material in the range of thickness from 2×0.3 mm to 2×4 mm and occasionally thicker materials. Stitch and seam welding are used for the manufacture of pressure-tight seams, stitch welding being more suitable for irregularly shaped components and seam welding for long, straight runs or curves with regular or generous radii. Multiple pressure and heating cycles are possible in stitch welding and roller spot welding, but not in seam welding. Roller spot welding is used for producing long, straight rows of spots at higher production rates than are possible in spot welding.

Projection welding may also be used for lap joining of sheets provided the material has sufficient ductility for the production of suitable projections and sufficient strength in the projections to withstand the high loads employed. This process is also used for the production of T-joints and the attachment of studs, nuts, collars and discs to sheet materials. Cross-wire welding is regarded as a form of projection welding.

Resistance butt welding is mainly used for the butt joining of wire and light gauge rods. Heating is more widespread, power consumption is higher and the condition of the end faces is more important than in *flash butt welding.* The latter process is used for butt joining of heavier and more complex sections and bevel joining.

33.3.1   The influence of metallurgical properties on resistance weldability

The properties of most importance which influence weldability, and therefore the selection of suitable welding conditions, are conductivity, expansion characteristics, nature and condition of the surface film, high temperature strength and the structure of the fusion and or heat affected zone.

High conductivity materials require more current than mild steels to give an equivalent heat input for two reasons, first, due to the increased electrical conductivity and secondly, due to the increased conduction of heat away from the weld area. In practice, high conductivity materials such as aluminium are welded for short times with exceptionally high currents. There is, therefore, a need for more complex and expensive equipment for welding these materials than would be required for mild steel. Splashing or boiling of the weld metal may occur in low conductivity materials, and short times and high currents are used for such cases also.

Coefficient of thermal expansion and shrinkage contraction on solidification are important factors in governing the type of mechanical system used in welding machines. In materials of high thermal expansion and of high thermal conductivity, where shrinkage takes place relatively quickly, it is necessary to provide a high electrode force immediately following the current pulse, in order to avoid shrinkage cavities and cracks.

Consistency of surface condition is extremely important in most resistance welding processes (flash butt welding is an exception), particularly in materials with thick natural oxide films, such as aluminium and magnesium alloys. Cleaning procedures are invariably recommended in such cases.

Thin and uniform oxide films, such as those obtained on pickled stainless steels and Nimonic alloys, give consistent welding behaviour, particularly with high electrode forces. Rust, paint and grease influence consistency, and should be removed. Metallic coatings may interfere with weldability seriously, although consistency may suffer slightly and electrode tip life in spot welding may be reduced.

Materials which have high strength when hot require high electrode forces in order to maintain a seal around the molten weld metal.

It is important that the metallurgical structure of both weld and heat affected zone should be adequate to withstand the demands made upon the joint in service. The heat affected zone in many alloys is softened, and it is therefore important to limit its extent by the use of short times. Ferritic steels suffer from hardening, which increases with carbon and alloy content. In serious cases this may necessitate some form of post-weld heat treatment to overcome the resulting brittleness.

33.3.2 The resistance welding of various metals and alloys

STEELS

Low carbon steels may be readily resistance welded by all processes, clean deep drawing steel being commonly regarded as excellent in this respect (Table 33.2). A guide to the maximum carbon content which can be tolerated in spot and projection welding without excessive hardening is given by the formula

$$C_{max} = 0.1 + 0.012t$$

where $t =$ thickness in millimetres of the thinnest sheet in the combination.

Spot and projection welds in medium carbon and low alloy steels may be made, and it is desirable that a high electrode force be applied after the welding current pulse to prevent cracking followed by a tempering treatment which is most conveniently carried out in the welding machine. The electrode force may be maintained at a high level during tempering or reduced to its original value. Hardening is not such a serious problem in resistance butt or flash welding, since cooling rates are lower; however, butt welding is usually confined to steels that do not form refractory oxides.

Table 33.2   THE RESISTANCE WELDING OF METALS AND ALLOYS—SUITABILITY OF PROCESSES

	Process			
Material	*Spot*	*Projection*	*Resistance butt*	*Flash butt*
Low carbon steel	S	S	S	S
Low alloy steel / Medium carbon steel	P	P	S	S

S = Suitable.   N = Not recommended.   P = Possible under certain conditions.   — = Information not available.

Table 33.3   RELATIVE CONDITIONS FOR SPOT WELDING MILD STEEL AND OTHER MATERIALS

Material	*Electrode force*	*Weld time*	*Welding current*	*Remarks*
Mild steel	A-70 MPa on tip area	Short B	High C	
Low alloy steels	A × 1	B × 1	C × 1	Post-heating needed
18/8 stainless steels	A × 3	B × 1	C × 0.9 ⎫	Surface oxides may cause
Nimonic alloys	A × 4	B × 1	C × 0.9 ⎭	trouble in rare cases
Nickel	A × 2.5	B × 1	C × 1.5	
Monel, Inconel	A × 4	B × 1	C × 0.9	
Aluminium alloys	A × 2	B × 0.5	C × 4	Surface oxide must be removed
Cupronickel, silicon bronze, 70/30 brass, nickel–silver, etc.	A × 0.8	B × 0.8	C × 1.2–2.0	Current depends on conductivity of alloy
Titanium and its alloys	A × 2	B × 1	C × 1	Avoid excessive penetration

Taken from 'Resistance Welding', published by the former British Welding Research Association.

Austenitic stainless steels require somewhat lower currents and higher electrode forces in spot and projection welding. In flash butt welding these materials require similar currents to mild steel, but with higher open-circuit voltages and upset forces.

Relative conditions for spot welding mild steel and other materials are summarised in Table 33.3.

ALUMINIUM AND ALUMINIUM ALLOYS

The resistance weldability of aluminium alloys is governed mainly by their relatively high conductivity and the presence of a tenacious high resistance oxide film. Care is therefore required in surface preparation to produce a consistent contact resistance, and this is normally done by controlled scratch brushing or chemical dipping. The use of paste fluxes is not recommended, due to inconsistent quality. Degreasing alone is occasionally practised in applications where consistency is less important. Cleaning of outer surfaces improves tip life in spot welding.

The need for high currents and short weld times has already been mentioned, and comparative figures are given in Table 33.3.

In this group, pure aluminium is the most difficult material to spot weld, and probably the easiest to resistance butt weld. Strong aluminium alloys clad with pure aluminium do not give the same trouble in spot welding due to their lower conductivity and higher resistance to indentation. Generally, spot welding difficulties increase with decreasing parent metal strength and increasing conductivity. All the common sheet materials may be spot welded.

There is little experience with projection welding, the main difficulty being the relatively low strength in compression of the projection. Resistance butt welding is used only for pure aluminium and low strength alloys in small sections, and care with surface preparation is again necessary. Flash butt welding can be used for most aluminium alloys, provided rapid heating and careful control in the time and speed of application of the upset force is applied.

COPPER AND COPPER ALLOYS

Due to its high conductivity, copper is not normally regarded as weldable by the spot and projection welding processes, although very thin copper may be spot welded with molybdenum tipped electrodes using very high currents and short times. The alternative of interposing of shim of relatively high resistance brazing filler metal is often employed, giving a resistance brazed joint rather than a weld. Pure copper may be satisfactorily resistance butt and flash butt welded, and both processes are used in the wire industry.

Cadmium–copper is difficult to resistance weld, and resistance brazing is preferred, but beryllium–copper may be readily spot or butt welded, provided the normal precautions for high conductivity materials are taken.

Brasses increase in weldability with increasing zinc content, and it is difficult to spot weld gilding metals, though 70/30 and particularly 60/40 brass may be welded satisfactorily by this process. Resistance butt welding is frequently used for brass wire, but flash butt welding is not suitable, due to zinc volatilisation. Information on current, weld time and upset force compared with mild steel

is given in Table 33.3. Certain brasses should be rendered immune from season cracking by a low temperature annealing treatment after welding.

Tin bronzes have relatively low conductivity, and may be readily joined by practically all resistance welding methods. Phosphor bronzes may, however, tend to stick to copper alloy electrodes in spot welding, and plating of the electrodes may be required.

Information on aluminium bronze is meagre, but satisfactory resistance welds of all types have been produced in single phase alloys. Flash butt welding has been used for complex alloys.

Silicon bronzes have low conductivity, and may be satisfactorily spot and resistance butt welded. Weld times and electrode forces are rather lower than for mild steel and currents somewhat higher. It is important that rapid follow up of the electrodes during heating should take place.

Cupronickels and nickel-silvers behave in a similar manner to silicon bronze.

MAGNESIUM AND MAGNESIUM ALLOYS

Magnesium and its alloys may be satisfactorily spot welded for low duty service using equipment similar to that used for aluminium alloys. Reference has been made to the satisfactory weldability of Mg–Mn, Mg–Al–Zn, Mg–Zn–Zr and Mg–Th–Zr alloys. Cleaning is important, chemical methods being preferred to mechanical methods, although good results can be obtained by brushing with wire wool. Electrode cleanliness is important if copper contamination of the work-piece is to be avoided. High currents and short weld times are used together with a rapid follow up of the electrodes to give a force somewhat lower than that used for aluminium. Radiused tip electrodes help to form a pressure seal around the weld.

Flash butt welding may also be used for magnesium alloys.

NICKEL AND NICKEL ALLOYS

Nickel, Monel,* Inconel* and the Nimonic* alloys may be satisfactorily spot, projection and flash butt welded.

Conditions for spot welding Nimonic alloys are similar to those for austenitic stainless steel but with somewhat higher electrode forces. Nickel requires higher currents and lower forces although forces are still much higher than for mild steel. Monel and Inconel require currents and forces similar to those recommended for Nimonic alloys. Comparative figures are given in Table 33.3. Cleanliness is important, sulphur and lead contamination being particularly dangerous. Sticking which may occur when spot welding annealed nickel, may be overcome by silver plating of the electrodes. Cracking may be encountered with some precipitation hardening alloys if electrode pressure is too low. Increased weld time and pressure are beneficial.

Flash butt welding is satisfactory if clamping is firm to prevent arcing, clamping distances are kept short because of the low conductivity and upset forces are high. Open-circuit voltages require to be higher than used for mild steel.

REFRACTORY METALS

Among this group of materials are included titanium, zirconium, tantalum, niobium, molybdenum and tungsten. The problem of contamination by reaction with the atmosphere is not as serious in spot welding as in fusion welding, but the quality of projection welds may be improved by the use of an inert atmosphere.

Titanium may be readily spot or flash butt welded. Conditions for spot welding are similar to mild steel but with higher electrode forces. The high electrical resistance tends to give a large weld with high penetration, and seam welding may need to be done under water to prevent contamination after welding. Flash welding conditions are similar to those used for aluminium alloys. Projection welds have also been made in titanium.

Zirconium in thin gauges may be spot welded using conditions similar to those used for stainless steel. No special cleaning other than degreasing is normally necessary. Projection welding and flash butt welding are also possible.

Tantalum may be spot welded in thin gauges, and welding may be carried out in air if the time is less than one cycle. Larger times require water cooling of the weld area. Surfaces should be degreased and pickled in a sulphuric/chromic acid mixture. Niobium should be treated in a similar way.

———————————

* Henry Wiggin & Co. Ltd.

Resistance welds in molybdenum and tungsten are often inherently brittle due to the high brittle/ductile transition temperature of the recrystallised and as cast materials. Other problems are contamination of surfaces with electrode materials and contamination of the electrodes themselves. These troubles are minimised by welding under water. Surfaces should be thoroughly cleaned, if possible by grit blasting. Both materials may be resistance brazed readily, using shims of tantalum, zirconium or nickel. Both materials have been satisfactorily flash butt welded.

DISSIMILAR METALS

It is normally easier to make satisfactory joints between dissimilar metals by resistance welding or resistance brazing than by fusion welding or normal brazing techniques, since the problem of fluxing does not arise and techniques may be chosen to minimise the danger of brittle intermetallic phases within the joint. Copper and aluminium, for example, form a series of brittle phases when melted together, but flash butt welding of copper to aluminium is widely practised, since these phases are forced out of the joint when the upset force is applied.

When spot welding dissimilar metals, it may be necessary to use electrodes of differing conductivity against the different parts, i.e. a high conductivity electrode against the lower conductivity material.

Some indication of the spot welding characteristics of dissimilar metals is given in Table 33.4. In some cases where spot welding is not possible due to excessive formation of intermetallics, it is possible to interpose a layer of a third material compatible with both the parts requiring to be joined.

33.4   Solid-state welding

33.4.1   Friction welding

The most common method of generating frictional heat for welding is to rotate one component relative to the other under an axial load. When the metal temperature at the interface is sufficiently high, the rotation is stopped, and the workpieces are forced together under the original or higher load. Inertia welding is a variant of the process, using the kinetic energy of a flywheel to provide rotation and thermal energy. In friction welding, one component usually has a circular cross-section, but this is not always essential, particularly when orbital rather than rotational differential movement of the workpieces is used.

In radial friction welding, two lengths of tube are aligned axially with a small gap, and a collar of tapered cross-section is rotated between them to generate heat at both interfaces simultaneously. The tubes do not rotate but are forced together during the forging stage of the operation. For linear friction welding, the parts to be joined are oscillated along one axis parallel to the faying surfaces, and are aligned as required immediately prior to forging.

The principal welding variables are the welding speed, applied heating pressure, forge pressure, and heating duration. For any particular joint configuration, selection of optimum welding conditions is primarily dependent on material strength and thermal conductivity characteristics, although with dissimilar metal joints, it may be necessary to use conditions minimising the formation of brittle phases at the interface.

Welding speed is not generally critical, peripheral velocities of between 0.3 and $7\,\mathrm{m\,s^{-1}}$ being common for a range of materials. Higher welding speeds increase the width of the heat-affected zone (HAZ) and welding time.

Both heating and forge pressures must be selected to achieve uniform heating and maintain the faying surfaces in intimate contact. Typical values for mild steel are 45 MPa and 75 MPa for heating and forging, respectively. With mild steel, doubling the heating pressure increases the power required by 50%. Excessive pressure is to be avoided with alloy steels, since the steep temperature gradient may lead to the formation of hard structures, with reduced ductility. Higher pressures are required for materials of greater hot strength. The heating pressure is particularly important in determining both the torque required to make the weld, and the temperature gradient at the interface. With high conductivity materials, such as copper, it is advantageous to use a low heating pressure to obtain rapid local heating, followed by a high forge pressure. Duration of heating is selected to obtain suitable thermal conditions for the production of a sound joint on forging, without overheating of surrounding material. For mild steel, times of 0.5–5 s are general depending on the joint geometry, lower times being applicable to smaller sections, or higher conductivity materials.

Since it is to some extent self-cleaning, the method is tolerant with respect to surface preparation. The atmosphere is excluded from the weld area, and reactive metals can be joined with no special

precautions, while the absence of a liquid phase during welding may avoid problems of porosity, cracking, etc., associated with fusion processes. In fact, if a low melting point liquid area is formed at the interface, it may act as a lubricant, and restrict the development of frictional heat essential for welding. This can arise when welding on to galvanised steel, unless the zinc is removed from the abutting region. Sulphur-bearing free machining steels cause similar difficulties.

Most common alloys are weldable to themselves, while a number of dissimilar metal combinations can be joined, that are normally weldable by other techniques. Table 33.5 illustrates the relative weldability of a range of materials.

FRICTION STIR WELDING

Friction stir welding is a variant of friction welding, in which a solid-state weld is made between two butting workpieces by the frictional heating and plastic material flow caused by a high speed rotating tool that is slowly plunged into and then traverses along the weld line. The workpieces have to be clamped onto a backing bar in a manner that prevents the abutting joint faces from being forced apart. Frictional heat is generated between the wear resistant welding tool and the material of the workpieces. This heat causes the latter to soften without reaching the melting point and allows traversing of the tool along the weld line. The plasticised material is transferred from the leading edge of the tool to the trailing edge of the tool probe and is forged by the intimate contact of the tool shoulder, which leaves a solid phase bond between the two workpieces.

Developed and patented in early 1990s at the Welding Institute (TWI) in England, friction stir welding has already been used in production, particularly for joining aluminium alloys in aerospace structures because of the advantages of this process over conventional arc processes, such as the

* For further information, *see* P. M. Bartle, *Welding J.*, 1975, **54**, 799–804.

absence of a melt zone, reduced distortion, freedom from porosity, and ease of automation. The process is well proven for many aerospace aluminium alloys up to 75 mm thick, and for carbon manganese steels, magnesium alloys and copper alloys. Work is being performed to extend the process to titanium and nickel based alloys.

33.4.2   Ultrasonic welding

Ultrasonic welding may be considered as a variation of friction welding, in which a solid-state weld is formed by applying high-frequency vibratory energy at the faying surfaces while the workpieces are clamped together under light pressure. The process is widely used in the semiconductor, microcircuit, electrical, aluminium fabricating and chemical industries. When the process is used in semiconductor and microcircuit industries, it is called (ultrasonic) wire bonding, used to install wire jumpers to connect components to conducting tracks. There are two basic types of wire bonds, ball/wedge using gold wires and wedge/wedge using aluminium wires.

33.4.3   Diffusion welding

In diffusion welding, contacting surfaces are joined by the simultaneous application of temperature and pressure, using conditions adequate for diffusional processes to occur, but insufficient for macroscopic deformation. As most commonly practised, it is a solid-state process. Interlayers can be applied by vacuum spraying, galvanising or as powder or foils, and are employed to accelerate diffusion or to prevent the formation of brittle intermetallic phases. Welding is normally carried out in vacuum, although protective gas shielding can be used. The range of metals and alloys which have been bonded either directly or indirectly via an interlayer is illustrated by Table 33.6, with butt joint properties in Table 33.7. Bonds between metallic and non-metallic components such as glass or ceramics have been made.

The process is governed by four main interrelated variables: pressure, temperature, time and surface condition. A summary of reported welding conditions is given in Table 33.8.

Table 33.7   EXAMPLES OF DIFFUSION BUTT JOINT PROPERTIES*

Material combination	Joint strength			Tensile joint efficiency, %
	tonf in^{-2}	ksi	MPa	
Mild steel/mild steel	30	66	465	100

PRESSURE

It is necessary to obtain intimate contact between the faying surfaces, and hence the pressure must be high enough to cause plastic deformation at the tips of abutting surface asperities and to induce creep so that contact over the entire surface area can be achieved. This implies pressures below, but often close to, the material yield stress at temperature and hence welding pressures for a range of metals and alloys are typically 5–15 MPa, although higher pressures are required for refractory metals.

TEMPERATURE

To achieve sufficiently rapid creep for practical purposes, a minimum temperature of $0.7T_m$ is normal, T_m being the material melting point in degrees kelvin. Higher temperatures may be used to accelerate welding.

TIME

The diffusion time is strongly dependent on the temperature. Welding can occur after only a few minutes, but times of 0.5–2.0 hours are preferred to give complete interface void removal by diffusion, and improved joint ductility.

SURFACE PREPARATION

The rate of welding depends on the flatness and roughness of the faying surfaces, and a finish of $\sim 0.4\,\mu m$ is preferred. Removal of thick oxide layers and degreasing prior to welding are required, although to some extent contaminants and oxides can dissolve in the parent material, especially with iron- and copper-base systems.

33.5   Fusion welding

While gas welding using an oxy-acetylene torch is still frequently used for mild steel and some non-ferrous metals in sheet gauges, arc welding processes account for the greater proportion of welding carried out at the present time.

Metal arc welding using a coated electrode is the most popular for the manual welding of mild and alloy steels, and electrodes are available for welding cast iron, nickel and its alloys, certain copper alloys and a limited range of aluminium alloys.

A greater number of processes are available for the mechanised welding of mild steel plates. The submerged arc process employs a bare wire electrode and a flux cover continuously supplied via a hopper ahead of the arc. In alternative processes, the flux is applied as a wrapping on the continuously fed electrode or in the core of an electrode formed from folded strip. Other processes using both flux and shielding gas (carbon dioxide) have been developed for mechanised fillet welding.

The gas-shielded processes may be applied to almost all metallurgical materials. They fall into two principal groups, namely those employing a non-consumable electrode, and those wherein the electrode is in the form of a continuous consumable wire.

The argon arc, or TIG, process is the best known of the former type and has been successfully employed for practically all the materials mentioned below, with the possible exception of cast iron. A.c. argon arc welding is normally recommended for aluminium and magnesium alloys and materials forming refractory films, such as aluminium bronze and beryllium copper, while d.c. electrode negative is used for steels, copper and nickel alloys. D.c. nitrogen arc welding is used for copper, and d.c. helium arc welding may be used in circumstances where the high gas cost can be justified in terms of higher welding speeds or increased penetration.

The gas-shielded metal arc processes have been applied to almost as wide a range of materials as the TIG process. The shielding gases used vary with the metals being welded, argon being used for aluminium, magnesium, nickel alloys and refractory metals, argon or nitrogen for pure copper, argon for copper alloys, and argon, argon–oxygen mixtures or carbon dioxide for all types of steel, including stainless steels. D.c. electrode positive is invariably used in present commercial equipment. CO_2 welding is particularly valuable as a low hydrogen process for welding low alloy steels.

Atomic hydrogen and carbon-arc welding are only occasionally used, mainly for mild steel sheet metal welding.

Fusion welding can also be achieved by the electron beam and laser processes. Both processes are applicable to a range of ferrous and non-ferrous alloys, and because of the high energy density, they give a rapid thermal cycle and little distortion. The former method is normally (although not solely) carried out in vacuum and hence is especially appropriate for reactive metals. Laser welding commonly employs helium shielding, this gas having a high ionisation potential with reduced energy loss from the laser beam and, for the same reason, helium is also used for out-of-vacuum electron welding.

33.5.1   The fusion welding of metals and alloys—ferrous metals

MILD STEELS

The welding of mild steel may be accomplished by the majority of processes, the choice of method being dependent upon thickness, type and position of joint and to some extent the type of steel employed. The processes most applicable to thin sheet are gas welding, TIG welding, CO_2 shielded metal arc welding, and less commonly, atomic hydrogen welding. The TIG and atomic hydrogen processes may be manual or mechanised.

Joints in thicker sheet and plate will generally employ the manual metal arc, or, if circumstances permit, one of the mechanised processes such as submerged arc or CO_2 welding. Cored wire welding, employing a continuous tubular consumable with a flux or metal power core, also finds application. Plate of around 100 mm thickness and above may be welded in a single pass using the electroslag process.

The composition of the steel to be welded may limit the choice of process. Rimming steels can give porous welds in gas-shielded welding, and if a mechanised welding process is required, atomic hydrogen, providing a reducing atmosphere, would seem to be the most suitable. Killed steels give better results with argon arc and gas-shielded metal arc welding. High sulphur-free cutting steels are not recommended for welding, since the sulphur gives rise to hot cracking. If such steel has to be welded, basic coated metal arc electrodes should be used.

Gas welding

A neutral flame and no flux is used. The filler material is preferably copper coated to ensure freedom from rust. For general purposes, filler metal to EN 12536:2000 A1 should be used. This is a low carbon mild steel giving a tensile strength of 330 MPa minimum. For somewhat higher strength A2 filler, containing manganese and silicon, is available; *see* Table 33.9.

Metal arc welding

The choice of electrode depends upon the application and the type of welding power source available. All electrodes supplied to EN 499:1994 are coded according to the following system:

1. *Compulsory part:*

   (a) The letter E for a covered manual metal-arc electrode.
   (b) Tensile and yield strength of deposited weld metal.
   (c) Elongation and Charpy impact values of deposited weld metal.
   (d) Type of flux coating.

2. *Optional part:*

   (e) Nominal electrode efficiency.
   (f) Welding positions in which the electrode can be used.
   (g) Recommended current and voltage conditions.
   (h) Whether or not the electrode is hydrogen controlled.

For full details of this system, EN 499:1994 should be consulted. The salient coating characteristics are summarised in Table 33.10.

Table 33.9   FILLER RODS FOR THE GAS WELDING OF FERRITIC STEELS (EN 12536:2000)

Type	C	Si	Mn	Ni	Cr	Mo	Typical application

* If present as a residual element.
Both S and P to be 0.040% max, for A1 to A7, and 0.030% max for A32 and A33.

Table 33.10 TYPES OF COATINGS FOR CARBON AND CARBON MANGANESE STEEL ELECTRODES IN EN 499:1994

Coding	Type of covering	Resultant slag	Special features
B	Basic lime-fluospar	Dense	Low weld metal hydrogen contents are possible, with high resistance to solidification cracking. Generally suitable for all welding positions
BB	Basic lime-fluospar with metallic material	Dense	As **B**, but higher deposition efficiency. Not normally suitable for vertical or overhead welding
C	Cellulosic	Thin and friable	High fusion rate and penetration. Can normally be used in all welding positions. High hydrogen level
R	Rutile	Fluid	Smooth arc with little spatter, and usable in all welding positions
RR	Rutile	Fluid, but more viscous than **R**	Similar to **R**, but with heavier coating thickness. Good weld surface finish
S	Various	Various	Includes acid or oxide fluxes. Consult manufacturer

Automatic processes employing flux

As with manual metal arc welding, the flux type involved is of considerable importance in the submerged arc process and in techniques employing flux-cored consumables. The choice of flux obtainable with these processes is more limited than is the case with manual metal arc welding but both rutile and basic fluxes (equivalent to Classes **R** and **B** in Table 33.10) are available for particular applications, together with more neutral fluxes.

Submerged arc welding fluxes may be in a fused or agglomerated form, depending on the method of manufacture, and have in the past normally been of a neutral or acidic character with high silicate content. More basic fluxes have been developed, which may offer advantages in the mechanical properties of deposited weld metal, but usually with more difficult slag detachment and a more irregular weld surface. Although not giving a full description of reactivity, fluxes are commonly categorised in terms of the 'basicity index' (BI), wt% of constituents:

$$BI = \frac{CaO + CaF_2 + MgO + \frac{1}{2}(MnO + FeO)}{SiO_2 + \frac{1}{2}(Al_2O_3 + TiO_2 + ZrO_2)}$$

Values of BI range from about 0.7 for an acid flux to 3.5 for a basic system. For details of BI see S. S. Tuliani *et al.*, *Welding Metal Fabrication*, August 1969, 327–339.

Low carbon wire consumables are used, generally with added manganese and silicon as deoxidants.

Gas-shielded welding processes

Consumables used for gas-shielded welding of steels contain added deoxidants (usually silicon and manganese). Examples for mild steel are given in Table 33.11, A15 and A17. TIG welding is usually carried out using argon shielding for optimum weld pool control, although helium may be used on thicker sections to increase penetration of the weld. With gas-shielded metal arc welding of mild steel, the surrounding gas is generally CO_2 or argon/CO_2 mixtures.

LOW ALLOY STEELS

In general, the application of the various welding processes is similar for both mild and low alloy steels, the principal difference being that the choice of consumables for low alloy steels may be more limited. Manual metal arc and submerged arc welding are most widely used for low alloy steels in industry, consumables for the former process being given in Table 33.12.

It must be appreciated that in the heat-affected zone (HAZ) around a weld, very high cooling rates may be experienced. Particularly with alloy steels, hard HAZ microstructures can be produced, having a high susceptibility to cracking under the influence of residual welding stresses, and hydrogen picked up during the welding operation. The necessity to avoid hydrogen induced cracking is a major factor in the selection of welding conditions for low alloy steels.

HAZ cracking in ferritic steels is influenced by the following inter-related variables:

1. Steel composition and transformation behaviour.
2. Welding process and type of consumable.
3. Energy input of the welding process, and preheating temperature.
4. Joint restraint.

In general, more highly alloyed steels have a greater tendency to cracking, due to their lower transformation temperature and the formation of harder transformation products. In practice, the important aspects of transformation behaviour of a steel are the hardenability of the steel, and the susceptibility of the hardened structure to cracking.

Both hardenability and susceptibility generally increase with increases in carbon and alloying element content. The dominant effect of carbon has been recognised by the empirical derivation of carbon equivalent (CE) formulae which are intended to describe the weldability of a steel. A widely used formula for carbon–manganese structural steels to BS 4360:1986, is as follows:

$$CE = C + \frac{Mn}{6} + \frac{Cu + Ni}{15} + \frac{Cr + Mo + V}{5}$$

This relationship is recognised by the International Institute of Welding and ISO. The following may be also considered:

$$Pcm = C + \frac{Si}{30} + \frac{Mn + Cu + Cr}{20} + \frac{Ni}{60} + \frac{Mo}{15} + \frac{V}{10} + 5B$$

$$CEN = C + A(C) \left[\frac{Si}{24} + \frac{Mn}{6} + \frac{Cu}{15} + \frac{Ni}{20} + \frac{Cr + Mo + V + Nb}{5} + 5B \right]$$

where

$$A(C) = 0.75 + 0.25 \tanh[20(C - 0.12)]$$

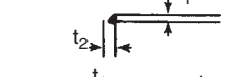
The Pcm formula was derived primarily for higher strength low alloy steels, while the CEN relationship recognises a non-linear contribution of carbon to hardenability and cracking risk at higher carbon levels. With increased CE, more stringent precautions are necessary to avoid cracking. It should be appreciated that such formulae apply only to the particular compositions used in determining them, and are not universally applicable.

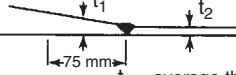
The risk of HAZ cracking is highly dependent upon the hydrogen content of the freshly deposited weld metal. With respect to manual metal arc welding, the risk of cracking in a particular steel is lower when low hydrogen basic electrodes are used rather than the common rutile type, particularly if the former electrodes are dried at temperatures above about 300°C. The submerged-arc and gas-shielded metal-arc processes can produce weld metal deposits having hydrogen contents comparable to or lower than those of basic electrodes, and some relaxation of welding conditions may be possible with these processes, provided that clean dry consumables are used. Typical weld metal hydrogen levels determined following the procedures in BS 6693 are given in Table 33.13.

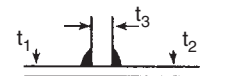
Table 33.13 TYPICAL HYDROGEN CONTENTS FOR DIFFERENT STEEL WELD METALS
(EN 499:1994)

Weld metal type	*Range of hydrogen contents* (ml per 100 g *of deposited metal*)
Classification C	70–100
Classification R	20–35
Classification B (dried 100–150°C)	10–15
Classification B (baked 350–450°C)[†]	3–10
Submerged arc	5*–25
Gas-shielded metal arc (Ar or CO_2)	3*–10
Cored CO_2: basic flux	3–5
rutile flux	5–15

* Lower values for clean, dry consumables.
[†] Consumable manufacturer's advice on drying conditions should be sought.

Thermal conditions prevailing during welding are controlled for one or both of two reasons. First, by control of the cooling rate, it is often possible to determine the transformation product after welding. Secondly, cracking may be avoided by holding the weld area at about 250°C (when the embrittling effect of hydrogen is negligible) for a sufficient length of time for hydrogen to diffuse away from susceptible regions.






For a given weld geometry, increased heat input during welding will result in a lower cooling rate. In many materials, such reduction in cooling rate will be sufficient to avoid transformation to hard, susceptible microstructures. Increased heat input may be achieved by increasing the welding current or voltage, or by reducing the speed of travel. If cracking cannot be controlled by increasing energy input, preheat may be applied to reduce the cooling rate after welding. The preheat temperature required in a particular case will depend upon the material composition, the joint restraint, and the welding process used, but it will usually be in the range 100–250°C. In multipass welds, the preheat temperature must be maintained between weld runs as an interpass temperature.

Joint restraint may be defined as resistance to deformation which would relieve contractural welding stresses. Restraint will, in general, increase with increasing thickness of the component parts being joined. Increase in material size will also increase the cooling rate of the weld by affording a larger heat sink. Joint type is significant in determining the number of paths along which heat may be conducted away from the weld, and the effect of joint geometry on cooling conditions can be described by a 'combined thickness' parameter. The combined thickness is the total thickness of material in mm through which heat can flow away from the weld, as indicated in Table 33.14.

When doubt exists regarding the risk of cracking in a given situation, it must be recommended that a procedural trial be undertaken.

It has been found possible with carbon–manganese structural steels to avoid cracking by controlling welding conditions so that the microstructure in the HAZ is not harder than a critical value. When using manual metal arc welding consumables of relatively high hydrogen potential, the HAZ hardness should not exceed 350 HV. With low hydrogen consumables or CO_2 welding, a hardness of 400 HV or even above is appropriate. Figure 33.1 is a nomogram for material of CE determined as above, showing welding conditions such that the critical hardness is not exceeded, and cracking can be avoided. Allowance is made for the use of processes with different hydrogen potentials, and for the combined thickness of the weldment. From the intended welding process, the relevant CE scale is selected. A vertical line is drawn from the CE of the material being considered, to intersect the intended preheat temperature. From this intersection, a line is taken horizontally to the appropriate

Table 33.14   DETERMINATION OF COMBINED THICKNESS

Type of joint and heat flow	Combined thickness (mm)
t ... t	$2t$

CE Scale A: Normal welding processes; HAZ hardness restricted to below 350 HV, CE Scale B: Low hydrogen welding processes; HAZ hardness restricted to below 400 HV,
CE Scale C: Very low hydrogen welding processes; HAZ hardness restricted to below 450 HV.

Table 33.15   CLASSIFICATION OF LOW ALLOY STEELS

Class	Hardenability	Susceptibility to HAZ cracking	Examples	Precautions in welding
1	Low	None	Mild steel	None
2	Low	Low	(1) Mild steel with C >0.15% but <0.25%, and Mn <1.0%. (2) C–Mn steels with C <0.2% and Mn <1.4%	Thin sections, none; with thicker sections, lower H_2 processes, high heat input and some preheat are all advantageous
3	Low	High (twinned martensite)	Medium carbon steels, e.g. 080M30, 080M40*	Production of non-martensitic HAZ more important than low hydrogen. Use high heat inputs, and 250–350°C preheat
4	High	Low (low carbon martensite)	Low carbon, low alloy high strength steels, e.g. 9%Ni HY80, C–Mn steels in thick sections	Low hydrogen processes, increased heat input and some preheat generally necessary
5	High	High (twinned martensite or bainitic constituents)	(1) Medium carbon alloy steels, e.g. 530H32, 835M30* (2) Some creep resistant steels, e.g. 5Cr $\frac{1}{2}$Mo, 2$\frac{1}{4}$Cr 1Mo	Preheat and interpass temperature in the range 200–350°C. (May be possible to use 150°C in thin sections.) Post-weld heat treatment advisable

* BS 970:Part 1:1996.

combined thickness, and then vertically down to determine the minimum arc energy input necessary during welding to avoid exceeding the critical hardness. Similarly, given a material, thickness and arc energy, the minimum preheat temperature can be determined. Further reference to EN 1011-1:1998, EN 1011-2:2001 should be made. One caveat is that the critical hardness to avoid cracking is slightly dependent on carbon equivalent. Conservatism is recommended when applying Figure 33.1 to steels of CE <0.40 for welds to be made without preheat.

The CE approach for formulating welding procedures is unworkable at CEs above 0.6. With low alloy steels, it is possible to classify susceptibility to HAZ cracking according to their transformation behaviour. Five general classifications are shown in Table 33.15, together with summaries of precautions necessary for avoiding cracking. Appropriate preheat and interpass temperatures for steels in Classes 4 and 5 can be obtained from Figure 33.2. More precise definition of behaviour is not possible since cracking susceptibility is not uniquely related to hardness, while the effect of joint geometry cannot be adequately quantified for these materials.

In general, weld metals used for mild and low alloy steels contain rather less carbon than the parent material, and in consequence are less susceptible to hydrogen-induced cracking than is a HAZ. The factors outlined above for HAZs are nonetheless applicable, and precautions to avoid hydrogen-induced weld metal cracking may be necessary in some cases.

HAZ liquation cracking

Another problem in the welding of ferritic steels is cracking associated with liquation of nonmetallic phases at prior austenite grain boundaries in the HAZ, under the influence of thermal stresses in this area. Susceptibility is dependent mainly on the relative amounts of sulphur, carbon, manganese and phosphorus in the steel and, in plain iron–carbon alloys, the problem becomes significant with carbon contents above about 0.2%. At this carbon content, a manganese to sulphur ratio of at least 20 : 1 is required to avoid the problem, and with higher carbon contents, this ratio may need to be as high as 30 : 1 or 50 : 1.

Lamellar tearing

Lamellar tearing may arise in joints in which the fusion boundary of the weld is parallel to the plate surface, and tensile residual stresses act across the plate thickness. Cracking is generally
Figure 33.2 *Suggested preheat conditions for procedural tests for steels in Classes 4 and 5 of Table 33.15.*

step-like in character, and is associated with inclusions which are rolled into planar form during plate manufacture. Such inclusions result in reduced ductility in the through-thickness direction of the plate. Lamellar tearing will not normally arise in plate with a through-thickness ductility above 20% reduction in area (RA). Between 10 and 20% RA, it may be encountered in highly restrained cases, such as fully penetrating nozzles. If the ductility is below 10% RA, cracks may form even in relatively lightly restrained T-joints. Lamellar tears have been found in plate of 10 to 175 mm thickness, but are not common below 25 mm thickness. Where experience with a particular material and joint configuration indicates a risk of lamellar tearing, consideration must be given to joint design and welding procedure to reduce the effect of restraint, and to ensure that the fusion boundary of the weld runs across possible planes of weakness in the material.

Stress relief cracking

A number of ferritic steels may be subject to stress relief, or reheat, cracking. Cracking is intergranular, and occurs in the HAZ when restrained joints are given a post-weld heat treatment. The problem is analogous to that in austenitic steels considered below, and arises primarily in alloys showing secondary hardening. Cracking behaviour cannot be predicted at the present time with any precision. Cracking has not been reported in alloys such as $2\frac{1}{4}$Cr/1Mo or $\frac{1}{2}$Mo/B steels at below 75 mm thickness, or in $\frac{1}{2}$Cr/$\frac{1}{2}$Mo/$\frac{1}{4}$V at below 18 mm thickness. The risk of cracking can be reduced by weld dressing to reduce local stress concentrations, and by controlled heat treatment procedures.

HIGH ALLOY HEAT AND CORROSION-RESISTANT STEELS

These fall into three basic categories: the martensitic chromium-containing steels, the higher chromium ferritic steels and the chromium–nickel austenitic steels. With different chromium and nickel contents, materials containing mixtures of the three main microstructural constituents may be produced. The welding behaviour of such materials is generally dependent on the major phase present.

MARTENSITIC STAINLESS STEELS

The principal problem with the martensitic alloys is that of hydrogen-induced cold cracking, as with low alloy steels. Preheating is required, generally to over 200°C, followed by slow cooling and post-weld heat treatment at 650–750°C. The likelihood of cracking depends on a number of factors, and procedural trials are normally required to determine the optimum welding conditions in any

Table 33.16   SUGGESTED WELDING CONDITIONS FOR 13%Cr STEELS

	Temperature, °C		
Material	*Preheat*	*Interpass*	*Post-weld heat treatment*
13%Cr/0.1%C	250	250–350	700–750
13%Cr/0.2%C	250	250–350	700–750
13%Cr/4%Ni/0.06%C	150	150–250	600–650

given instance. Carbon content is of particular importance, and thin plate material of less than 0.1% carbon can often be welded without preheat or post-weld heat treatment; with thicker material or carbon content above 0.2%, both preheat and heat treatment are necessary. At higher carbon levels, it is essential that the welds do not cool to room temperature between completion of welding and application of heat treatment (although the joint should cool sufficiently for complete transformation to martensite to occur in the HAZ, prior to heat treatment), unless sufficient time is given to permit hydrogen diffusion out of the weld area. The martensite transformation finish temperature (M_f) may not be well defined, and in such cases, a suitable cool-out temperature should be defined by procedural tests. Suggested welding conditions for typical alloys are given in Table 33.16. If matching composition consumables are required (e.g. Table 33.17), careful consideration to hydrogen-induced weld metal cracking should be paid, and adequate electrode baking is essential. The use of austenitic consumables is preferred. Although these are of lower strength than the parent material, hydrogen is more soluble in austenite than in martensite, and thus hydrogen tends to remain in the weld metal, reducing the risk of cracking. Manual metal arc welding is generally employed for martensitic stainless steels, with TIG welding finding application for thin gauge material.

FERRITIC STAINLESS STEELS

Ferritic stainless steels suffer embrittlement on welding due to grain growth and grain boundary, martensite formation in the heat affected zone that is heated above 1100°C. These materials are notch sensitive, and the grain growth raises the ductile–brittle transition temperature to above room temperature, resulting in a brittle joint when the weldment cools out. Preheat to 200°C and post-heat treatment at 750–850°C are recommended. These measures do not avoid the deleterious microstructure, but serve to reduce residual welding stresses as far as possible and obtain some HAZ softening. The toughness of matching composition weld metal (e.g. Table 33.17) may be lower than that of the heat affected zone. Thus, austenitic consumables are preferred unless differences in coefficient of expansion between the weld metal and parent material are likely to cause thermal fatigue in service. Manual metal arc and TIG welding are most commonly used for ferritic grades of stainless steel.

Ferritic stainless steels are also sensitive to intercrystalline corrosive attack in the region around a weld that is heated to above 1 100°C. The problem may be avoided by post-weld heat treatment at between 700 and 850°C. In some circumstances sigma phase may form during heat treatment, causing brittleness below 200°C. This can be eliminated by annealing at above 850°C.

The problems of loss of toughness and corrosion resistance in the weld area restrict the industrial use of fusion welded ferritic stainless steel assemblies. These materials can, however, offer good general corrosion resistance, and are considerably more resistant to chloride-induced stress corrosion than are austenitic grades. To avoid the welding problems of conventional ferritic stainless steels, alloys have been developed based either on reduction in interstitial elements, or on balanced chromium–nickel contents so that mixed ferrite–martensite or ferrite–austenite microstructures are obtained. Such materials have been successfully welded in thin gauges for service conditions where a risk of stress corrosion has precluded the use of austenitic steels.

AUSTENITIC STAINLESS STEELS

For practical purposes, austenitic stainless steels can be regarded as among the most weldable materials, and virtually any process can be used to make a joint. The manual metal arc and TIG processes are most common, with MIG and submerged arc welding being used when high deposition rates are required. Manual metal arc and gas-shielded welding consumables are given in Tables 33.17 and 33.18. Oxyacetylene welding is readily carried out with consumables as in Table 33.19, but is not preferred since excessive heating and a carburising flame can cause weld decay, as considered below. A flux is desirable, and a neutral flame is recommended, oxidising conditions causing porosity.

The main metallurgical problems with austenitic stainless steels are the avoidance of weld metal and heat affected zone cracking, and maintenance of full corrosion resistance in the weld area.

Fully austenitic weld metals are susceptible to cracking both during solidification and in underlying reheated runs. The problem may be entirely avoided by the use of consumables with composition such that the deposited weld metal contains more than about 3–5% ferrite. A guide to the relationship between composition and structure is given by the Schaeffler diagram, reproduced in Figure 33.3. Dilution from parent material must be taken into account when using the Schaeffler diagram.

The presence of ferrite in the weld metal may promote transformation to the embrittling sigma phase during heat treatment or in service at temperatures between 550 and 850°C. The compositional range likely to suffer rapid embrittlement is indicated in Figure 33.3. Particularly if sigma formation is a hazard, the preferred weld metal compositions lie in the shaded area.

In certain corrosion-resistant applications, notably urea plant, the presence of ferrite may be undesirable since it can lead to preferential attack taking place on the weld metal. In such cases,

S and P each to be 0.030% max.

low or zero ferrite consumables should be used, and the risk of cracking controlled by minimising joint restraint and welding with minimum heat input. Increased manganese contents of 3–5% are beneficial.

During the welding cycle, intergranular precipitation of chromium-rich carbides can occur in areas heated to within 500–900°C. This precipitation causes local loss of chromium from the matrix, with a consequent reduction in corrosion resistance and susceptibility to intercrystalline attack, or 'weld decay'. The problem is normally avoided by the use of material either with carbon contents below 0.03%, or containing strong carbide forming elements such as niobium or titanium. Such 'stabilised' steels are not immune to intercrystalline attack under all circumstances, and heat treatment within the sensitising range 500–900°C can induce sensitisation to intercrystalline corrosion. If post-weld heat treatment is carried out, the temperature should be above 900°C. For practical purposes, intercrystalline attack due to arc welding is unlikely to be encountered in unstabilised molybdenum-free material of 0.06% carbon and below, provided that the arc energy per unit length of weld metal is below 2 kJ mm^{-1}, although service in highly oxidising media should be regarded with caution.

Austenitic steels may suffer HAZ liquation cracking during welding. The problem is minimised by the use of low arc energy welding conditions and with wrought material, by avoiding grain sizes coarser than about ASTM 3–4. In castings, cracking can often be suppressed by using material containing above 5% ferrite. The liquation cracks are of the order of 0.5 mm long, and are not generally
Figure 33.3   *Modified Schaeffler diagram for constitution of stainless steel weld metal*

significant in service. In welds of high restraint, however, they can form initiation points for 'reheat cracking' during elevated temperature service or post-weld heat treatment. At elevated temperature, intragranular strain-induced precipitation occurs in the HAZ. This causes a loss of creep ductility, and if joint restraint is high enough, intergranular cracking results. All common grades of austenitic stainless steel are susceptible to reheat cracking, with the exception of the 18%Cr/12%Ni/3%Mo types, provided that these do not contain residual carbide forming elements such as niobium or titanium. The risk of reheat cracking is reduced by dressing weld toes to remove liquation cracks, by the use of low hot strength weld metal, and by stress relief at above 950°C.

High proof stress variants of the common austenitic stainless steels have been developed, based either on solid solution hardening by nitrogen or on 'warm working' by rolling at down to 850°C to obtain a work hardening effect. These materials can generally be welded with normal consumables with no loss of strength in the weld area. With the nitrogen-bearing steels, excessive dilution of the weld pool by parent material causes a fully austenitic weld metal, with a risk of solidification cracking. High dilution situations, such as the root pass of a butt weld in thick plate, should therefore be regarded with caution. Joint preparation should be such that at least 50% of the molten weld pool is filler material.

CLAD STEELS

These consist of mild or low alloy steel clad with an overlay by rolling, explosively or by weld deposition. A number of overlays such as nickel, Monel, Inconel or stainless steel are available, to fulfil different requirements.

Various welding processes may be used for joining clad plate, although manual metal arc welding is normally employed in view of the range of electrodes available, and the facility of control. The recommended procedure is to prepare the ferritic side of the joint, and weld this conventionally with suitable electrodes, taking care that no cladding material is picked up by the weld metal. The clad side is then chipped out to sound metal to below the depth of the cladding, and welded using suitable filler metal. The choice of consumable for this weld is determined primarily by the necessity to accept dilution from the ferritic substrate material, and give the desired final weld metal composition without the formation of undesirable microstructures. A two-pass technique is usually specified, the first pass

Table 33.20   MANUAL METAL ARC WELDING ELECTRODE COMPOSITIONS FOR WELDING CLAD STEELS ON THE CLADDING SIDE

employing a consumable tolerant of dilution, and the second pass being intended to deposit weld metal of matching composition to the cladding. Typical consumable compositions are given in Table 33.20.

CAST STEELS

The welding of cast steels presents no special problems additional to those encountered in wrought metal of similar composition. Silicon and manganese contents are usually high, and this has an influence on weldability. Repairs to steel castings are usually subject to the same conditions of restraint as repairs to cast iron, and preheating is often desirable for this reason alone. Plain carbon steels with less than 0.25% C may otherwise be welded without preheat following the procedure in Figure 33.1. For steels containing 0.25–0.50% C, preheat temperatures up to 300°C may be used, while for steels of carbon content greater than 0.50%, a preheat of 300°C and a post-weld stress relief at 650°C should be employed. It may be necessary to use nickel-bearing electrodes when carbon contents are very high. Alternatively, bronze welding may be used.

Preheating, when recommended, should preferably be applied to the whole casting and the figures in Table 33.21 should be regarded as minima. Manual metal arc welding is normally employed, although other methods are possible.

CAST IRONS

Malleable irons, grey iron, spheroidal graphite cast irons and austenitic cast irons may be welded, provided suitable precautions are taken.

Difficulties are due to lack of ductility in the parent material to accommodate weld shrinkage stresses, the transfer of carbon to the weld metal, resulting in hard, brittle deposits, and hardening in the heat affected zone. In addition, high sulphur contents may result in hot shortness in the weld and subsequent cracking.

Table 33.22   FILLER RODS FOR GAS WELDING CAST IRON (EN 12536:2000)

Type	*Element*, wt %						
	C	Si	Mn	Ni	S	P	*Applications*

B2	3.0–3.6	2.0–2.5	0.5–1.0	—	0.15 max	1.5 max	Hard (valve seats)
B3	3.0–3.5	2.0–2.5	0.5–1.0	1.25–1.75	0.10 max	0.50 max	Ni cast iron

Table 33.23   ELECTRODES FOR METAL ARC AND BRONZE WELDING OF CAST IRON

Electrode type	Applications and remarks
High nickel	Minimum preheat, easily machined. Not for high sulphur irons
60% nickel, 40% iron	Suitable for spheroidal graphite irons. Moderate machineability
Cast iron (soft iron)	General purpose, preheat essential
Austenitic stainless	Austenitic castings
Phosphor bronze	Not affected by sulphur, poor machineability
Aluminium bronze	Good strength, wear resistance and machineability

Spheroidal graphite irons and other alloy cast irons have increased ductility and impact resistance over normal grey iron, and so may be welded with rather less difficulty. White cast irons can seldom be welded satisfactorily.

The choice of process is influenced by the type of component and its composition, gas welding and braze welding being suitable for light components, and metal arc and bronze welding for the heavier types of construction. Filler rods for gas welding are given in Table 33.22. For braze welding, consumables C4, C5, or C6 in Table 33.29 may be used. Types of electrodes for manual metal arc and bronze welding are given in Table 33.23.

To accommodate shrinkage stresses and to minimise hardening in the heat affected zone, preheating to 550°C and slow cooling is essential unless minimum penetration techniques are employed. In the latter case, repairs in thin sections may be made using high nickel, nickel–iron or bronze electrodes; and in heavy sections, buttering of the edges of the joint with nickel–iron alloy should be followed by welding with soft iron electrodes. If preheating is not employed, minimum heat input is essential, by the use of short weld runs and small diameter electrodes.

33.5.2   Non-ferrous metals

ALUMINIUM AND ALUMINIUM ALLOYS

The main processes for fusion welding this group of materials are the TIG and MIG systems. Manual metal arc and oxyacetylene welding find very limited application, and then only when alternative processes are not available.

The gas-shielded MIG and TIG processes may be used for all the weldable alloys. Sound joints with good mechanical properties can be obtained, as long as weld cleaning is carefully carried out. TIG is suitable for sheet metal work, butt welds up to 6 mm thick and fillet welds where runs are short. It is also valuable in cases where the edge preparation permits autogenous welding to be used. MIG welding is particularly suitable for fillet welding and for the butt welding of material 5 mm thick and above. MIG welding normally employs commercial purity argon as a shielding gas. This gas is also general for TIG welding, although in sections above 6 mm thickness, helium may offer advantages in increased penetration and travel speed.

The majority of aluminium alloys may be welded without difficulty, provided the correct filler wire is used. Recommendations for all processes are given in Table 33.24, and consumable compositions are in Table 33.25. Certain wrought (and cast) alloys, notably aluminium–$2\frac{1}{4}$% magnesium, aluminium–magnesium silicide and duralumin types, suffer from hot cracking when welded with parent metal fillers and such fillers should be used only under closely controlled conditions of low restraint. The fusion welding of the latter types of alloy is not recommended.

* Ti content can include other grain refining elements.

ALUMINIUM CASTINGS

For welding heat treatable castings, the choice of filler wire should be based upon the composition of the casting itself if post-weld heat treatment is to be employed. If cracking is encountered, a higher alloy content in the filler wire may be required. Alloys containing zinc are generally difficult to weld. For welding LM6, LM9 and LM20, as in EN 1559-1:1997, EN 1559-4:1999, 4047A wire may be used: 4043A is recommended for LM18 and LM25, while 5356 and 5556A can be used for LM5 and LM10. Parent material is suggested for the remainder of the weldable materials.

DISSIMILAR ALUMINIUM ALLOYS

Welding different aluminium alloys together frequently involves a compromise between mechanical or corrosion properties and joint soundness. Recommendations are given in Table 33.26a, b and c.

33.5.3 Copper and copper alloys

Copper is produced in several grades, which vary in weldability according to the nature and quantity of the residual elements present. The material has a high thermal conductivity, and heat conduction away from the weld area may restrict the size of molten pool that can be obtained. Preheat is applied to counteract this, particularly with thicker material. Table 33.27 gives an indication of the preheat temperatures for copper and various copper alloys.

Welding is normally carried out using the gas shielded processes, and the choice of gas influences the thickness above which preheat is desirable as in Table 33.28. In general, the welding speed and penetration increase with change in shielding gas in the order Ar, He, N_2, and the level of preheat decreases with the same order of gases.

Manual metal arc welding of copper and its alloys is possible, but the gas-shielded processes are preferred. Manual metal arc welding is used mainly when other methods or suitable gas-shielded consumables are not available.

Filler wires for gas welding and gas shielded arc welding of copper and copper alloys are given in Tables 33.29 and 33.30.

Tough pitch copper, which contains residual oxygen, is available in several degrees of purity, and only the high conductivity grades of tough pitch copper should be used for welding. The inert gas-shielded processes are suitable using boron deoxidised copper filler (Table 33.30, C21) where electrical conductivity is important, or silicon–manganese deoxidised filler (Table 33.30, C7). Argon, helium, or mixtures of these gases should be used for shielding. Tough pitch copper may also be bronze welded with silicon bronze or aluminium bronze electrodes, or braze welded with filler to

Table 33.26a   PARENT METAL GROUPS USED IN TABLE 33.26c

Parent metal	*Alloys*
1XXX series	1080A, 1050A, 1200, 1350, LMO*
2XXX series	2014A, 2024, 2618A
3XXX series	3103, 3105
5XXX series	5251, 5454, 5154A
6XXX series	6063, 6061, 6082, 6101A
Al–Si castings	LM6, LM9, LM18, LM20, LM25
Al–Mg castings	LM5, LM10

* Included in this group for simplicity.

Table 33.26b   FILLER METAL GROUPS USED IN TABLE 33.26c

Filler metal group	*Alloys*
Pure Al	1080A, 1050A
Al–Si	4043A, 4047A*
Al–Mg	5056A, 5356, 5556A, 5183

* 4047A is used to prevent weld metal cracking in joints of high dilution and restraint. In most other cases, 4043A is preferable.

Table 33.26c   SELECTION OF FILLER ALLOYS FOR GAS SHIELDED ARC WELDING MATCHING AND DISSIMILAR ALUMINIUM ALLOYS

Parent metal combination	Al–Si castings	Al–Mg castings	3XXX	2XXX	1XXX	7020	6XXX	5005	5XXX	5083
5083	NR[1]	Al–Mg	Al–Mg	NR[2]	Al–Mg	556A	Al–Mg	Al–Mg	Al–Mg	5556A
5XXX	NR[1]	Al–Mg	Al–Mg	NR[2]	Al–Mg	Al–Mg	Al–Mg	Al–Mg[3]	Al–Mg[3]	
5005	Al–Si	Al–Mg	Al–Si	NR[2]	Al–Si	Al–Mg	Al–Si	Al–Mg[3]		
6XXX	Al–Si	Al–Mg	Al–Si	NR[2]			Al–Si or Al–Mg[4]			
7020	NR[1]	Al–Mg	Al–Mg	NR[2]	Al–Si	Al–Mg				
1XXX	Al–Si	Al–Mg	Al–Si	NR[2]	Al–Mg	5556A				
2XXX	NR[2]	NR[2]	NR[2]	NR[2]	Pure Al[5]					
3XXX	Al–Si	Al–Mg	3103[4]							
Al–Mg castings	NR[1]	Al–Mg								
Al–Si castings	Al–Si									

NR = not recommended.

[1] The welding of alloys containing approximately 2% or more of Mg with Al–Si filler metal (and vice-versa) is not recommended because sufficient Mg_2Si precipitate is formed at the fusion boundary to embrittle the joint.

[2] 2XXX alloys covered by British Standards are not regarded as weldable alloys, but 4047A gives the best chance of success.

[3] The corrosion behaviour of weld metal is likely to be better if its alloy content is close to that of the parent metal and not markedly higher. For service in potentially corrosive environments it is preferable to weld 5154A with 5154A filler metal or 5454 with 5554 filler metal. This may only be possible at the expense of weld soundness.

[4] Al–Si gives better crack resistance; Al–Mg gives higher weld metal ductility.

[5] For welding 1080A to itself, 1080A filler metal should be used.

§ 0.05%Mg max.

Table 33.29, C2 (silicon brass). The presence of arsenic does not affect weldability. Oxyacetylene welding is not recommended, due to the risk of 'gassing'.

Phosphorus-deoxidised (PDO) copper may be welded by the oxy-acetylene, TIG or MIG processes. Argon, helium or nitrogen may be used for gas-shielded methods, either separately or mixed. The use of nitrogen produces a hotter arc with increased penetration, but with MIG welding, less satisfactory metal transfer may result. Phosphorus content is important, and should be as low as possible to minimise porosity. Phosphorus does not act as an efficient deoxidant in gas-shielded welding, and for this reason filler wires containing additional deoxidants should be used. Autogenous welding is not possible without the risk of porosity, and if welding without filler wire is required, zinc deoxidised (cap) copper can be employed, using the TIG process. Zinc content is relatively unimportant within the range 0.5–3.0% zinc. Oxy-acetylene welds are made using a copper–silver–phosphorus filler rod (Table 33.29, Cl) and a flux. Such welds are hot hammered during welding to remove porosity and frequently cold hammered to improve mechanical properties.

Oxygen-free high conductivity copper may be oxy-acetylene welded without gassing, but if TIG or MIG welding is employed, there is a risk of porosity formation which may be overcome by using boron–copper filler wire.

All grades of copper may be bronze welded using the manual metal arc, TIG or MIG processes and fillers of the aluminium, silicon or tin bronze types. The technique involves the use of a wide edge preparation, preferably a fillet and the use of soft arcs to minimise penetration. Deoxidised and oxygen-free copper may also be braze welded using silicon brass (Table 33.29, C2) or manganese bronze (Table 33.29, C4) fillers.

COPPER–ALUMINIUM ALLOYS

Gas welding is not recommended but carbon arc welding using cryolite flux, manual metal arc welding, or preferably the argon or helium TIG welding processes may be used. The iron-bearing single phase alloy Cu/7 Al/3 Fe is normally welded with a nickel-bearing duplex alloy (Table 33.30, C20). Most duplex and complex bronzes are welded with fillers of matching composition, as are the manganese–aluminium bronzes. An important consideration is corrosion resistance, and care should be taken to avoid a combination of manganese–aluminium bronze and the normal single phase and duplex bronzes. The nickel-bearing filler C20 is resistant to dealuminification in all but the most severe environments and is frequently used as a facing deposit in welds in BS 1400: AB2C castings, which are normally made with 10% aluminium fillers (Table 33.30, C13). If a single phase deposit is required, C12 Fe filler may be used for a corrosion resistant layer on top of a more crack resistant filler. If stress corrosion is a problem, a small tin addition may be made to both parent and filler metals.

The welding of the aluminium bronzes should be carried out with as low a heat input as possible. Thus, preheating and high inter-run temperatures should be avoided, as should weaving when depositing filler metal. It is often necessary to give a post-weld thermal treatment to eliminate the risk of stress corrosion cracking.

COPPER–NICKEL ALLOYS

The problems of embrittlement and porosity in welding cupro-nickel may be overcome by using filler wires containing manganese as a desulphuriser and titanium as a deoxidant. Filler wires are available for 90/10 and 70/30 cupro-nickels (Table 33.30, C16 and C18). Either argon arc or inert-gas metal arc welding is normally employed, but flux-coated manual metal arc electrodes are available for some alloys.

COPPER–SILICON ALLOYS

Silicon bronzes and 'Everdur' are readily weldable, the inert-gas processes being preferred. Parent metal filler is employed (Table 33.30, C9). Bronze welding is also possible.

COPPER–TIN ALLOYS

Tin bronzes usually contain phosphorus, and their welding behaviour is somewhat similar to phosphorus deoxidised copper, both oxy-acetylene and TIG welds tending to be porous. Filler rods employed are given in Table 33.30 (C10, C11). Bronze welding is preferable.

The weldability of the gunmetals depends upon the lead content. Those containing 0.1%Pb are weldable by the TIG, MIG, manual metal arc and gas welding processes. At 0.1–0.5%Pb, manual metal arc with phosphorus bronze electrodes or bronze welding offers a reasonable chance of success. The leaded gunmetals can be considered to be unweldable although single layer cosmetic repairs may sometimes be made successfully.

Both classes of material have long freezing ranges and are consequently hot short. They are also subject to coring and shrinkage porosity if large molten pools are employed.

COPPER–ZINC ALLOYS

The welding of brass is not easy, due to excessive fume formation, and fume extraction plant may prove necessary. Oxy-acetylene welding using an oxidising flame and parent metal filler or silicon or manganese–brass or nickel–silver fillers is possible. TIG and MIG welding both employ zinc-free filler alloys in preference to brass, although brass fillers are available for the former process (Table 33.30). For manual metal arc and MIG welding, silicon bronze or aluminium bronze electrodes are employed. The susceptibility of brasses to season cracking should be borne in mind, and stress relief of brass components is desirable.

BERYLLIUM–COPPER

Alternating current TIG welding is preferred. In order to obtain the maximum joint efficiency, welding speed should be high, and post-weld heat treatment is essential. Both the high Be/low Co and high Co/low Be alloys should be welded in the solution heat-treated condition using high Be filler rods. Post-weld ageing will restore most of the strength and hardness. Although possible, consumable electrode methods are not recommended due to the toxicity problem.

CADMIUM–COPPER

Experience is limited, but it is suggested that for gas welding, filler rods to BS 1453 C1 (Table 33.29) should be used. Parent metal filler may be suitable for inert-gas welding. Cadmium is extremely toxic and fusion welding should be attempted only under stringent ventilation control.

CHROMIUM–COPPER

Chromium–copper is heat-treatable and suffers from a loss in mechanical properties in the heat affected zone. It also exhibits a tendency to hot shortness. Bronze welding with aluminium bronze filler has been successfully employed, but joint efficiencies are low after post-weld heat treatment. Joints of low restraint may be made using a d.c. electrode negative TIG technique with helium shielding. The components should be solution treated prior to welding, and subsequently aged.

OTHER COPPER-RICH ALLOYS

Silver–copper may be welded by the inert-gas processes using boron–copper filler wire. Tellurium– and selenium–copper suffer from excessive weld porosity. Leaded copper is hot short, and welding is difficult.

33.5.4   Lead and lead alloys

Lead and its alloys may be welded by the oxy-acetylene process using no flux and a neutral flame. Other fuel gases, such as hydrogen, butane or coal gas, may be used. The edges should be cleaned before welding, and parent metal filler is used. Other processes are little used.

33.5.5   Magnesium alloys

Magnesium alloys are preferably welded by the a.c. TIG process with argon shielding. Normal inert-gas metal arc welding is not suitable for magnesium because of the high deposition rates required.

Table 33.31 FILLER RODS AND WIRES FOR GAS-SHIELDED WELDING OF MAGNESIUM ALLOYS
(AFTER BS 2901:PART 4:1990)

Type	*Element*, wt %

MAG 111	2.5–3.5	0.6–1.4	0.15–0.40			
MAG 141	0.02 max	0.75–1.5	0.15 max	0.4–0.8		

However, the pulsed version of this process has found application. The use of gas welding is confined to the wrought Mg–Mn and Mg–Al–Zn alloys, and should never be used for fillet or lap welds or for welds in zirconium-bearing alloys due to the corrosion hazard from flux residues. Proprietary fluxes are available. Flux removal and chemical cleaning should be followed by chromating.

The argon arc process may be used for welding all the commercially available alloys, with the exception of the wrought Mg–3%Zn–0.7%Zr and Mg–5.5%Zn–0.7%Zr alloys and the cast Mg–4.5%Zn–0.7%Zr alloy.

British Standard filler alloys are listed in Table 33.31. For castings parent metal filler is invariably used. A guide to filler metal selection is given in Table 33.32 for wrought and cast products to BS 3370, 3372, 3373 and 2970.

33.5.6 Nickel and nickel alloys

These materials fall into two groups, namely solid solution and precipitation hardening alloys. Nickel alloys are highly sensitive to contamination during welding and to the presence of various minor impurities. To avoid weld cracking and porosity, all surfaces to be welded and filler rods must be grease-free and scrupulously clean. The presence of sulphur, lead and zinc are particularly detrimental, the effects of sulphur being most marked with the chromium-free alloys. Most nickel alloy weld metals are quite fluid and, if possible, components should be welded in the flat position.

It is normally recommended that nickel alloys be stress-free prior to welding. The solid solution hardened grades should be annealed, although a certain amount of cold work is permissible. Post-weld heat treatment is not usually necessary. Incoloy DS* containing silicon is sensitive to hot cracking and restraint must be kept to a minimum. Precipitation hardened materials should be solution treated before welding, and aged afterwards. Some materials based on the Ni–Al–Ti precipitation hardening system are susceptible to post-weld heat treatment cracking, depending on the joint restraint, as are austenitic stainless steels. In such cases, a full heat treatment after welding is recommended. HAZ liquation cracking may arise and in certain precipitation hardened alloys, such as Nimonic* 80A, 90 and PK33, restricts the thickness that can be welded to below 5 mm.

TIG welding, both manual and mechanised, is the most widely used process for sheet material. A.c. or d.c. may be employed, although the latter is preferred. Most alloys may be welded and suitable fillers are listed in Tables 33.33 and 33.34. Chromium-free grades are susceptible to porosity during autogenous welding, and the addition of filler is recommended so that at least 50% of the weld pool volume is constituted by filler metal. Commercial purity argon is generally used for shielding with additions of up to 10% hydrogen helping to reduce porosity and increase welding speeds. Helium or argon–helium mixtures are applicable and may also be advantageous in increasing welding speed. Nitrogen in the gas or from the atmosphere can cause porosity. Complete coverage of the weld area with shielding gas is essential. The largest gas nozzle possible should be used with the minimum practicable distance from the nozzle to the workpiece, while adequate gas backing must be applied. Many nickel alloys form tenacious oxide films, which tend to be patchy and interfere with weld uniformity. Argon–5% hydrogen mixtures can be used as backing and shielding gases to overcome such problems. Nickel–molybdenum alloys may give a very fluid weld pool, when the TIG process is preferred for positional welding, in view of the facility of control.

For welding nickel and its alloys in heavier gauges, manual metal arc and MIG welding are generally suitable, the welding technique differing little from that practised with austenitic stainless steels. With manual metal arc welding, it is advisable to use small gauge electrodes, and to allow cooling between weld runs. Complete slag removal is imperative, particularly for high temperature service where reactions between the metal and residual slag may cause severe corrosion. Table 33.34 gives typical consumables for some of the more common commercial alloys: d.c. current is essential with positive electrodes. There is no British Standard for manual metal arc electrodes for nickel alloys, but a number of proprietary makes are obtainable.

Argon shielding is preferred with MIG welding, although the addition of up to 20% helium may be of benefit in spreading the weld pool and reducing the incidence of cold laps. Spray, globular dip, or dip transfer conditions have been employed for most nickel alloys, with consumables shown in Tables 33.33 and 33.34. Spray transfer gives the highest deposition rates but may cause weld metal cracking, particularly if the welding conditions are such that a weld bead with a concave surface is produced. Pulsed MIG welding has also been found applicable for nickel alloys, especially for positional welding.

Oxy-acetylene welding is little used for nickel alloys. It is suitable for most solid solution hardened alloys and Monel K-500, although carbon pick-up may reduce corrosion resistance. Nickel and Incoloy DS can be welded without flux while fluxes are available for the Monel, Incoloy, Inconel, Brightray and Hastelloy D alloys. Fluxes used with the chromium-containing alloys must be free from boron, since the presence of boron compounds can cause weld metal cracking. Complete flux removal after welding is essential. The flame should be slightly reducing for nickel and Monel 400, more reducing with the chromium-containing alloys, and highly reducing for Monel K-500 and Hastelloy D. Filler alloys are given in Table 33.34.

Submerged-arc welding is applicable to various nickel alloys, generally when heavy section material is being joined for corrosion resistant applications. Only a limited range of flux types is available. D.c. is used, with electrode positive being preferred to obtain deeper penetration and reduced risk of slag entrapment.

Electron beam welding can be used for most nickel alloys, and is a common fabrication process for high temperature items such as gas turbine components.

33.5.7 Noble metals

SILVER

Silver is difficult to weld due to its property of oxygen absorption. A slightly reducing flame is used for oxy-acetylene welding with a borax–boric acid flux. Silver–0.5% aluminium rods reduce the tendency to porosity formation. Argon arc welding using d.c. is possible, though slight porosity is usually present. A.c. argon arc welding using aluminium bearing fillers or traces of aluminium powder in the joint preparation is also possible.

GOLD

Gold and gold–copper alloys are readily welded by the gas welding process using parent metal filler and borax fluxes. A reducing flame is recommended for the alloys.

PLATINUM

An oxidising oxy-hydrogen flame is used without flux. The platinum–rhodium and platinum–iridium alloys may also be welded using this technique.

33.5.8 Refractory metals

The problem common to the welding of this group of materials is their strong affinity for atmospheric and other gases, and the consequent need to avoid contamination, both of the molten pool and the surfaces of the cooling solidified weld bead and heat affected zones. For arc welding this problem is overcome in two ways, either by provision of a complete argon-filled chamber in which the workpiece and welding head is placed, or by the provision of extended argon shrouds and argon backing.

These materials may all be welded by the tungsten inert gas arc process, and titanium has been successfully welded by the inert-gas metal arc process. The use of this process may eventually be extended to cover other materials in this group. Electron beam welding is also generally applicable, while, given appropriate gas shielding, laser welding may be suitable in some cases. Solid state joining by friction welding and diffusion welding is summarised in Tables 33.5 and 33.6, respectively.

TITANIUM AND TITANIUM ALLOYS

The α titanium alloys (e.g. commercially pure Ti, Ti–5%Al–2$\frac{1}{2}$%Sn) are fully weldable, as are alloys with only small amounts of eutectoid formers or β stabilisers (e.g. Ti–2$\frac{1}{2}$%Cu, Ti–8%Al–1%Mo–1%V, Ti–7%Al–2%Nb–1%Ta). As the β stabiliser content rises, the weld zone becomes less ductile and eventually brittle. The Ti–6%Al–4%V alloy represents about the limiting composition for $\alpha\beta$ alloys for good weldability.

In the weldable alloys, TIG welds (d.c., electrode negative) may be made without filler or with parent metal filler depending on thickness. For $\alpha\beta$ alloys, the ductility of the weld metal can be increased by using commercially pure Ti filler, but this will not improve the ductility of the heat affected zone. MIG welding is feasible, but experience is limited. All metal reaching higher than 600–650°C should be protected by argon.

NIOBIUM AND TANTALUM AND THEIR ALLOYS

The same technique as for titanium should be used, except that argon protection will be required at and above 400°C.

MOLYBDENUM

Electron beam and TIG (d.c., electrode negative) welds can be made, but the weld zone will be brittle below 300–500°C. The techniques used for titanium should be applied. The metal produced by sintering gives grossly porous welds, and that made by arc casting should be used.

ZIRCONIUM ALLOYS

Experience is limited to the zirconium–tin and zirconium–niobium alloys, which are used in nuclear engineering. These materials are particularly susceptible to nitrogen contamination, which is harmful to the corrosion resistance. Superficial contamination during welding is removed by pickling. D.c. electrode negative is used, and gas cover should extend to areas in excess of 400°C.

URANIUM

Uranium may be welded without difficulty by the TIG process using d.c. electrode negative. It is less sensitive to contamination than titanium.

33.5.9   Zinc and zinc alloys

Zinc and zinc-base castings are difficult to weld. The oxy-acetylene process using a slightly reducing flame and a zinc-ammonium chloride flux is most suitable. Parent metal filler should be used.

33.5.10   Dissimilar metals

Direct fusion welding of dissimilar metals is possible in certain cases, and special techniques have been developed for difficult combinations.

Steels may be joined to nickel alloys, but the joint dilution and selection of filler materials must be made to give either a high nickel-alloy weld or a weld composition falling within the shaded area of the Schaeffler diagram (Figure 33.3).

Combinations of copper and chromium should be avoided, as when welding Monel to chromium bearing steels, and in such cases, nickel-base filler should be interposed.

Steels may be joined to copper and copper alloys by bronze welding techniques, but joining to aluminium involves precoating of the steel with aluminium–silicon brazing alloy, and joint ductility is low.

Copper may be welded direct to nickel, provided a deoxidant (titanium) is present either in the nickel or the filler wire.

Copper to aluminium joints are made by coating the copper with a layer of silver solder (BS 1845: Type AG1 or AG2) and welding by argon arc or inert gas metal arc processes, using aluminium 10% silicon filler.

33.6   Major standards relating to welding, brazing and soldering

It is impossible to list all the standards relating to welding, brazing and soldering, considering the quantity of standards issued by many different nations and organizations and the growth of this body of documents on a daily basis. Therefore, internationally-agreed standards are becoming more and more important, especially considering the increasing economic globalisation in the past few decades. It is a recently accelerating trend that individual European national standards, such as British Standards (BS), are being gradually replaced by European standards, and/or by the International Organization for Standardization (ISO) standards. European standards issued by the European Committee for Standardization (CEN) are increasingly similar in structure and scope to the ISO. The following tables cover some of the major ISO, European, British, AWS, and Canadian standards relating to welding, brazing and soldering, in which the ISO and European standards are listed according to the International Classification for Standards (ICS). European Standards that are identical to ISO are not included. Instead, the listing for the ISO standards (Table 1) includes cross-references. Similarly, British Standards that are identical to ISO or EN are not included. Instead, the listing for the ISO standards (Table 33.35) or European Standards (Table 33.36) includes a cross-reference.

9692:	Welding and allied processes—Joint preparation Part 2:1998 Submerged arc welding of steels (Incorporated in EN ISO 9692-2:1998, BS EN ISO 9692-2:1998) Part 3:2000 Metal inert gas welding and tungsten inert gas welding of aluminium and its alloys (Incorporated in EN ISO 9692-3:2001)
9956:	Specification and approval of welding procedures for metallic materials Part 1:1995 General rules for fusion welding Part 1:1995/Amd 1:1998 Part 2:1995 Welding procedure specification for arc welding Part 2:1995/Amd 1:1998 Part 3:1995 Welding procedure tests for arc welding of steels Part 3:1995/Amd 1:1998 Part 4:1995 Welding procedure tests for the arc welding of aluminium and its alloys Part 4:1995/Amd 1:1998 Part 5:1995 Approval by using approved welding consumables for arc welding Part 6:1995 Approval related to previous experience Part 7:1995 Approval by a standard welding procedure for arc welding Part 8:1995 Approval by a pre-production welding test Part 10:1996 Welding procedure specification for electron beam welding (Incorporated in EN ISO 9956-10:1996, BS EN ISO 9956-10:1997) Part 11:1996 Welding procedure specification for laser beam welding (Incorporated in EN ISO 9956-11:1996, BS EN ISO 9956-11:1997)
11970:2001	Specification and approval of welding procedures for production welding of steel castings
13916:1996	Welding—Guidance on the measurement of preheating temperature, interpass temperature and preheat maintenance temperature (Incorporated in EN ISO 13916: 1996, BS EN ISO 13916:1997)
13920:1996	Welding—General tolerances for welded constructions—Dimensions for lengths and angles—Shape and position (Incorporated in EN ISO 13920:1996, BS EN ISO 13920:1997)
14555:1998	Welding—Arc stud welding of metallic materials (Incorporated in EN ISO 14555: 1998, BS EN ISO 14555:1998)
15609:	Specification and qualification of welding procedures for metallic materials—Welding procedure specification Part 2:2001 Gas welding (Incorporated in EN ISO 15609-2:2001, BS EN ISO 15609-2:2001)
15620:2000	Welding—Friction welding of metallic materials (Incorporated in BS EN ISO 15620:2000)

ICS: 25.160.20 Welding consumables (including electrodes, filler metals, gases, etc.)

544:1989	Filler materials for manual welding—Size requirements
636:1989	Bare solid filler rods for oxy-acetylene and tungsten inert gas arc (TIG) welding, depositing an unalloyed or low alloyed steel—Codification

(*continued*)

Table 33.35 ISO STANDARDS RELATING TO WELDING, BRAZING AND SOLDERING—*continued*

864:1988	Arc welding—Solid and tubular cored wires which deposit carbon and carbon manganese steel—Dimensions of wires, spools, rims and coils
1071:1983	Covered electrodes for manual arc welding of cast iron—Symbolisation
2401:1972	Covered electrodes—Determination of the efficiency, metal recovery and deposition coefficient (Incorporated in EN 22401:1994, BS EN 22401:1994)
2560:1973	Covered electrodes for manual arc welding of mild steel and low alloy steel—Code of symbols for identification ISO 2560:1973/Add 1:1974
3580:1975	Covered electrodes for manual arc welding of creep-resisting steels—Code of symbols for identification
3581:1976	Covered electrodes for manual arc welding of stainless and other similar high alloy steels—Code of symbols for identification
5182:1991	Welding—Materials for resistance welding electrodes and ancillary equipment
5184:1979	Straight resistance spot welding electrodes (Incorporated in EN 25184:1994, BS EN 25184:1995)
6847:2000	Welding consumables—Deposition of a weld metal pad for chemical analysis (Incorporated in EN ISO 6847:2001, BS EN 6847:1994)
6848:1984	Tungsten electrodes for inert gas shielded arc welding, and for plasma cutting and welding—Codification (Incorporated in EN 26848:1991, BS EN 26848:1991)
10446:1990	Welding—All-weld metal test assembly for the classification of corrosion-resisting chromium and chromium–nickel steel covered arc welding electrodes
14175:1997	Welding consumables—Shielding gases for arc welding and cutting
14372:2000	Welding consumables—Determination of moisture resistance of manual metal arc welding electrodes by measurement of diffusible hydrogen
15792:	Welding consumables—Test methods Part 1:2000 Test methods for all-weld metal test specimens in steel, nickel and nickel alloys Part 2:2000 Preparation of single-run and two-run technique test specimens in steel Part 3:2000 Classification testing of positional capacity and root penetration of welding consumables in a fillet weld

ICS: 25.160.30 Welding equipment (including thermal cutting equipment)

669:2000	Resistance welding—Resistance welding equipment—Mechanical and electrical requirements (Incorporated in BS 3065:2001)
693:1982	Dimensions of seam welding wheel blanks (Incorporated in EN ISO 20693:1991, BS EN 20693:1992)
865:1981	Slots in platens for projection welding machines (Incorporated in EN 20865:1991, BS EN 20865:1992)
1089:1980	Electrode taper fits for spot welding equipment—Dimensions (Incorporated in EN 21089:1991, BS EN 21089:1992)
2503:1998	Gas welding equipment—Pressure regulators for gas cylinders used in welding, cutting and allied processes up to 300 bar
3253:1998	Gas welding equipment—Hose connections for equipment for welding, cutting and allied processes
3821:1998	Gas welding equipment—Rubber hoses for welding, cutting and allied processes
5171:1995	Pressure gauges used in welding, cutting and allied processes
5172:1995	Manual blowpipes for welding, cutting and heating—Specifications and tests (Incorporated in EN ISO 5172:1996, BS EN ISO 5172:1997) ISO 5172:1995/Amd 1:1995
5175:1987	Equipment used in gas welding, cutting and allied processes—Safety devices for fuel gases and oxygen or compressed air—General specifications, requirements and tests
5183:	Resistance welding equipment—Electrode adaptors, male taper 1:10 Part 1:1998 Conical fixing, taper 1:10 (Incorporated in EN ISO 5183-1:2000, BS EN ISO 5183-1:2001) Part 2:2000 Parallel shank fixing for end-thrust electrodes (Incorporated in EN 25183-2:1991, BS EN 25183-2:1992)

Table 33.35 ISO STANDARDS RELATING TO WELDING, BRAZING AND SOLDERING—*continued*

5186:1995	Oxygen/fuel gas blowpipes (cutting machine type) with cylindrical barrels—General specifications and test methods
5821:1979	Resistance spot welding electrode caps (Incorporated in EN 25821:1991, BS EN 25821:1992)
5822:1988	Spot welding equipment—Taper plug gauges and taper ring gauges (Incorporated in EN 25822:1991, BS EN 25822:1992)
5826:1999	Electric resistance welding—Transformers—General specifications applicable to all transformers (Incorporated in BS 7125:1989)
5827:1983	Spot welding—Electrode back-ups and clamps (Incorporated in EN 25827:1992, BS EN 25827:1992)
5828:2001	Resistance welding equipment—Secondary connecting cables with terminals connected to water-cooled lugs—Dimensions and characteristics (Incorporated in EN ISO 5828: 2001, BS EN 5828:2001)
5829:1984	Resistance spot welding—Electrode adaptors, female taper 1 : 10
5830:1984	Resistance spot welding—Male electrode caps
6210:	Cylinders for robot resistance welding guns Part 1:1991 General requirements
7284:1993	Resistance welding equipment—Particular specifications applicable to transformers with two separate secondary windings for multi-spot welding, as used in the automobile industry (Incorporated in EN ISO 7284:1996, BS EN ISO 7284:1996)
7285:1995	Pneumatic cylinders for mechanised multiple spot welding
7286:1986	Graphical symbols for resistance welding equipment (Incorporated in EN 27286:1991, BS EN 27286:1995)
7287:1992	Graphical symbols for thermal cutting equipment (Incorporated in EN ISO 7287:1995, BS EN ISO 7287:1995)
7289:1996	Quick-action couplings with shut-off valves for gas welding, cutting and allied processes
7291:1999	Gas welding equipment—Pressure regulators for manifold systems used in welding, cutting and allied processes up to 300 bar (Incorporated in BS EN ISO 7291:2001)
7292:1997	Flowmeter regulators used on cylinders for welding, cutting and allied processes—Classification and specifications
7931:1985	Insulation caps and bushes for resistance welding equipment (Incorporated in EN 27931:1992)
8167:1989	Projections for resistance welding (Incorporated in BS EN 28167:1992)
8205:	Water-cooled secondary connection cables for resistance welding Part 1:1993 Dimensions and requirements for double-conductor connection cables (Incorporated in EN ISO 8205-1:1996, BS EN ISO 8205-1:1997) Part 2:1993 Dimensions and requirements for single-conductor connection cables (Incorporated in EN ISO 8205-2:1996, BS EN ISO 8205-2:1997) Part 3:1993 Test requirements (Incorporated in EN ISO 8205-3:1996, BS EN ISO 8205-3:1997)
8206:1991	Acceptance tests for oxygen cutting machines—Reproducible accuracy—Operational characteristics (Incorporated in EN 28206:1992, BS EN 28206:1992)
8207:1996	Gas welding equipment—Specification for hose assemblies for equipment for welding, cutting and allied processes
8430:	Resistance spot welding—Electrode holders Part 1:1988 Taper fixing 1:10 (Incorporated in EN 28430-1:1992, BS EN 28430-1:1992) Part 2:1988 Morse taper fixing (Incorporated in EN 28430-2:1992, BS EN 28430-2:1992) Part 3:1988 Parallel shank fixing for end thrust (Incorporated in EN 28430-3:1992, BS EN 28430-3:1992) Part 3:1988/Cor 1:1990
9012:1998	Gas welding equipment—Air-aspirated hand blowpipes—Specifications and tests
9090:1989	Gas tightness of equipment for gas welding and allied processes (Incorporated in EN 29090:1992, BS EN 29090:1992)
9312:1990	Resistance welding equipment—Insulated pins for use in electrode back-ups (Incorporated in EN ISO 9312:1994, BS EN ISO 9312:1995)

(*continued*)

Table 33.35 ISO STANDARDS RELATING TO WELDING, BRAZING AND SOLDERING—*continued*

9313:1989	Resistance spot welding equipment—Cooling tubes (Incorporated in EN 29313:1992, BS EN 29313:1992)
9539:1988	Materials for equipment used in gas welding, cutting and allied processes (Incorporated in EN 29539:1992, BS EN 29539:1992)
10656:1996	Electric resistance welding—Integrated transformers for welding guns ISO 10656:1996/Cor 1:2000
11032:1994	Manipulating industrial robots—Application oriented test—Spot welding
12145:1998	Resistance welding equipment—Angles for mounting spot welding electrodes
12166:1997	Resistance welding equipment—Particular specifications applicable to transformers with one secondary winding for multi-spot welding, as used in the automobile industry
12170:1996	Gas welding equipment—Thermoplastic hoses for welding and allied processes
14112:1996	Gas welding equipment—Small kits for gas brazing and welding
14113:1997	Gas welding equipment—Rubber and plastic hoses assembled for compressed or liquefied gases up to a maximum design pressure of 450 bar (Incorporated in 14113:1997)
14114:1999	Gas welding equipment—Acetylene manifold systems for welding, cutting and allied processes—General requirements (Incorporated in EN ISO 14114:1999, BS EN ISO 14114:1999)
14744:	Welding—Acceptance inspection of electron beam welding machines Part 1:2000 Principles and acceptance conditions (Incorporated in BS EN ISO 14744-1:2001) Part 2:2000 Measurement of accelerating voltage characteristics (Incorporated in BS EN ISO 14744-2:2001) Part 3:2000 Measurement of beam current characteristics (Incorporated in BS EN ISO 14744-3:2001) Part 4:2000 Measurement of welding speed (Incorporated in BS EN ISO 14744-4:2001) Part 5:2000 Measurement of run-out accuracy (Incorporated in BS EN ISO 14744-5:2001) Part 6:2000 Measurement of stability of spot position (Incorporated in BS EN ISO 14744-6:2001)

ICS: 25.160.40 Welded joints (including welding position and mechanical and non-destructive testing of welded joints)

1106:	Recommended practice for radiographic examination of fusion welded joints Part 1:1984 Fusion welded butt joints in steel plates up to 50 mm thick Part 2:1985 Fusion welded butt joints in steel plates thicker than 50 mm and up to and including 200 mm in thickness Part 3:1984 Fusion welded circumferential joints in steel pipes of up to 50 mm wall thickness
2400:1972	Welds in steel—Reference block for the calibration of equipment for ultrasonic examination
2437:1972	Recommended practice for the X-ray inspection of fusion welded butt joints for aluminium and its alloys and magnesium and its alloys 5 to 50 mm thick
2504:1973	Radiography of welds and viewing conditions for films—Utilisation of recommended patterns of image quality indicators (I.Q.I.)
2553:1992	Welded, brazed and soldered joints—Symbolic representation on drawings (Incorporated in EN 22553:1994, BS EN 22553:1995)
3088:1975	Welding requirements—Factors to be considered in specifying requirements for fusion welded joints in steel (technical influencing factors)
3690:2000	Welding and allied processes—Determination of hydrogen content in ferritic steel arc weld metal (Incorporated in EN ISO 3690:2000, BS EN ISO 3690:2001)
4136:2001	Destructive tests on welds in metallic materials—Transverse tensile test
5173:2000	Destructive tests on welds in metallic materials—Bend tests
5178:2001	Destructive tests on welds in metallic materials—Longitudinal tensile test on weld metal in fusion welded joints
5817:1992	Arc-welded joints in steel—Guidance on quality levels for imperfections (Incorporated in EN 25817:1992, BS EN 25817:1992)

Table 33.35   ISO STANDARDS RELATING TO WELDING, BRAZING AND SOLDERING—*continued*

6520:	Welding and allied processes—Classification of geometric imperfections in metallic materials Part 1:1998 Fusion welding (Incorporated in EN ISO 6520-1:1998, BS EN ISO 6520-1:1998)
6947:1990	Welds—Working positions—Definitions of angles of slope and rotation (Incorporated in EN ISO 6947:1997, BS EN ISO 6947:1997)
7963:1985	Welds in steel—Calibration block No. 2 for ultrasonic examination of welds (Incorporated in EN 27963:1992, BS EN 2763:1992)
8249:2000	Welding—Determination of Ferrite Number (FN) in austenitic and duplex ferritic-austenitic Cr–Ni stainless steel weld metals (Incorporated in EN ISO 8248:2000, BS EN ISO 8249:2000)
9015:	Destructive tests on welds in metallic materials—Hardness testing Part 1:2001 Hardness test on arc welded joints
9016:2001	Destructive tests on welds in metallic materials—Impact tests—Test specimen location, notch orientation and examination
9017:2001	Destructive tests on welds in metallic materials—Fracture test
9692:1992	Metal-arc welding with covered electrode, gas-shielded metal-arc welding and gas welding—Joint preparations for steel (Incorporated in BS EN ISO 29692-3:2001)
9764:1989	Electric resistance and induction welded steel tubes for pressure purposes—Ultrasonic testing of the weld seam for the detection of longitudinal imperfections
9765:1990	Submerged arc-welded steel tubes for pressure purposes—Ultrasonic testing of the weld seam for the detection of longitudinal and/or transverse imperfections
10042:1992	Arc-welded joints in aluminium and its weldable alloys—Guidance on quality levels for imperfections (Incorporated in EN 30042:1994, BS EN 30042:1994)
10447:1991	Welding—Peel and chisel testing of resistance spot, projection and seam welds
12096:1996	Submerged arc-welded steel tubes for pressure purposes—Radiographic testing of the weld seam for the detection of imperfections
13663:1995	Welded steel tubes for pressure purposes—Ultrasonic testing of the area adjacent to the weld seam for the detection of laminar imperfections
13919:	Welding—Electron and laser-beam welded joints—Guidance on quality levels for imperfections Part 1:1996 Steel (Incorporated in EN ISO 13919-1:1996, BS EN ISO 13919-1:1997) Part 2:2001 Aluminium and its weldable alloys
14270:2000	Specimen dimensions and procedure for mechanised peel testing resistance spot, seam and embossed projection welds
14271:2000	Vickers hardness testing of resistance spot, projection and seam welds (low load and microhardness)
14272:2000	Specimen dimensions and procedure for cross tension testing resistance spot and embossed projection welds
14273:2000	Specimen dimensions and procedure for shear testing resistance spot, seam and embossed projection welds

ICS: 25.160.50 Brazing and soldering (including brazing and soldering alloys and equipment)

857:	Welding and allied processes—Vocabulary Part 1:1998 Metal welding processes
3677:1992	Filler metal for soft soldering, brazing and braze welding—Designation (Incorporated in EN ISO 3677:1995, BS EN ISO 3677:1995)
5179:1983	Investigation of brazeability using a varying gap test piece
5187:1985	Welding and allied processes—Assemblies made with soft solders and brazing filler metals—Mechanical test methods
9453:1990	Soft solder alloys—Chemical compositions and forms (Incorporated in EN 29453:1993, BS EN 29453:1994)

Table 33.35   ISO STANDARDS RELATING TO WELDING, BRAZING AND SOLDERING—*continued*

9454:	Soft soldering fluxes—Classification and requirements Part 1:1990 Classification, labelling and packaging (Incorporated in EN 29454-1:1993, BS EN 29454-1:1994) Part 2:1998 Performance requirements (Incorporated in EN ISO 9454-2:2000, BS EN ISO 9454-2:2001)
9455:	Soft soldering fluxes—Test methods Part 1:1990 Determination of non-volatile matter, gravimetric method (Incorporated in EN 29455-1:1993, BS EN 29455-1:1994) Part 2:1993 Determination of non-volatile matter, ebulliometric method (Incorporated in EN ISO 9455-2:1995, BS EN ISO 9455-2:1996) Part 3:1992 Determination of acid value, potentiometric and visual titration methods (Incorporated in EN ISO 9455-3:1994, BS EN ISO 9455-3:1995) Part 5:1992 Copper mirror test (Incorporated in EN 29455-5:1993, BS EN 29455-5:1993) Part 6:1995 Determination and detection of halide (excluding fluoride) content (Incorporated in EN ISO 9455-6:1997, BS EN ISO 9455-6:1997) Part 8:1991 Determination of zinc content (Incorporated in EN 29455-8:1993, BS EN 29455-8:1993) Part 9:1993 Determination of ammonia content (Incorporated in EN ISO 9455-9:1995, BS EN ISO 9455-9:1996) Part 10:1998 Flux efficacy tests, solder spread method (Incorporated in EN ISO 9455-10:2000, BS EN ISO 9455-10:2001) Part 11:1991 Solubility of flux residues (Incorporated in EN 29455-11:1993, BS EN 29455-11:1993) Part 12:1992 Steel tube corrosion test (Incorporated in EN ISO 9455-12:1994, BS EN ISO 9455-12:1994) Part 13:1996 Determination of flux spattering (Incorporated in EN ISO 9455-13:1999, BS EN ISO 9455-13:2000) Part 14:1991 Assessment of tackiness of flux residues (Incorporated in EN 29455-14:1993, BS EN 29455-14:1993) Part 15:1996 Copper corrosion test (Incorporated in EN ISO 9455-15:1999, BS EN ISO 9455-15:2000) Part 16:1998 Flux efficacy tests, wetting balance method (Incorporated in EN ISO 9455-16:2001)
10564:1993	Soldering and brazing materials—Methods for the sampling of soft solders for analysis (Incorporated in EN ISO 10564:1997, BS EN ISO 10564:1997)
12224:	Solder wire, solid and flux cored—Specification and test methods Part 1:1997 Classification and performance requirements (Incorporated in EN ISO 12224-1:1998, BS EN ISO 12224-1:1998) Part 2:1997 Determination of flux content (Incorporated in EN ISO 12224-2:1999, BS EN ISO 12224-2:1999)
14112:1996	Gas welding equipment—Small kits for gas brazing and welding

440:1994	Welding consumables—Wire electrodes and deposits for gas shielded metal arc welding of non alloy and fine grain steels—Classification (Incorporated in BS EN 440:1995)
499:1994	Welding consumables—Covered electrodes for manual metal arc welding of non alloy and fine grain steels—Classification (Incorporated in BS EN 499:1995)
60974:	Arc welding equipment Part 11:1995 Electrode holders (Incorporated in BS EN 60974: Part 11:1996)
756:1995	Welding consumables—Wire electrodes and wire-flux combinations for submerged arc welding of non alloy and fine grain steels—Classification (Incorporated in BS EN 756:1996)
757:1997	Welding consumables—Covered electrodes for manual metal arc welding of high strength steels—Classification (Incorporated in BS EN 757:1997)
758:1997	Welding consumables—Tubular cored electrodes for metal arc welding with and without a gas shield of non alloy and fine grain steels—Classification (Incorporated in BS EN 758:1997)
759:1997	Welding consumables—Technical delivery conditions for welding filler metals—Type of product, dimensions, tolerances and marking (Incorporated in BS EN 759:1997)
760:1996	Welding consumables—Fluxes for submerged arc welding—Classification (Incorporated in BS EN 760:1996)

(*continued*)

Table 33.36   EUROPEAN STANDARDS RELATING TO WELDING, BRAZING AND SOLDERING—*continued*

1597:	Welding consumables—Test methods Part 1:1997 Test piece for all-weld metal test specimens in steel, nickel and nickel alloys (Incorporated in BS EN 597:1997) Part 2:1997 Preparation of test piece for single-run and two-run technique test specimens in steel (Incorporated in BS EN 1597-2:1997) Part 3:1997 Testing of positional capability of welding consumables in a fillet weld (Incorporated in BS EN 1597-3:1997)
1599:1997	Welding consumables—Covered electrodes for manual arc welding of creep-resisting steels—Classification (Incorporated in BS EN 1599:1997)
1600:1997	Welding consumables—Covered electrodes for manual arc welding of stainless and heat resisting steels—Classification (Incorporated in BS EN 1600:1997)
1668:1997	Welding consumables—Rods, wires and deposits for tungsten inert gas welding of non alloy and fine grain steels—Classification (Incorporated in BS EN 1668:1997)
12070:1999	Welding consumables—Wire electrodes, wires and rods for arc welding of creep-resisting steels—Classification (Incorporated in BS EN 12070:2000)
12071:1999	Welding consumables—Tubular cored electrodes for gas shielded metal arc welding of creep-resisting steels—Classification (Incorporated in BS EN 12071:2000)
12072:1999	Welding consumables—Wire electrodes, wires and rods for arc welding of stainless and heat-resisting steels—Classification (Incorporated in BS EN 12072:2000)
12073:1999	Welding consumables—Tubular cored electrodes for metal arc welding with or without a gas shield of stainless and heat-resisting steels—Classification (Incorporated in BS EN 12073:2000)
12074:2000	Welding consumables—Quality requirements for manufacture, supply and distribution of consumables for welding and allied processes (Incorporated in BS EN 12074:2000)
12534:1999	Welding consumables—Wire electrodes, wires, rods and deposits for gas shielded metal arc welding of high strength steels—Classification (Incorporated in BS EN 12534:1999)
12535:2000	Welding consumables—Tubular cored electrodes for gas shielded metal arc welding of high strength steels—Classification (Incorporated in BS EN 12535:2000)
12536:2000	Welding consumables—Rods for gas welding of non alloy and creep-resisting steels—Classification (Incorporated in BS EN 12536:2000)
12943:1999	Filler materials for thermoplastics—Scope, designation, requirements, tests (Incorporated in BS EN 12943:2000)
28167:1992	Projections for resistance welding (8167:1989) (Incorporated in BS EN 28167:1992)

ICS: 25.160.30 Welding equipment (including thermal cutting equipment)

559:1994	Gas welding equipment. Rubber hoses for welding, cutting and allied processes (Incorporated in BS EN 559:1994)
560:1994	Gas welding equipment. Hose connections for welding, cutting and allied processes (Incorporated in BS EN 560:1995)
561:1994	Gas welding equipment. Quick-action couplings with shut-off valves for welding, cutting and allied processes (Incorporated in BS EN 561:1995)
562:1994	Gas welding equipment—Pressure gauges used in welding, cutting and allied processes
730:1995	Gas welding equipment—Equipment used in gas welding, cutting and allied processes, safety devices for fuel gases and oxygen or compressed air—General specifications, requirements and tests (Incorporated in BS EN 730:1995)
731:1995	Gas welding equipment—Air-aspirated hand blowpipes—Specifications and tests (Incorporated in BS EN 731:1996)
874:1995	Gas welding equipment—Oxygen/fuel gas blowpipes (cutting machine type) of cylindrical barrel—Type of construction, general specifications, test methods (Incorporated in BS EN 874:1995)
961:1995	Gas welding equipment. Manifold regulators used in welding, cutting and allied processes up to 200 bar (Incorporated in BS EN 961:1996)
1256:1996	Gas welding equipment. Specification for hose assemblies for equipment for welding, cutting and allied processes (Incorporated in BS EN 1256:1996)

(*continued*)

Table 33.36   EUROPEAN STANDARDS RELATING TO WELDING, BRAZING AND SOLDERING—*continued*

1327:1996	Gas welding equipment. Thermoplastic hoses for welding and allied processes (Incorporated in BS EN 1327:1996)
50063:1989	Specification for safety requirements for the construction and the installation of equipment for resistance welding and allied processes (Incorporated in BS 5924:1989)
50199:1995	Electromagnetic compatibility (EMC). Product standard for arc welding equipment (Incorporated in BS EN 50199:1996)
60974:	Arc welding equipment. Part 1:1998, IEC 60974-1:1998 Welding power sources (Incorporated in BS EN 60974:Part 1:1998) Part 7:2000, IEC 60974-7:2000 Arc welding equipment. Torches (Incorporated in BS EN 60974:Part 11:2000) Part 12:1995 Arc welding equipment. Coupling devices for welding cables (Incorporated in BS EN 60974:Part 12:1996)

ICS: 25.160.40 Welded joints (including welding position and mechanical and non-destructive testing of welded joints)

875:1995	Destructive tests on welds in metallic materials—Impact tests—Test specimen location, notch orientation and examination (Incorporated in BS EN 875:1995)
876:1995	Destructive tests on welds in metallic materials—Longitudinal tensile test on weld metal in fusion welded joints (Incorporated in BS EN 876:1995)
895:1995	Destructive tests on welds in metallic materials—Transverse tensile test (Incorporated in BS EN 895:1995)
910:1996	Destructive tests on welds in metallic materials—Bend tests (Incorporated in BS EN 910:1996)
970:1997	Non-destructive examination of fusion welds—Visual examination (Incorporated in BS EN 970:1997)
1043:	Destructive tests on welds in metallic materials—Hardness testing Part 1:1995 Hardness test on arc welded joints (Incorporated in BS EN 1043-1:1996) Part 2:1996 Micro hardness testing on welded joints (Incorporated in BS EN 1043-2:1997)
1289:1998	Non-destructive examination of welds—Penetrant testing of welds—Acceptance levels (Incorporated in BS EN 1289:1998)
1290:1998	Non-destructive examination of welds—Magnetic particle examination of welds (Incorporated in BS EN 1290:1998)
1291:1998	Non-destructive examination of welds—Magnetic particle testing of welds—Acceptance levels (Incorporated in BS EN 1291:1998)
1320:1996	Destructive tests on welds in metallic materials—Fracture test (Incorporated in BS EN 1320:1997)
1321:1996	Destructive tests on welds in metallic materials—Macroscopic and microscopic examination of welds (Incorporated in BS EN 1321:1997)
1435:1997	Non-destructive examination of welds—Radiographic examination of welded joints (Incorporated in BS EN 1435:1997)
1708:	Welding—Basic weld joint details in steel Part 1:1999 Pressurised components (Incorporated in BS EN 1708-1:1999) Part 2:2000 Non internal pressurised components (Incorporated in BS EN 1708-2:2000)
1711:2000	Non-destructive examination of welds—Eddy current examination of welds by complex plane analysis (Incorporated in BS EN 1711:2000)
1712:1997	Non-destructive examination of welds—Ultrasonic examination of welded joints—Acceptance levels (Incorporated in BS EN 1712:1997)
1713:1998	Non-destructive examination of welds—Ultrasonic examination—Characterisation of indications in welds (Incorporated in BS EN 1713:1998)
1714:1997	Non-destructive examination of welds—Ultrasonic examination of welded joints (Incorporated in BS EN 1714:1998)
2497:1989	Specification for dry abrasive blasting of titanium and titanium alloys (Incorporated in BS EN 2497:1990)

Table 33.36   EUROPEAN STANDARDS RELATING TO WELDING, BRAZING AND SOLDERING—*continued*

2574:1990	Aerospace series—Welds—Information on drawings
10246:	Non-destructive testing of steel tubes Part 10:2000 Radiographic testing of the weld seam of automatic fusion arc welded steel tubes for the detection of imperfections (Incorporated in BS EN 10246-10:2000) Part 16:2000 Automatic ultrasonic testing of the area adjacent to the weld seam of welded steel tubes for the detection of laminar imperfections (Incorporated in BS EN 10246-16:2000) Part 8:1999 Automatic ultrasonic testing of the weld seam of electric welded steel tubes for the detection of longitudinal imperfections (Incorporated in BS EN 10246-8:2000) Part 9:2000 Automatic ultrasonic testing of the weld seam of submerged arc welded steel tubes for the detection of longitudinal and/or transverse imperfections (Incorporated in BS EN 10246-9:2000)
12062:1997	Non-destructive examination of welds—General rules for metallic materials (Incorporated in BS EN 12062:1998)
12345:1998	Welding—Multilingual terms for welded joints with illustrations (Incorporated in BS EN 12345:1999)
12517:1998	Non-destructive examination of welds—Radiographic examination of welded joints—Acceptance levels (Incorporated in BS EN 12517:1998)
12732:2000	Gas supply systems—Welding steel pipework—Functional requirements (Incorporated in BS EN 12732:2000)
12814:	Testing of welded joints of thermoplastic semi-finished products Part 1:1999 Bend test (Incorporated in BS EN 12814-1:2000) Part 2:2000 Tensile test (Incorporated in BS EN 12814-2:2000) Part 3:2000 Tensile creep test (Incorporated in BS EN 12814-3:2000) Part 4:2001 Peel test Part 5:2000 Macroscopic examination (Incorporated in BS EN 12814-5:2000) Part 6:2000 Low temperature tensile test (Incorporated in BS EN 12814-6:2000) Part 8:2001 Requirements
13100:	Non destructive testing of welded joints of thermoplastics semi-finished products Part 1:1999 Visual examination (Incorporated in BS EN 13100-1:2000)

ICS: 25.160.50 Brazing and soldering (including brazing and soldering alloys and equipment)

1044:1999	Brazing—Filler metals (Incorporated in BS EN 1044:1999)
1045:1997	Brazing—Fluxes for brazing—Classification and technical delivery conditions (Incorporated in BS EN 1045:1997)
12797:2000	Brazing—Destructive tests of brazed joints (Incorporated in BS EN 12797:2000)
12799:2000	Brazing—Non-destructive examination of brazed joints (Incorporated in BS EN 12799:2000)
13133:2000	Brazing—Brazer approval (Incorporated in BS EN 13133:2000)
13134:2000	Brazing—Procedure approval (Incorporated in BS EN 13134:2000)
1326:1996	Gas welding equipment—Small kits for gas brazing and welding (Incorporated in BS EN 1326:1996)

Note: European Standards that are identical to ISO are not included in this table. Instead, the listing for the ISO standards (Table 33.35) includes cross-references.

Table 33.37   BRITISH STANDARDS RELATING TO WELDING, BRAZING AND SOLDERING

ICS: 25.160.01 Welding, brazing and soldering in general

BS

499:	Welding terms and symbols Part 1:1991 Glossary for welding, brazing and thermal cutting Part 2C:1999 European arc welding symbols in chart form
4515:	Specification for welding of steel pipelines on land and offshore Part 1:2000 Carbon and carbon manganese steel pipelines Part 2:1999 Duplex stainless steel pipelines
4870:	Specification for approval testing of welding procedures Part 3:1985 Arc welding of tube to tube-plate joints in metallic materials

(*continued*)

Table 33.37   BRITISH STANDARDS RELATING TO WELDING, BRAZING AND SOLDERING—*continued*

4871:	Specification for approval testing of welders working to approved welding procedures Part 3:1985 Arc welding of tube to tube-plate joints in metallic materials
4872:	Specification for approval testing of welders when welding procedure approval is not required Part 1:1982 Fusion welding of steel Part 2:1976 TIG or MIG welding of aluminium and its alloys
7670:	Steel nuts and bolts for resistance projection welding Part 1:1993 Specification for dimensions and properties

ICS: 25.160.10 Welding processes

1140:1993	Specification for resistance spot welding of uncoated and coated low carbon steel
1724:1990	Specification for bronze welding by gas
1821:1982	Specification for class I oxy-acetylene welding of ferritic steel pipework for carrying fluids
2630:1982	Specification for resistance projection welding of uncoated low carbon steel sheet and strip using embossed projections
2633:1987	Specification for Class I arc welding of ferritic steel pipework for carrying fluids
2640:1982	Specification for Class II oxy-acetylene welding of carbon steel pipework for carrying fluids
2971:1991	Specification for class II arc welding of carbon steel pipework for carrying fluids
4204:1989	Specification for flash welding of steel tubes for pressure applications
4570:1985	Specification for fusion welding of steel castings
4677:1984	Specification for arc welding of austenitic stainless steel pipework for carrying fluids
6265:1982	Specification for resistance seam welding of uncoated and coated low carbon steel
6944:1988	Specification for flash welding of butt joints in ferrous metals (excluding pressure piping applications)
6990:1989	Code of practice for welding on steel pipes containing process fluids or their residuals
7123:1989	Specification for metal arc welding of steel for concrete reinforcement
7670:	Steel nuts and bolts for resistance projection welding Part 2:1997 Specification for welding of weld nuts and weld bolts

ICS: 25.160.20 Welding consumables (including electrodes, filler metals, gases, etc.)

807:1955	Specification for spot welding electrodes
1453:1972	Specification for filler materials for gas welding
2901:	Filler rods and wires for gas-shielded arc welding Part 3:1990 Specification for copper and copper alloys Part 4:1990 Specification for aluminium and aluminium alloys and magnesium alloys Part 5:1990 Specification for nickel and nickel alloys
4129:1990	Specification for welding primers and weld-through sealants, adhesives and waxes for resistance welding of sheet steel
4215:	Resistance spot welding electrodes, electrode holders and ancillary equipment Part 2:1987 Specification for straight resistance spot welding electrodes Part 6:1987 Specification for electrode adaptors, female taper 1 : 10 Part 7:1987 Specification for male electrode caps
4577:1970	Specification for materials for resistance welding electrodes and ancillary equipment
7384:1991	Guide to laboratory methods for sampling and analysis of particulate matter generated by arc welding consumables

ICS: 25.160.30 Welding equipment (including thermal cutting equipment)

499:	Welding terms and symbols Part 1:Supplement:1992 Glossary for welding, brazing and thermal cutting. Supplement Definitions for electric welding equipment
638:	Arc welding power sources, equipment and accessories Part 4:1996 Specification for welding cables Part 5:1988 Specification for accessories Part 7:1984 Specification for safety requirements for installation and use Part 9:1990, EN 50060:1989 Arc welding power sources, equipment and accessories Specification for power sources for manual arc welding with limited duty

Table 33.37   BRITISH STANDARDS RELATING TO WELDING, BRAZING AND SOLDERING—*continued*

34 Soldering and brazing

34.1 Introduction and cross-reference

Soldering and brazing are useful, fairly simple joining processes in which metals are wetted and joined together by a dissimilar metal of lower melting temperature. When compared with mechanical joints and adhesives, the join is permanent unless remelted, has good electrical and thermal conductivity and is unaffected by organic solvents. It is also resistant to failures at temperatures under those of the original joining technique. There are many filler metals available for a variety of applications with melting temperatures from just above room temperature upwards, the majority of conventional solders being molten below 300°C. Brazing is basically similar to soldering but takes place at a higher temperature, above 450°C according to the definitions of BS 499 but, unlike welding, always below the melting temperature of the parent metals. Brazing is also distinguished from welding by the fact that the brazed joint is formed mainly by capillary action between adjacent surfaces whereas welding starts by local melting of the base metals and continues with the addition of larger fillets of welding filler metal.

The majority of soldering and brazing alloys are based on binary or ternary eutectic systems, sometimes with small amounts of other addition elements. The compositions are chosen to have good wetting and capillarity at the joining temperatures, good corrosion resistance and reasonable strength. Brazed joints are generally significantly stronger than soldered ones and are usually intended to be permanent. The higher the joining temperature, the greater will be the heat-affected zone in the parent metals, with consequential possibilities of loss of temper due to annealing effects.

For joining to be successful the metal surfaces must be clean initially and are normally protected from oxidation during heating by the presence of a suitable flux. The wetting of a parent metal by a filler creates a metallurgical bond, the depth of which is diffusion controlled with the usual time- and temperature-dependent relationships. Overheating a joint, or repeated remaking of a joint usually has a deleterious effect on properties due to the formation of brittle intermetallic compounds.

Tin is present in most common soft solders and rapidly forms intermetallics with most base metals during soldering processes. These intermetallics may then continue to grow by solid-state reactions during storage and operational life of a joint. Under some time- and temperature-controlled conditions the tin can be totally converted to an intermetallic compound. The higher-temperature brazing operations form much deeper reaction zones of modified composition. Properly chosen brazing alloys will not form brittle intermetallics but the modified composition and microstructure will elevate the melting temperature, possibly to a value as high as the parent metal which will preclude the possibility of reworking joints.

For discussion of fusion welding and other joining processes, *see* Chapter 33. Chapter 33 also includes standards related to brazing and soldering.

34.2 Quality assurance

While soldering and brazing techniques have been employed satisfactorily for many years by skilled and semi-skilled personnel, modern manufacturing and quality control systems frequently require that process instructions be fully documented and refer to standards where relevant. Typical organizations preparing product standards covering the fluxes and filler metals include British Standards Institute, American Society for Testing and Materials (ASTM), Deutsches Normenausschuss (DIN) and many others, some specifically aimed at particular industries or defence applications. The European standards are issued by the European Committee for Standardization (CEN) and are very similar

in structure and scope to the ISO (International Organization for Standardization). It is a general trend for individual European national standards, such as British Standards (BS), to be gradually replaced by European standards or by ISO standards. Some major ISO, European, British and AWS standards relating to soldering and brazing are listed in Section 33.6

The requirements included in these specifications are typical of those needed for initiating a full quality control specification. For specific industries there are many other documents published both by national standards institutions and by organizations such as the European Space Agency and NASA. For military requirements for processing, cleanliness, protection and packaging there are additional defence standards such as the American MIL and QQ series of specifications.

34.3   Soldering

Soldering is commonly used for structural applications, for the assembly of pipes and fittings for gas, water or other liquid services and is vital for electrical connections, especially on printed circuit boards. The relatively low melting temperatures of solders are beneficial in having little effect on the properties of the parent metals and adjacent items.

34.3.1   General considerations

Since the solder is weaker than the parts being fastened, the design of the joint must allow for this fact. Significant overlapping areas should be allowed and tensile and peeling forces should be avoided, leaving only shear stresses at most on the solder which is mainly intended to act as filler and seal. Clearances of 0.07 to 0.25 mm are permissible between overlapping parts with approximately 0.1 mm being optimum for capillarity and joint strength. During soldering and solidification there should be no relative movement between joint faces and the use of jigs, self-locating designs or temporary solder-tagging is therefore recommended. The jigs and fixtures should not, however, act as local heat sinks that prevent efficient soldering.

Soldering itself should be carried out as quickly as possible in order to avoid the effects of overheating. The choice of heating method may be either direct, which is fast, or indirect, which reduces surface oxidation effects. For all joints it is essential to start with the components clean and for most it is also essential to protect surfaces from oxidation during soldering with a suitable flux.

34.3.2   Choice of flux

Fluxes have several purposes. They conduct heat to the component, modify or remove surface oxides and other contaminants and eliminate air from the solder wetting front.

The earliest and most active of fluxes are those water-based solutions such as the original 'killed spirits', zinc dissolved in hydrochloric acid, latterly with additions of ammonia and perhaps alcohol and/or a detergent. While very effective on the common metals such as steel, tinplate, copper and brass they are also very corrosive if not washed off thoroughly immediately soldering is completed. Aqueous solutions of orthophosphoric acid are also used for some applications, especially for the low melting point solders and for special steels. Subsequently organic-based fluxes have been developed, now forming four main groups, rosin, synthetic, synthetic resin and water-based organic fluxes.

Dependent on the application and the extent to which subsequent corrosion must be avoided, rosins may be mildly activated, with a halide content of less than 0.2%, activated with 0.2–0.5% halide or super-activated with even higher halide levels. Synthetic activated fluxes are based on formulations giving good wetting and excellent residue removal properties when cleaned with CFCs or other suitable solvents. Synthetic resin fluxes are now made with a low solids content which minimises the need for cleaning and the latest water-soluble organic fluxes combine the best of soldering results with ease of washing clean. For critical assemblies such as wave-soldered printed circuit boards, it is essential to take expert opinion from manufacturers or other specialists in order to assure reproducible success.

The choice of flux is influenced by many factors including type and mass of metal to be soldered, cleanliness, heating techniques, type of solder and after-cleaning requirements. For example, the use of torch soldering techniques will require the use of a more active flux to deal with the extra tarnish caused by the flame.

The notes in Table 34.1 cover the common, and some of the less common, commercial metals (arranged in order of electrochemical potential, *see* Table 34.2).

Table 34.1 RECOMMENDED SOLDER FLUXES FOR ENGINEERING MATERIALS

Group No.	Category	Flux type and possible protective finish with precautions
1	Gold, solid or plated; gold–platinum alloys; wrought platinum	Both gold and platinum have excellent solderability. Soldering to gold and its alloys should be avoided because gold–tin intermetallics embrittle joints. Gold platings can be removed by solder-dipping to dissolve the gold followed by pre-tinning in a second, uncontaminated, solder pot. Rosin, non-activated flux is adequate. If gold cannot be removed, use indium–lead solder. Bright, hard gold platings may be difficult to wet due to the presence of certain alloying elements or organic additives derived from plating solutions: activated rosin flux is then required.
2	Rhodium	Not easy—inorganic flux.
3	Silver, solid or plated on copper; high silver alloys	Easily soldered with mildly activated flux or, when free of surface sulphide, non-activated rosin is preferable. If chloride-contaminated (from plating bath), may need abrasion. Use silver-loaded solder when joining to thin silver plate. The silver-saturated liquid reduces danger of scavenging. Silver-plated parts are not recommended for electrical circuits due to problem of silver migration and subsequent short circuits.
4(a)	Nickel, solid or plated; Monel	Difficult to solder. Use inorganic or organic acid for pre-tinning with solder and non-activated rosin after pre-tinning.
4(b)	Titanium	Impossible to solder without prior copper plating.
5(a)	Copper, solid or plated, tin-bronzes, gunmetals	With red oxide tarnish, can be soldered with mildly activated rosin. Black oxide only removable with activated rosin, organic acids or zinc ammonium chloride solutions (e.g. for radiator plates).
5(b)	Copper–nickel alloys	Not difficult to solder if clean and well fluxed but soldering is not commonly suitable for the severe conditions for which these alloys are specified.
5(c)	Nichrome alloys, austenitic, high corrosion-resistant steels; Nilo-K, Kovar, Monel, etc.	Very difficult to solder with inorganic acid fluxes, zinc chloride and ammonium chloride solutions. Some proprietary brands are available. Can be nickel-plated, but deposit must be non-porous or substrate will become oxidised by plating salts. All ionic matter, including handling contamination, must be thoroughly and immediately removed because this group is susceptible to stress corrosion cracking.
5(d)	Copper–aluminum alloys (aluminium bronzes)	Due to the tenacious alumina film which forms so rapidly, these alloys can only be soldered after copper plating or with techniques used for aluminium alloys.
6	Gilding metals (CuZn10 and CuZn20)	If clean, quite easy to solder with mildly activated resin. May be copper or silver-plated, but ensure good plating adhesion.
7	Commercial brasses (CuZn30 and CuZn40)	Use activated rosin if tarnish is thin. Impossible to solder—even with inorganic flux—if significant oxidation is visible, due to surface film of zinc oxide. Barrier plating of more than 3 μm nickel or copper is recommended for preserving solderability during shelf-life (should prevent zinc diffusion to surface). Barrier of 5 μm necessary if brass is leaded free-machining grade.
8	18% chromium-type stainless steel	*See* Group 5(b).
9	Tin-plated metals	New coatings are easily soldered with non-activated rosin flux. Activation of rosin depends on extent of tin oxide. Fused tin is preferred as it is less porous. Pure tin coatings not recommended for electronic applications due to risk of whisker growth. Should exceed 1 μm thickness as otherwise will react with copper and completely convert to intermetallic, which is extremely difficult to solder.
10	Tin–lead coatings, solid, plated or fused	Most suitable finish for easy soldering with non-activated rosin flux. Porous platings need activated flux. Should exceed 1 μm thickness, but lead slows down intermetallic formation. Good shelf-life for fused coatings on copper wire and printed circuits.

Table 34.1   RECOMMENDED SOLDER FLUXES FOR ENGINEERING MATERIALS—*continued*

Group No.	Category	Flux type and possible protective finish with precautions
11	Lead, solid or plated; high lead alloys	Mildly activated flux required to penetrate surface oxides. High dissolution of lead in tin–lead solder produces joints with extremely low shear strength.
12	Aluminium–copper alloys (e.g. Duralumin and most of AA 2xxx series)	Impossible with tin–lead alloys. Generally, welding or dip-brazing are more suitable. Plate with zincate and copper. The low melting solders are preferred to avoid thermal stressing platings.
13	Iron, wrought, grey or Armco; plain carbon and low alloy steels	Solderability depends on oxide thickness. Clean, pickled surfaces can be easily soldered with mild or activated rosin flux. Passivated or phosphated steels require special fluxes.
14	Aluminium and most alloys other than in Group 12 (e.g. AA 1xxx, 3xxx and 5xxx series)	Can be soldered, but with special alloys (e.g. tin–zinc or cadmium–zinc alloys). May be friction-soldered without flux or, when aluminium oxide is removed, by ultra-sound. Some proprietary fluxes are available. Corrosion in aluminium-soldered joints is particularly troublesome; a water-proof coating is essential.
15(a)	Cast aluminium alloys other than aluminium–silicon alloys	As for Group 14 but choice of solder and flux requires specialist advice.
15(b)	Cadmium plating	Easy to solder with mildly or fully activated rosin fluxes. If passivated by chromate film, they are very difficult and require ammonium chloride-type flux. Fumes are toxic.
16	Hot dipped zinc plate	As for Group 15(b).
17	Zinc, wrought; zinc-based casting alloys; zinc plating	Generally, very difficult to solder due to oxidation. Use inorganic acid or special proprietary flux. Water-tight protection necessary to avoid corrosion.
18	Magnesium and magnesium-based alloys, cast or wrought	Not recommended because of poor strength and corrosion.

Table 34.2   ELECTROCHEMICAL POTENTIAL OF COMMON ENGINEERING MATERIALS

Group No.	Category	Electrochemical potential V*
1	Gold, solid or plated; gold–platinum alloys; wrought platinum	+0.15
2	Rhodium	+0.05
3	Silver, solid or plated on copper; high silver alloys	0
4(a)	Nickel, solid or plated; Monel	−0.15
4(b)	Titanium	−0.15
5(a)	Copper, solid or plated, tin–bronzes, gunmetals	−0.20
5(b)	Copper–nickel alloys	−0.20
5(c)	Nichrome alloys, austenitic, high corrosion-resistant steels; Nilo-K, Kovar, Monel, etc.	−0.20
5(d)	Copper–aluminium alloys (aluminium bronzes)	−0.20
6	Gilding metals (CuZn10 and CuZn20)	−0.25
7	Commercial brasses (CuZn30 and CuZn40)	−0.30
8	18% chromium-type stainless steel	−0.35
9	Tin-plated metals	−0.45
10	Tin–lead, solid, plated or fused	−0.50
11	Lead, solid or plated; high lead alloys	−0.55
12	Aluminium–copper alloys (e.g. Duralumin and most of AA 2xxx series)	−0.60
13	Iron, wrought, grey or Armco; plain carbon and low alloy steels	−0.70
14	Aluminium and most alloys other than in Group 12 (e.g. AA 1xxx, 3xxx and 5xxx series)	−0.75
15(a)	Cast aluminium alloys other than aluminium–silicon type	−0.80
15(b)	Cadmium plating	−0.80
16	Hot dipped zinc plate	−1.05
17	Zinc, wrought; zinc-based casting alloys; zinc plating	−1.10
18	Magnesium and magnesium-based alloys, cast or wrought	−1.60

* Calomel electrode/sea water. For reasonable galvanic compatibility, the maximum potential difference between soldered metals should be less than 0.5 V.

34.3.3   Control of corrosion

If long storage periods are expected between manufacture of components and solder assembly, the surfaces of the common industrial metals can be plated initially with copper or nickel and subsequently with a pre-tinning eutectic composition of tin–lead solder which can be fused in hot oil to form a 4–12 μm thick pore-free protective layer possessing excellent solderability even after many years in storage. Less active fluxes may then be employed which will reduce the need for post-soldering cleaning.

Subsequently to joining, corrosion may occur near a joint if flux residues are present. These residues are frequently hygroscopic and can cause severe discoloration or worse problems in the joint locality given only the presence of atmospheric humidity. It is therefore essential to clean off flux residues, preferably as soon as possible after soldering. The choice of cleaning agent will depend on the type of joint, the flux used and the extent to which cleanliness is critical.

If aqueous fluxes are used, the simplest wash is to quench the joint in water prior to inspection and possible further cleaning. Pickling in dilute acid is sometimes used but the active surface left by this aggressive process must be subsequently passivated. For cleaning organic residues a variety of solvents are possible and the recommendations of the flux manufacturer should be followed in the absence of any other process standard.

In service it is possible to suffer galvanic corrosion if dissimilar metals are exposed in damp or wet service or storage environments. In any bi-metallic couple the more noble metal will not be corroded but the less noble will be attacked at a rate dependent on the environment and the electrical potential difference between the metals. Its effect may be reduced if the area of the less noble, or sacrificial metal is significantly greater than the noble metal. Fortunately tin–lead, the most common soldering alloy, is generally compatible with most solderable metals, except gold. The galvanic series is useful as a first approximation in selecting materials for both solderability and corrosion control, but for many applications it may be too simplistic because it does not provide information about corrosion rates or changes in surface chemistry which may pacify or accelerate corrosion at bi-metallic interfaces.

34.3.4   Solder formulations

Generally, solder alloys are based on the metals tin, lead, cadmium, zinc and indium. They are available in a variety of physical forms to facilitate different means of application. Solder ingots are used to replenish large baths for dip or wave-soldering. Solder creams, containing a gel of solder powder, flux and wetting agent, can be painted or screen-printed for microelectronic applications. Preforms of solder are used for furnace and torch-soldering and include formed wires and parts punched from flat sheet.

Solder alloys can be divided into four groups according to their melting ranges. Melting temperatures are not recommended soldering temperatures. Typically, 20–70°C above the liquidus temperatures ensures good alloy fluidity and wetting characteristics. Compositions, melting ranges, and typical uses for these types are given in Tables 34.3 to 34.6.

Many worldwide initiatives have been taken to find lead-free alternatives to currently used lead containing solders because of the toxicity of lead. Eutectic tin–lead solder (63Sn/37Pb) is currently very widely used in electrical and electronic assembly, particularly in surface mount printed circuit boards. The National Center for Manufacturing Sciences (NCMS) in USA has completed a project in which alternatives to eutectic tin/lead solder have been identified and evaluated from an initial list of more than 70 candidate alloys. Although the project concluded that no drop-in replacement is available for eutectic Sn/Pb solder, it has indicated that promising alternatives exist. More detailed information is needed however before implementing any wholesale changes to present industrial practice. The project has also recommended three alloys that might perform substantially better than eutectic Sn/Pb in certain applications (Table 34.7). Lead-containing solders, usually Pb/Sn or Pb/Sn/Sb, have also been very widely used in the past for assembly of copper pipework in domestic plumbing. In many parts of the world, lead-containing solder alloys are no longer approved for use on systems handling potable water. Where such prohibitions exist, the current trend is to use Sn/Sb or Sn/Ag solder alloys (i.e. similar to alloys 95A or 96S in Table 34.7).

34.3.5   Cleaning

Soldered joints should be cleaned after completion in order to prevent surface corrosion and stress corrosion cracking. Cleaning also facilitates inspection. Immersion cleaning is improved by ultrasonic agitation.

Table 34.3   VERY LOW MELTING POINT SOLDERS (BELOW 183°C)

Uses include joining heat-sensitive components or adding components to existing circuits (one solder operation on another where second soldering does not remelt initial joint). Contamination with certain other solder compositions may cause alloying and even lower melting temperatures.

* Eutectic type solders with single discrete melting point; they solidify with smooth bright fillets which can be readily inspected—recommended for highly reliable electrical connections. These are used for hand or machine soldering of printed circuit boards but care should be taken to avoid trace impurities, e.g. Zn or Al <0.005% to prevent oxide skin; Fe or Au or Cu or As or Sb <0.2% to prevent hard or embrittled joints.

Table 34.5 INTERMEDIATE TEMPERATURE SOLDERS (270–370°C)

Elevated temperature applications where some creep strength is required. The lead-based alloys, which contain additions of up to 8% tin and/or silver, may be used to about 130°C. Higher service temperatures may be satisfied by selecting tin-free lead alloys, but these have poor wetting properties and require the use of special organic fluxes which will not decompose at the high soldering temperatures. Alloys containing in excess of 90% lead are selected for cryogenic applications because they retain ductility and can take up mismatches in thermal expansion at the low temperatures. The final inspection of cleaned connections made with these alloys may reveal high contact angles and dull surface finishes, but these should not be construed as a sign of cold solder joints.

* Rarely used because of high dissolution of many base metals into the solder. Rapid tarnishing of adjacent areas to the joint unless special protection by flux or inert gas is provided. Only high temperature stable inorganic fluxes useful.

Table 34.7   PROMISING LEAD-FREE ALLOYS FOR PARTICULAR ELECTRONIC SMT APPLICATIONS*

Alloys	*Liquidus and solidus temperature* (°C)	*Industrial sectors*	*Evidence for recommendation*
Sn/58Bi	139 (eutectic)	Consumer Electronics Telecommunications	Simple two-component eutectic alloy but low eutectic temperature restricts maximum use temperature.
			SMT: Better fatigue life than eutectic tin/lead for both thermal cycling ranges; less fatigue.
			THT: Mixed results with fatigue life for CPGA-84 better than eutectic tin/lead; for CDIP-20 worse than eutectic tin/lead.
Sn/3.5Ag/ 4.8Bi	210–205	Consumer Electronics Telecommunications Aerospace Automotive	SMT: Longer fatigue life than eutectic tin/lead at 0° to 100°C; no failures in 1 206 resistors up to 6 673 cycles; fatigue life equivalent to eutectic tin/lead at −55° to 125°C; less fatigue damage than eutectic tin/lead seen in surface mount cross sections.
			THT: Most joints show failure by fillet lifting.
Sn/3.5Ag	221 (eutectic)	Consumer Electronics Telecommunications Aerospace Automotive	Simple two-component eutectic alloy.
			SMT: Fatigue life equivalent to eutectic tin/lead at 0° to 100°C; worse than eutectic tin/lead at −55° to 125°C.
			THT: Less susceptible than other high-tin solders to fillet lifting but results with Sn/2.6Ag/ 0.8Cu/0.5Sb indicate through-hole reliability still may be compromised.

* For further information, *see* NCMS Lead-free Solder Project Final Report, National Center For Manufacturing Science, Ann Arbor, Michigan, USA, August 1997. The data in this table are reproduced, with permission, from the NCMS report.

Subject to manufacturers' recommendations or other process control specifications, the following solvents are acceptable for the cleaning of electronic equipment provided cleaning takes place immediately after the soldering operation (e.g. before the flux and residues have had time to polymerise or age):

1. Ethyl alcohol, 99.5 or 95% pure by volume.
2. Isopropyl alcohol, 99% pure.
3. Trichlorotrifluorethane, clear, 99.8% pure.
4. Any mixture of the above.

5. De-ionised water at 40°C maximum may be used for certain fluxes. Items shall be thoroughly dried directly after the use of de-ionised water.

34.3.6 Product assurance

Acceptable solder connections are generally characterised as:

1. Clean, smooth, undisturbed surfaces.
2. Concave fillets between solder and joined surfaces.
3. Complete wetting as evidenced by a low contact angle between the solder and the joined surfaces.

Unacceptable solder conditions, which may be cause for rejection, are:

1. Damaged, crushed, cracked, melted, corroded, etc. surfaces.
2. Improper tinning.
3. Flux residues or other contamination.
4. Cold joints, as shown by the contact angle.
5. Fractured joints.
6. Pits, holes or voids in the joint which are not attributable to liquid-to-solid solder shrinkage.
7. Excessive or insufficient solder.
8. Splattering of flux or solder on adjacent areas.
9. De-wetting, etc.

34.4 Brazing

34.4.1 General design consideration

Brazing is a very useful technique for making permanent, strong joints between metals at moderately elevated temperatures without fusing the parent metals themselves. It should be considered when one or more of the following design requirements must be met:

1. Joints will be loaded in shear.
2. For the joining of thin sections to heavy sections.
3. For joining of sections too thin for welding.
4. When hermetically sealed assemblies are required.
5. For joints with low distortion and minimal residual stress distribution.
6. For high volume production.
7. For joining dissimilar metal combinations which cannot be welded.
8. For producing complex, permanent assemblies with multiple joints which would be inaccessible to welding.

34.4.2 Joint design

Normally only small or medium sized assemblies can be brazed as the heat required to melt the braze alloy must be applied to a broad, or usually the entire area of the component parts being joined.

Both lap and butt joints can be made with flat or tubular parts. *The strength of the join depends on the amount of bonding surface.* The simple butt joint will have a small bonding area that will not exceed the cross-sectional area of the thinner member and this type of joint is therefore not recommended. The preferred type of joint loading is in shear and lap or lap-butt joints are the most reliable. The joint should be designed to prevent stress from being concentrated at a single point. Most of the specialised textbooks and codes of good practice include diagrams showing the optimum ways in which joints such as lap-butt, tees, corners, tube-to-tube, tube caps and tube-through-plate can be designed considering the process to be used. For joints in metals such as aluminium and its alloys, tapering clearances are required to enable fluxes to float clear rather than be entrapped.

During the brazing operation provisions must be made to hold the various components to be joined. This is best done by using an interlocking design where alignment is obtained by fitting parts into each other under gravity but if this is not possible, jigs or fixtures will be needed. Parts may also be positioned by means of spot or tack welding, crimping and pinning.

Based on data from 'Materials Selector', Reinhold Publishing Co., Penton/IPC; *see* also Chapter 14—General physical properties.

The joint clearance, which is the dimension between the interfaces of the completed brazed joint, has a direct bearing on the mechanical strength of any brazed joint. Normally the highest strengths are obtained with the smallest possible thickness of filler and this is particularly true where there is little or no solubility of the parent material in the braze filler (e.g. stainless steels brazed with silver- or copper-based alloys). More clearance is required if material solubility exists, particularly in furnace brazing when long heating cycles are required (e.g. austenitic stainless steels brazed with nickel fillers).

It is extremely important to plan a joint clearance based on the brazing temperatures and not room temperature. The coefficients of expansion of the metals being joined must be taken into account, especially in tubular assemblies in which dissimilar metals are being joined. If the metal with the

[a] Ensure that the solidus value of the parent metal is at least 100°C above the liquidus of the selected brazing material.
[b] Special formulations are available which will permit wider gaps than 0.375 mm to be brazed in a satisfactory manner.
Reprinted from Brooker and Beatson, 'Industrial Brazing', 2nd edn, Newnes-Butterworth, 1975.

greater expansion coefficient is on the inside there may be no clearance at the brazing temperature and under reverse conditions a room temperature gap can become too large for adequate capillary flow at the brazing temperature.

As a design rule the filler metal should remain in slight compression once the assembly returns to room temperature. The metal having the greater coefficient of expansion is therefore normally used as the female member of the joint. Ideally, parts to be brazed should have a similar coefficient of expansion in order to facilitate joint clearance calculation and prevent the generation of large residual stresses caused by badly matched materials. The optimum joint clearance will depend on the nature and sizes of the parts being joined, the heating methods and the configuration of the joint itself. As there are many variables involved in assuming the actual clearance at brazing temperatures it is recommended that simple calculations are made utilising the coefficients of expansion presented in Table 34.8 and these are followed up by trial operation using representative test samples. For most brazing alloys effective capillary action occurs when the braze path gap at the brazing temperature is maintained within the range 0.025–0.200 mm. Table 34.9 may also be used as a guide.

34.4.3 Precleaning and surface preparation

Uniform capillary action may only occur when all grease, oil, oxides and dirt have been removed from both the base metals and braze alloy. Fluxes cannot be relied upon to clean the area to be brazed—they are mainly intended to prevent the formation of oxides during brazing and reduce the surface tension of the filler metal. Cleaning may be performed by chemical, mechanical or vacuum methods. Chemical cleaning is most frequently carried out utilising commercial solvents, vapour degreasing, alkaline mixtures (detergents, soaps, carbonate, hydroxides), electrolytic methods (anodic and cathodic), acidic solutions and salt bath pickling. Mechanical cleaning methods include grinding, filing, machining, shot blasting and ultrasonics. In all cases care must be taken to avoid the embedment of oxides or ferrous materials into the surfaces to be brazed as these will interfere with the proper wetting of the base metal by the liquid braze alloy. Very smooth, polished surfaces are less satisfactory for brazing than slightly roughened surfaces.

34.4.4 Positioning of filler metal

Dependent on the design of the joint and the type of heating technique used, the braze filler metal may be pre-placed prior to heating or applied when the joint is at temperature. It may be in the form of wire, ring, shim, clad sheet, powder, paste or slurry, depending upon the specific application and process. These forms of filler metals can be positioned by grooves, shoulders and/or recesses which serve as reservoirs for filling the braze paths. Designs of joint suitable for hand feeding will be different from those used when pre-formed inserts of brazing filler are used. In the latter case, the manufacturers of the fillers are generally glad to advise on optimum joint design and for the positioning of the components to allow for movement as the pre-form melts.

All braze assemblies should be designed so that the parent metals and the filler metals are uniformly heated when component parts have different thermal capacities. Two-stage heating with

long dwell times may be necessary to ensure that liquation and flow of the filler metal occur simultaneously in all locations. Gravity flow of the filler metal through the braze path should be provided when possible. Machined grooves should be provided when large ($>50\,\text{mm}^2$) flat surfaces are united by brazing. Unless full penetration by the brazing alloy is achieved, an internal crevice will remain as a potential site for flux and residue. In certain configurations the presence of visible filler metal fillets will aid inspection.

34.4.5   Heating methods

TORCH BRAZING

Parts should be pre-heated with a neutral or slightly reducing flame so that uniform heating or the surfaces to be joined can be achieved. Localised overheating must be avoided. Flux is usually applied (some proprietary fluxes indicate the part's surface temperature by a colour change) and the braze alloy is introduced at one of the mating surfaces. Torch brazing is frequently used for the attachment of small parts on to large surfaces, one-off jobs and repairs. Automation, generally on a rotary table, is not difficult when long production runs are planned.

FURNACE BRAZING

This process can frequently be employed with the use of little or no flux, dependent on the materials being brazed and the extent to which the furnace atmosphere is kept reducing in character. Where possible, the furnace atmosphere should be strictly controlled, particularly with respect to the hydrogen potential and the dew point which should be instrumented for continuous control. Braze alloy pre-forms are located between pre-assembled parts which are usually fluxed and self-jigging.

Vacuum furnaces may be used, employing pressures of 1.0 to 1.0×10^{-9} torr and being heated either by radiation from resistance elements or by induction coils. Metal–metal oxide equilibrium diagrams are useful to show the relationship which exists between the furnace operating temperature and the reducing or oxidising behaviour of the atmosphere. Figure 34.1 indicates the effect of dew point of hydrogen and partial pressure of water on the brazeability of pure metals.

INDUCTION BRAZING

Heating is localised, fast, and generally accomplished within one or two minutes. Coils may be shaped to follow the contours of the assembly and adjustment to the coil separation distances can cause heavier sections to heat up at the same rate as thin sections. The mating surfaces can be coated with flux, or pre-assembled units with braze alloy pre-forms may be heated in a suitable atmosphere. It must be remembered that high-resistance metals such as steel heat up rapidly whereas low-resistance metals take longer to reach the brazing temperature. Amongst other factors, the efficiency of heating is controlled by the frequency of the equipment which should be suitable for the size of assemblies normally expected.

ELECTRIC RESISTANCE BRAZING

This technique is suitable only for relatively small joint areas because it is difficult to maintain uniform current distributions. Localised heating does not usually modify the mechanical properties of the parent metals. Success will depend upon the thermal capacities and thermal conductivities of the metals being joined. The presence of an intermediate layer of flux can be detrimental if direct heating is employed (i.e. when heating current passes through two work pieces sandwiching the brazing alloy). Once the optimum brazing schedule has been established this method can become semi-automated and requires minimal operator skills.

SALT BATH DIP BRAZING

The assembled joint, with the filler metal(s) preplaced, is dipped into a bath of molten salt which acts as flux. Occasionally the parts may be dipped into a bath of molten brazing alloy covered with a layer of flux. Dip brazing is widely used for joining aluminium components. Preheating of parts is recommended as it prevents excessive freezing of the salt on a cold surface, expels water entrapped
Figure 34.1   *Metal–metal oxide equilibria in hydrogen atmospheres. Oxidising conditions exist at the life of each curve: reducing conditions which facilitate brazing exist on the right of each curve. Note Au, Pt, Ag, Pd, Ir, Cu, Co, Ni and Os oxides are easier to reduce than those plotted.*

within the assembly thereby minimising the risk of explosions from immersed parts, and markedly increasing the speed of production. The specific gravity of the molten salt used is close to that of aluminium, reducing by half the weight of submerged pieces. This facilitates the dip-brazing of complex aluminium assemblies that are not strong enough to be self-supporting when brazed by other techniques. Personnel must of course wear protective clothing and face masks.

34.4.6   Brazeability of materials and braze alloy compositions

It is not possible to detail the optimum heating methods and filler metals for the wide range of base metals and combinations of base metals. Expert advice should be sought or literature searches and experimentation must be performed prior to the brazing of uncommon materials. It is strongly recommended that the referenced Standards are consulted for additional information. The brazing alloy systems in common use are listed in Table 34.10 with compositions detailed in Table 34.11.

A useful guide to the suitability of parent materials and filler metals for torch brazing, furnace brazing, induction brazing, electrical resistance brazing, and vacuum brazing is presented in Tables 34.12 to 34.16.

34.5   Diffusion soldering or brazing

Diffusion soldering or brazing is a variation of soldering or brazing processes in which a thin layer of liquid forms, by melting of a filler metal or formation of an in-situ liquid phase by reaction, and wets the faying surfaces, then solidifies isothermally at the bonding temperature as the elements responsible for the depression of melting temperature diffuse away into the surrounding solid. The process offers advantages such as joint microstructures and properties that are very similar to those of the base metal, and the need for only very low contact pressure during the process. This process is also known as liquid phase diffusion bonding or transient liquid phase (TLP) bonding.

A simple example to illustrate the process is the diffusion brazing of silver to silver using a thin copper or eutectic silver–copper interlayer. When the silver-interlayer-silver assembly is heated to

Aluminium–silicon	565–625	1	BAlSi–2, BAlSi–4	L–AlSil2 (3.2285)
Auminium–silicon–copper	550–570	1	BAlSi–3	

Note: Some alloys are available in only one specific form and this should be ascertained before joint-design is considered. The available forms are wire, foil, powder, clad sheet, deposited coating and, in many cases, paste.

[a] Some alloys contain elements which are volatile at the temperatures and pressures involved in the brazing process and caution is required under prolonged heating.

R—Recommended and known to be in general use. It should be recognised, however, that in many instances jointing by brazing results in a weakening of the parent material due to intercrystalline penetration, grain growth and other causes.

P—Possible but not known to be in general use.

N—Not recommended.

Note: This table is intended only as a guide and any further information should be obtained from the manufacturer of the filler metal.

* From EN 1723.

Table 34.17   MATERIALS COMBINATIONS USED FOR DIFFUSION BRAZING/SOLDERING

Substrate	*Filler metal (wt. %)*	*Bonding temperature* (°C)	*Remelting temperature* (°C)
Aluminium-based alloys and composites	Cu	550	600
Cobalt alloys	Ni-3.7B	1 175	1 495
Nickel alloys	Ni-15.5Cr-3.7B	1 100	1 455
	Ni-11P	900	
Silver alloys	Cu or Ag-28Cu	820	960
Steel	Fe-12Cr-4B	1 050	1 500
Titanium-base alloys and composites	Cu-50Ni	975	1 700
	Ag-15Cu-15Zn	700	700
	Ti-50Cu-25Zr	880	1 700
Copper metallisation	Sn	500	>900
	In	300	>600
Silver metallisation	Sn	250	>480
	In	300	>660
Gold metallisation	In	250	>450

a bonding temperature slightly above the silver–copper eutectic temperature (780°C), a liquid film is formed between the silver workpieces by melting of the eutectic silver–copper interlayer or by in-situ formation of eutectic silver–copper liquid by alloying between a copper interlayer and the base metal. This liquid phase wets the joint surfaces and fills the gap. If the assembly were then cooled with the liquid phase solidified during cooling, the joint would be a conventional brazed joint with a remelting temperature equivalent to the eutectic temperature. However, by maintaining the assembly at the bonding temperature, the liquid phase solidifies isothermally as the copper in the liquid phase diffuses away from the joint line into the silver workpieces. The resultant diffusion-brazed joint has a remelting temperature eventually equivalent to the melting point of silver!

Diffusion soldering/brazing is not limited only to material combinations that form solid solutions (such in the silver–copper system). Systems that form intermetallics or new phases at the joint interfaces may also be used to produce diffusion-brazed or -soldered joints because the same advantage of raised remelting temperature may also be realised. For example, during diffusion soldering of silver using tin, the tin will melt and react with the silver to form silver–tin intermetallics until no liquid tin remains. The remelt temperature of the diffusion-soldered joint is then determined by the new phase(s) formed in the process. Table 34.17 lists examples of material combinations used for diffusion brazing/soldering.

35 Vapour deposited coatings and thermal spraying

Vapour deposition processes are of two kinds: physical vapour deposition (PVD) and chemical vapour deposition (CVD). Process details and references for elements are given in Tables 35.1 and 35.2, for oxides in Tables 35.3 and 35.4, for nitrides in Tables 35.5 and 35.6, and for carbides in Tables 35.7 and 35.8. Section 35.3 discusses thermal spraying (*see* Chapter 33 for relevant standards).

35.1 Physical vapour deposition

Physical vapour deposition processes use a physical effect such as evaporation or sputtering to transport material, usually a metal, from a source to the substrate to be coated. If the material is transformed (e.g. into a carbide) during transport, then the process is described as reactive. All PVD processes are carried out in a relatively high vacuum (i.e. pressure $<10^{-4}$ Torr).

35.1.1 Evaporation (E)

The substrate to be coated is placed in a vacuum chamber with a line-of-sight to the source which is a pool of molten material. The pool is heated either by an electron beam or an arc or by resistance heating. The electron beam method is best for source materials with a high melting point.

REACTIVE EVAPORATION (RE)

The same process as evaporation except that the zone through which the evaporated species is passing contains a very small concentration of a reactive gas, usually a hydrocarbon, N_2, NH_3 or O_2. This results in the deposition of the carbide, nitride or oxide of the source material.

ACTIVATED REACTIVE EVAPORATION (ARE)

The same process as reactive evaporation except that an electrically excited plasma is established in the region where the evaporated species encounters the reactive gas.

ION PLATING (IP)

The same process as evaporation except that substrate is biassed negatively with respect to the source. This usually results in a plasma region around the substrate which can be enhanced by r.f. coupling. The ionised species actually represents only a small fraction of the total material flux.

REACTIVE ION PLATING (RIP)

The same process as ion plating except that a reactive gas (usually a hydrocarbon, N_2, NH_3 or O_2) is introduced into the flux travelling towards the substrate so that the carbide, oxide or nitride of the source material is formed.

35.1.2 Sputtering (S)

A process in which material is transferred from a target and deposited on a substrate by means of ionic bombardment of the target. Usually the ion bombardment is achieved by establishing a d.c. or r.f. plasma at the surface of the target, although ion guns can also be used.

SPUTTER ION PLATING (SIP)

The same process as sputter plating except that the substrate has an electrical negative bias, d.c. and r.f. possible (for non conductive materials), so that it is bombarded with positive ions as well as the neutral flux created by the sputtering.

REACTIVE SPUTTER PLATING (RSP)

The same process as sputter plating except that a reactive gas is introduced into the plasma region so that the transported target material reacts before it arrives at the substrate. For example, the conversion of Ti into a deposit of TiN by the introduction of nitrogen.

MAGNETRON SPUTTERING (MS)

The same process as sputter plating except that a magnetic field is used to direct the ion flux at the surface of the target.

35.1.3   Ion cleaning

An argon plasma may be used to bombard a surface with excited argon atoms. These transfer their momentum to atoms in the surface and some of these are ejected from the surface. This has the effect of gradually removing material from a surface, hence cleaning the surface. Ion cleaning is often used as a pretreatment in PVD coating.

35.2   Chemical vapour deposition

Chemical vapour deposition processes use the vapour phase to transport reactive material to the surface of a substrate where a chemical reaction occurs to form a coating, e.g. tantalum by the reaction: $TaCl_5 + H_2 \rightarrow Ta + 5HCl$. Normally the substrate is heated to activate the reaction. In many CVD processes the substrate takes no part in the formation of the coating, but in *diffusion coatings* the substrate takes part in the formation of the coating (e.g. aluminising).

CVD processes can be divided into two groups, hot wall and cold wall, as follows:

A hot-wall reactor is a chamber which is heated from the outside so that both the chamber and the work pieces reach the reaction temperature and so become coated. Consequently there is a certain amount of redundant plating which is undesirable with expensive materials.

A cold-wall reactor is a chamber in which only the work pieces are heated, usually by induction. Only the work pieces become coated.

CVD processes are a rather diffuse group because the physical conditions for each process differ widely so that there are no standard items of equipment as there are for PVD. Many CVD processes use a reduced pressure to improve throwing power (cf. PVD).

In the references *CVD* stands for the International Chemical Vapor Depositions Conference Proceedings published by The Electrochemical Society, Vapour Deposition in the refs. refers to that title by Powell, Oxley and Blocher, J. Wiley, N.Y. 1965. Process details Tables 35.2, 35.4, 35.6, 35.8.

Plasma Activated or Enhanced Chemical Vapour Deposition (*PACVD or PECVD*)

The same process as CVD except that a d.c. or r.f. plasma is established around the substrate, usually to permit a low coating temperature.

Metal Organic Chemical Vapour Deposition (*MOCVD*)

The same process as CVD except that organometallic chemicals (e.g. trimethylgallium) are used as the feed reagents. Many organometallics have a high vapour pressure and a low decomposition temperature so that coatings can be formed at low substrate temperatures. It is particularly used for the growth of epitaxial layers.

Chemical Vapour Infiltration (*CVI*)

The same process as CVD except that the substrate is a porous and usually fibrous material into which the deposited material is infiltrated. It is an extremely slow process, but it leads to composites of low final porosity.

Table 35.1 PHYSICAL VAPOUR DEPOSITION OF ELEMENTS AND METALLIC ALLOYS

Element	Process*	Coating thickness (μm)	Typical applications	Ref.
Ag	S	0.02–0.35	Window glass	2

Table 35.4   CHEMICAL VAPOUR DEPOSITION OF OXIDES

Material	Process	Temp. (°C)	Coating thickness (μm)	Typical applications	Ref.
Al_2O_3	$AlCl_3 + CO_2 + H_2$	850–1 800	2–8	Hard coating for tool tips. Coating for nuclear fuels	1–5
	$AlCl_3 + O_2$ plasma assisted	230–350		Passive sealing layer for integrated circuits. Single crystal growth	
	$Al(CH_3)_3$ or $Al(OC_3H_7)_3 + O_2$	275–500			
B_2O_3–SiO_2	$B_2H_6 + SiH_4 + O_2$	350	0.4–0.6	Diffusion source for doping electronic materials. Cladding for optical fibres	23
Cr_2O_3	$Cr(CO)_6 + O_2$	400–600	<25	Oxidation-resistant coating	6
Fe_2O_3	$Fe(acac)_3 + O_2$ plasma assisted	400–600	—	—	24
SiO_2	$SiH_4 + O_2 (+h\nu)$	300–430	5–25	Passive layer-encapsulant for electronics	7–12
	$Si(OEt)_4$ thermal decomp.	800–1 000		Anti-reflectance coating	25
	$Si(OEt)_4 + H_2O$	500–1 000		Corrosion-resistant coating for chemical plant. AGR plant Prep. of optical fibres	
	$SiH_4 + N_2O$	300–1 500			
	$SiCl_4 + O_2$ plasma assisted	>1 000	20–50		
SnO_2	$SnCl_4 + O_2$	600–1 000	0.1	Semiconductor assemblies. Optoelectronic applications. Transparent electrically conducting coatings	13–15
	$SnCl_4 + H_2O$	>430			
	$Sn(CH_3)_4 + O_2$	400–600	0.1		
TiO_2	$TiCl_4 + O_2 +$ hydrocarbon (in flame)	450–800	—	Pigment production	16–19
	$TiCl_4 + CO$ plasma assisted or $TiCl_4 + O_2$ plasma assisted			Dielectric films in MOS structure	
	$Ti(OC_3H_7)_4 + O_2$	450			26
$YBa_2Cu_3O_{7-x}$	$Y/Ba/Cu(acac) + O_2$	400–600	1–20	Superconductor with high T_c	27, 28
ZrO_2	$Zr(acac)_4 + O_2$	450–700	—	MOS devices	20–22
	$ZrCl_4 + CO_2 + CO + H_2$	1 000	5–10	Hard coatings on sintered carbides. Oxidation-resistant coatings	
	$Zr(OC_3H_7)_4$	500–600	12–75

35.3   Thermal spraying

Thermal spraying is a process in which a material is heated to a molten, partly-molten or highly plastic solid state by a heat source and is accelerated to the surface on a substrate by a gas jet. On impacting the substrate, the spray material droplets flatten, solidify and cool down on the surface or overlap on the fore-flattened droplets. In this way, the spray material is deposited to form a coating. Figure 35.1 shows the principle of thermal spraying schematically. A wide range of spray materials from ceramics to metal alloys can be deposited to protect a component against wear, corrosion, oxidation or heat or to generate special electric, magnetic or biomedical properties. Table 35.9 gives some of spray materials used commonly. The significant advantages of thermal spraying are:

1. Coatings of nearly all materials can be deposited on various substrates
2. Low heat load on the substrate material
3. Local coating is possible
4. Some facilities are mobile
5. High deposition rate.

Thermal spraying processes are usually distinguished by the heat sources used. The most widely used techniques are conventional combustion spraying, high velocity oxy-fuel spraying, wire arc spraying and plasma spraying. There are different processes variants under each one of the above mentioned heat sources.[1]
Figure 35.1   *Principle of deposition of a thermal sprayed coating*

Table 35.9   EXAMPLES FOR COATING MATERIALS FOR THERMAL SPRAYING[1,4]

Material group	Example
Pure metals	Al, Co, Mo, Ni, Ti, Zn,…
Alloys	Ni–Al, Ni–Cr, Ni–Cr–Al, Steel, …
Pseudo-Alloys	Cu–W, Bronze-Steel
Oxide-Ceramics	Al_2O_3, Cr_2O_3, TiO_2, …
Hard materials	Cr_3C_2/Ni, WC/Co, …
Synthetics	EMAA, ETFE,…

For most thermal spray processes, the particles are heated up very fast and can react with the gases of the surrounding atmosphere. Because of this, the material of the particles can change its characteristics during the spraying process. The different effects are selective evaporation of components, reaction of metal compounds and formation of non-volatile metal compounds like oxides, nitrides, and hydrides.[5]

35.3.1   Combustion wire spraying

In the combustion wire spray process the spray material in wire form is fed continually into a flame where it is melted. The spike of the wire is atomised by the surrounding compressed air. The flame reaches temperatures up to 3 160°C. The accelerated particles deposit on the workpiece surface. Typical fuel gases are acetylene, propane and hydrogen.[1]

35.3.2   Combustion powder spraying

The powder flame spray process is similar to the combustion wire spray process with the difference, that powder and not a wire is injected into the flame. This offers a much wider range of coating material options than the wire flame spray process. The powdered material is fed continually into the fuel gas-oxygen flame where it is typically melted or semi-melted by the heat of combustion. A powder feed carrier gas transports the powder particles into the combustion flame, and the gases transport the material towards the prepared workpiece surface. Typical choices for fuel gases are acetylene or hydrogen.[1]

35.3.3   Electric wire arc spraying

Two identical or different metallic wires are moved into a spray gun with a controlled speed. The two wires are electrically charged with opposing polarity. When the wires are brought together at the nozzle the arising arc melts the material. Compressed air atomises and accelerates the molten material onto the workpiece surface. The temperatures in the electric arc are approximately 6 500°C. This process can also be driven with three or four wires in the same way.[1]

35.3.4   High velocity oxy-fuel spraying (HVOF)

High velocity oxygen fuel spraying is a further development of the combustion powder spray process. HVOF has reached a good market position in a relatively short time. HVOF is characterised by very high gas and particle velocities. A reaction of oxygen and fuel gas in the combustion chamber generates the heat required for melting the powder. The expanding gas accelerates the particles to velocities up to 300–600 m/s.

Low particle temperature and high particle speed are the advantages of the HVOF process for a lot of materials and applications. The coatings are characterised by a low porosity, high adhesion, high hardness and a good resistance against wear.[1]

35.3.5   Plasma spraying

Plasma spraying is a very flexible thermal spray process. It can provide energy in the form of a plasma jet with temperatures higher than 20 000°C to melt any material. The number of coating materials

that can be deposited with the plasma spray process is almost unlimited. For the plasma spray process the plasma is generated by a arc between two water cooled electrodes in a torch (Figure 35.2). The atoms of the plasma gas are ionised when passing the arc. For a diatomic gas molecular dissociation will also happen. As plasma gas argon, helium, hydrogen, nitrogen and any mixture of these gases are used. During the ion/electron recombination process heat is released. The coating material is injected into the gas plume, melted, accelerated and deposited on a surface.

The sensitivity of the plasma spraying process to operating conditions and the great number of adjustable parameters makes the optimisation of the process for each application necessary.[2]
Figure 35.2 *Plasma spraying process*

Table 35.10 THERMAL SPRAY PROCESSES, CHARACTERISATION AND TYPICAL APPLICATIONS

Process	Process temperature/ particle velocity/ deposition rate	Typical applications
Combustion powder spray	<3 160°C/<50 m/s/ 1–6 kg/h	Repair operations Resistance to impact Abrasion and wear resistance Resistance to chemical attack Resistance to atmospheric and heat corrosion
Combustion wire spray	<3 160°C/<200 m/s/ 6–8 kg/h	Resistance to atmospheric and heat corrosion Repair operations
Electric wire arc spray	≈4 000°C/≈150 m/s/ 8–20 kg/h	Resistance to atmospheric and heat corrosion Repair operations Bond coats Electrically conductive and solderable coatings Anti-skid and traction coatings
High velocity oxy-fuel thermal spray (HVOF)	<3 160°C/<550 m/s/ 2–8 kg/h	Repair operations Abrasion, wear or erosion resistance Sliding wear resistance Resistance against cavitation Resistance to chemical attack Control of oxidation and sulphidation Resistance to atmospheric and heat corrosion

36 Superplasticity

Superplasticity is the ability of polycrystalline materials to sustain large plastic deformation in tension without rupture, and is phenomenologically delineated by tensile fracture elongations (e_f) in excess of $\sim$300%. Originally discovered in 1912 by Bengough[1], superplasticity is now employed industrially in metal shape forming operations around the world, with primary applications in the aerospace field (*see*, e.g. Ref. [2]).

Superplasticity is a viscous deformation process, and is frequently characterised by a simple flow law relating uniaxial stress σ and strain rate $\dot{\varepsilon}$:

$$\sigma = K \cdot \dot{\varepsilon}^m \tag{1}$$

where K is a temperature- and microstructure-dependent parameter, and m is referred to as the strain rate sensitivity; its reciprocal value, the stress-sensitivity, n, is also commonly reported. Whereas values of m are usually less than 0.25 for typical creep mechanisms in polycrystals, superplasticity is distinguished by values of $m \geq 0.3$. Higher values of m directly promote tensile ductility, by increasing the stability of necks, and by suppressing the tendency for grain-boundary cavitation. In the Newtonian limit of $m = 1$, there is no theoretical limitation to the achievable ductility, although inhomogeneities in temperature or microstructure can substantially impact superplastic extension.

There are two main classes of superplasticity, broadly referred to as *microstructural superplasticity* and *internal-stress superplasticity*, distinguished by deformation mechanisms at the microstructural level.

Microstructural superplasticity is by far the more studied mode of superplastic deformation, and relies on the increase in strain-rate sensitivity, m, observed in fine-grained materials (grain size, d, less than about 10 μm in most metals, and less than about 1 μm in ceramics). At these grain sizes, bulk deformation mechanisms occurring within each grain (i.e. dislocation creep) become secondary to the process of *grain boundary sliding*, involving the relative motion and reorientation of grains with respect to one another. Some general features of microstructural superplasticity are listed below; the reader is referred to Ref. [2] for details:

- The power-law form of Eq. (1), with a constant value of m, does not generally hold over a very broad range of stresses and strain rates in superplastic materials. Rather, a characteristic sigmoidal $\sigma - \dot{\varepsilon}$ relationship is observed, with a peak value of $m \geq 0.3$ occurring over a relatively narrow range of strain rate. This transition is associated with changes in the mechanism for accommodation of grain boundary sliding, from diffusional accommodation at low strain rates to dislocation-motion accommodation at high rates. In superplastic forming operations, it is of primary importance to identify this optimum condition for superplastic elongation.
- The parameter K incorporates an Arrhenius temperature dependence and a power-law grain-size dependence. In general, a finer grain size leads to improved superplastic flow, and the optimum temperature is high enough to promote rapid deformation, but not so high as to encourage rapid grain growth.
- In two-phase superplastic alloys, the optimum superplastic conditions are usually associated with equal proportions of the two phases.
- The optimum strain rate for superplasticity commonly falls in the range 10^{-5}–$10^{-3}\,\mathrm{s}^{-1}$. Recent research has focused on the possibility of high strain rate superplasticity, most commonly observed in aluminium-matrix composite and mechanically alloyed materials at very high temperatures. In such materials, the optimum strain rate may be as high as $10\,\mathrm{s}^{-1}$.
- The fine grain structure required for microstructural superplasticity is usually attained by a schedule of thermomechanical processing, such as rolling or forging, although many more exotic methods such as severe plastic deformation have been developed to refine metallic microstructures.

Table 36.1 summarises 184 investigations of superplasticity in metals and alloys, with an emphasis on the more technologically-relevant aluminium, copper, iron and titanium systems which form the basis of industrial superplastic forming operations. Tabulated are the range of experimental conditions (temperatures, strain rates, and grain sizes), as well as the strain rate sensitivity m, the tensile elongation to failure, e_f, and the optimum conditions for superplasticity. Experimental research in superplasticity has recently focused on emerging structural materials, such as intermetallics, metal-matrix composites, and ceramics. Tables 36.2 and 36.3 summarise recent work on microstructural superplasticity in intermetallics and metal-matrix composites, respectively.

Internal-Stress Superplasticity does not require a fine microstructure, but rather depends upon a renewable source of internal stresses within the material. Internal stresses are generated by, e.g. thermal expansion mismatch between phases or anisotropic grains, or by a polymorphic phase transformation. When an external stress is applied concurrently, the internal mismatch strains are biased to develop preferentially in the direction of the applied external stress, leading to macroscopic plastic deformation. In general, both an internal and a superimposed external stress are required for this deformation mechanism to be active, and the internal stresses must be renewed many times to accumulate large deformations. Thermal cycling is a common means of renewing internal stresses, especially in systems with a thermal expansion mismatch or a thermally-driven phase transformation. Upon each thermal cycle, an increment of plastic strain is developed, and many cycles are required to achieve superplastic strains.

Unlike microstructural superplasticity, which can exhibit a range of strain-rate sensitivities, internal-stress plasticity occurs under ideal Newtonian conditions, with $m = 1$. Unfortunately, this mechanism operates only at low strain rates, in the range 10^{-7}–10^{-4} s^{-1}, but because it does not require a fine microstructure it can be applied to hard-to-form engineering materials such as metal-matrix composites or alloys with coarse microstructures. Internal stress superplasticity has primarily been studied during thermal cycling for the case of thermal expansion-mismatch in aluminium-matrix composites, as well as during allotropic phase transformation (transformation superplasticity) in iron and titanium alloys. Table 36.4 summarises research on internal stress superplasticity.

[a] Optimum condition based on strain rate sensitivity, *m*, instead of elongation.
[b] Testing performed in compression.
[c] Testing performed in double-shear configuration.
[d] Dispersion-strengthened alloy.
[e] Tested under a 2 kV/cm applied electric field.

37   Metal-matrix composites

Metal-matrix composites are engineered materials typically comprising reinforceants of high elastic modulus and high strength in a matrix of a more ductile and tougher metal of lower elastic modulus and strength. The metal-matrix composite has a better combination of properties than can be achieved by either component material by itself. Normally, the objective of adding the reinforceant is to transfer the load from the matrix to the reinforceant so that the strength and elastic modulus of the composite are increased in proportion to the strength, modulus and volume fraction of the added material. Improvements in non-mechanical properties can also be achieved by adding a second phase, for example electrical conductivity, as compared with conventional alloying for strength.

The reinforcement can take one of several forms. The least expensive and most readily available on the market are the particulates. These can be round but are usually irregular particles of ceramics, of which SiC and Al_2O_3 are most frequently used. Composites reinforced by particulates are isotropic in properties but do not make best use of the reinforceant. Fine fibres are much more effective though usually more costly to use. Most effective in load transfer are long parallel continuous fibres. Somewhat less effective are short parallel fibres. Long fibres give high axial strength and stiffness, low coefficients of thermal expansion and, in appropriate matrices, high creep strength. These properties are very anisotropic and the composites can be weak and brittle in directions normal to that of the fibres. Where high two-dimensional properties are needed, cross-ply or interwoven fibres can be used. Short or long randomly oriented fibres provide lower efficiencies in strengthening (but are still more effective than particulates). These are most frequently available as SiC whiskers or as short random alumina ('Saffil') fibres or alumino-silicate matts.

Long continuous fibres include drawn metallic wires, mono-filaments deposited by CVD or multifilaments made by pyrolysis of polymers. The properties of some typical fibres are compared in Table 37.1. The relative prices are given as a very approximate guide. Because most composites are engineered materials, the matrix and the reinforceant are not in thermodynamic equilibrium and so at a high enough temperature, reaction will occur between them which can degrade the properties of the fibre in particular and reduce strength and more especially fatigue resistance. As many composites are manufactured by infiltration of the liquid metal matrix into the pack of fibres, reaction may occur at this stage. Some typical examples of interaction are listed in Table 37.2.

In order to obtain load transfer in service, it is essential to ensure that the reinforceant is fully wetted by the matrix during manufacture. In many cases, this requires that the fibre is coated with a thin interlayer which is compatible with both fibre and matrix. Commonly, this also has the advantage of preventing deleterious inter-diffusion between the two component materials. The data on most coatings are proprietary knowledge. However, it is well known that silicon carbide is used as an interlayer on boron and on carbon fibres to aid wetting by aluminium alloys.

The routes for manufacturing composites are still being developed but the most successful and lowest cost so far is by mixing particulates in molten metal and casting to either foundry ingot or as billets for extrusion or rolling. This is applied commercially to aluminium alloy composites. Another practicable route is co-spraying in which SiC particles are injected into an atomised stream of aluminium alloy and both are collected on a substrate as a co-deposited billet which can then be processed conventionally. This is a development of the Osprey process and can be applied more widely to aluminium and other alloys. Other routes involve the infiltration of molten metal into fibre pre-forms of the required shape often contained within a mould to ensure the correct final shape. This can be done by squeeze casting or by infiltrating semi-solid alloys to minimise interaction between the fibre and metal. Fibres can also be drawn through a melt to coat them and then be consolidated by hot-pressing.

To reduce interaction, solid state methods can be used, e.g. cold isostatic pressing (CIP) and sintering or hot isostatic pressing (HIP) of metal powders mixed with short fibres. Diffusion-bonding

Table 37.1   PROPERTIES OF REINFORCING FIBRES AT ROOM TEMPERATURE (BASED ON REFERENCES 9 and 16)

Fibre	Form	Preparation route	Diameter μm	Density g cm^{-3}	Weibull modulus	Fracture stress MPa	Elastic modulus GPa	Coefficient of thermal expansion K$^{-1} \times 10^6$	Price relative to glass fibre

Ti-B	Formation of TiB_2.	750	9
Ti-SiC	Formation of TiC, $TiSi_2$ and Ti_5Si_3.	700	9

laminates of layers of fibres and metal foil is also effective. Another successful method of fabricating continuous fibre composites is to pre-coat the individual fibres with metal-matrix by PVD prior to consolidation by hot pressing. Very fine composite microstructures can be made by co-deforming a dispersed metal in a metal matrix, for example, Cu-Cr, Cu-Nb, in these cases very high strengths can be achieved for large drawing strains.

The properties which can be achieved in composites include higher strength, higher stiffness, improved high-temperature properties, lower or matched coefficients of thermal expansion and improved wear resistance. This is usually at the expense of conventional ductility but in most cases improved fracture toughness can be obtained. The following tables illustrate what has been achieved in aluminium, magnesium, titanium, zinc and copper alloys. The improvement in strength is often larger in the weaker alloys with less benefit being realised in the stronger alloys, e.g. see Table 37.3. All the alloys show an improvement in elastic modulus when reinforced.

38 Non-conventional and emerging metallic materials

38.1 Introduction

Metallic materials that are outside the mainstream of conventional metals and alloys, with respect to composition, structure and/or processing, are discussed in this chapter. The materials considered are as follows:

- a. structural intermetallic compounds;
- b. metallic foams;
- c. metallic glasses;
- d. micro- and nanoscale materials;

These materials are in different stages of development. Metallic glasses are technologically mature materials, with long-established commercial applications, although there continue to be exciting developments in the area of bulk metallic glasses. Metallic foams are the subject of a quite intense research effort at the time of writing, but have already found commercial success in a number of markets. Structural intermetallic compounds have been the subject of major world-wide research activities dating back over many years. However, significant barriers remain to the widespread commercial implementation of these materials. Metallic nanomaterials feature in much contemporary research and the details of these are still very much subject to change. However, work on the fundamentals of these materials has reached a point where this can usefully be summarised.

38.2 Cross references

The following contain information that is relevant to the contents of this Chapter:

- a. crystallographic data on intermetallics—Chapter 6;
- b. shape memory alloys—Chapter 15;
- c. thermoelectric materials—Chapter 16;
- d. superconducting materials—Chapter 19;
- e. magnetic materials—Chapter 20;
- f. metal matrix composites—Chapter 37.

38.3 Structural intermetallic compounds

Intermetallic compounds are employed commonly to strengthen conventional alloys. Two examples are:

- Age-hardenable aluminium alloys, strengthened by a variety of intermetallic phases, as discussed in Section 29.3.
- Nickel-base superalloys (for which an overview can be found in reference 1), with a γ/γ' microstructure. In this case γ represents a nickel-base solid solution and γ' is the intermetallic phase $Ni_3(Al,Ti)$.

More recently, intermetallic compounds have attracted great interest as monolithic (stand-alone) structural materials, for high-temperature applications. Table 38.1 summarises some of the

Table 38.1   SOME EXAMPLES OF INTERMETALLIC COMPOUNDS OF INTEREST FOR HIGH-TEMPERATURE APPLICATIONS

Phases listed in brackets, within a given system, are relatively technologically immature. This table does not represent an exhaustive list, especially with respect to the 'exotic intermetallics'. For example, numerous ternary compounds are not included.

System	*Compounds of interest*
Aluminides	
Ni	Ni_3Al, $NiAl$
Ti	Ti_3Al, $TiAl$, ($TiAl_3$)
Fe	Fe_3Al, $FeAl$
Refractory metal	$NbAl_3$ etc.
Silicides	$MoSi_2$, ($NbSi_2$), ($TiSi_2$), ($CrSi_2$), (Co_2Si), (Ti_5Si_3) etc.

intermetallics that have been considered as structural materials (see [2] for discussion of the screening criteria needed for selecting structural intermetallic compounds).

Much of the interest in structural intermetallics has centred on the aluminides of nickel (Ni_3Al and $NiAl$) and titanium (Ti_3Al and $TiAl$). However, other aluminides feature prominently in the literature on intermetallics. In particular, interest has focused on the iron aluminides Fe_3Al and $FeAl$ (see some of the general references in the nickel aluminide section). However, other aluminide systems, for example refractory metal aluminides (e.g. [3–7]), have also been investigated. There is also a body of work on non-aluminide phases, such as silicides, in particular $MoSi_2$ (see e.g. [8, 9] for overviews). Nonetheless, in the interests of brevity, the discussion in this section is confined to the nickel and titanium aluminides.

38.3.1   Sources of information on structural intermetallic compounds

General overviews of intermetallic compounds, may be found in [10–14], including a historical perspective in the case of the first of these references. Other useful sources of collected work on structural intermetallics are the proceedings of the following:

- The Materials Research Society (MRS) has sponsored a long-running symposium series, 'High-Temperature Ordered Intermetallic Alloys'.[15]
- The Minerals, Metals and Materials Society (TMS), in some cases in conjunction with ASM International, has organised a number of conferences and symposia on structural intermetallics. An example of these is the 'International Symposium on Structural Intermetallics' series.[16]

A useful compilation of mechanical and other property data, collected up to the early to mid 1990s, for aluminides and other intermetallics, may be found in [17].

38.3.2   Focus of the section

At the time of writing, there has been nearly 20 years of intense research effort in the US, Europe, Japan and elsewhere on structural intermetallics and sporadic research dating back far longer. Following this work, the general features of the leading structural intermetallic systems are now relatively mature, for good or ill. In contrast, the detailed compositions and processing paths for these materials are still evolving. Hence, this section concentrates on the general features of these materials, and a large body of alloy-specific numerical data are not included (since the latter are still subject to change).

38.3.3   The nature of ordered intermetallics

In a solid-solution (A–B), the solute atoms (B) sit on random sites in the solvent (A) lattice. Small solute atoms (e.g. C in Fe) become interstitials and larger solute atoms (e.g. Cr in Fe) substitute for the solvent atoms. In contrast to a solid-solution, in an intermetallic compound (A_xB_y) the constituent (A and B) atoms occupy well defined sites within the structure of this phase. Hence, intermetallic
Figure 38.1 *The crystal structures of* NiAl (B2), Ni_3Al (L1$_2$) *and* TiAl (L1$_0$). *Crystallographic data for these phases* (*and many other intermetallics*) *may be found in* [18]. *A significant body of crystal structure data is available in Chapter 6*

compounds are referred to as 'ordered' and random solid-solutions as 'disordered'.* For example, Al atoms occupy random substitutional sites in the face centred cubic (FCC) Ni–Al solid solution. In contrast, ordering of this solid solution, to form the intermetallic compound Ni_3Al, involves placing the aluminium atoms at the cube corners and the nickel atoms at the face centre sites of the unit cell (Figure 38.1). Note, this ordering process results in a change in Bravais lattice and Ni_3Al is primitive cubic, not FCC.[18] Ordering is often described in terms of the production of a 'superlattice' that is superimposed on the disordered phase. Not all ordered intermetallic phases have crystal structures that can be related to those of their constituent metals. Consider an example. The Ni–Al phase diagram (which can be found in Chapter 11), contains several intermetallic compounds, including the phase NiAl. NiAl has the CsCl structure (Figure 38.1), whereas both nickel and aluminium are FCC.

Given the free electron model of metallic bonding, it might seem at first sight that metals of the same crystal structure should be fully mutually soluble (and this can be the case, as in the Ni–Cu system, for example). However, the Hume-Rothery rules (see e.g. [19, 20]) describe the circumstances under which solid-solubility is limited. These circumstances and the resulting phases are as follows:

a. Size misfit between the solvent and solute atoms. This leads to a 'size factor' compound. Examples include Laves phases, such as $MgZn_2$ and MX type interstitial compounds, for example Ti(C,N).
b. Large differences in electronegativity between the solvent and solute. In this case, there will be a tendency towards ionic bonding. Thus ionically bonded compounds, such as Mg_2Sn can form.

---

* The term 'disordered' in the present context refers to a random solid solution. Confusingly, however, the same term is sometimes applied to amorphous metals (see Section 38.5), even though a disordered solid solution possesses a well defined Bravais lattice and an amorphous metal does not.

   c. Unsuitable valence electron (e) to atom (a) ratios. The formation of 'electron compounds' occurs at specific e/a values. For example, there is a large class of 1.5 e/a electron compounds, sharing the B2 structure of ordered β brass.

Note, only in case 'b' above will the normal rules of valency be followed in the chemical formula of the intermetallic. A detailed discussion of the nature of solid solutions and the breakdown in solubility may be found in [21]. The same volume also includes a useful discussion of the structure of intermetallics.[22]

Regardless of the circumstances leading to ordering, a key point is that the formation of an intermetallic will result in unlike nearest neighbour atoms (e.g. in NiAl, the nearest neighbour of each aluminium atom is a nickel atom and vice versa). Thus, intermetallic formation is favoured when the energy of unlike neighbour bonds is lower than that of like neighbour bonds (the opposite is also possible, in which case cluster formation will occur), so that:

ordering is favourable if:	$2E_{AB} < E_{AA} + E_{BB}$
clustering is favourable if:	$2E_{AB} > E_{AA} + E_{BB}$
the solid-solution remains random if:	$2E_{AB} = E_{AA} + E_{BB}$

Note, however, that bonding in intermetallics can be quite complex and the reader is referred to work on structural modelling of intermetallics (see [23] and specific references in the text; Chapter 39 of the present work contains an overview of the modelling of materials).

Some intermetallics remain strongly ordered up to their melting point (for example NiAl), whereas other intermetallics (such as those in the Au–Cu system) undergo disordering at high temperatures, as can be seen by perusal of the phase diagrams contained in Chapter 11. The transition from ordered to disordered may be sudden (as in Cu_3Au, for which a well defined disordering temperature is seen) or gradual (as in the case of disordering of β-brass), depending on the system involved. The degree of order is usually represented by the long-range order (LRO) parameter (S), which is defined[24] as follows:

$$S = \frac{p - r}{1 - r}$$

where

p = fraction of species X on X sites
r = atom fraction of species X in the alloy.

Thus, for a fully ordered alloy, S equals unity and the value of S falls as the degree of order decreases. In cases where a solid-solution is not completely random, but does not possess a well-defined superlattice, the short-range order (SRO) parameter (σ) can be employed. The SRO parameter (see [25] for the original discussion), at a given temperature, is defined as:

$$\sigma = \frac{q - q_r}{q_m - q_r}$$

where

q = fraction of unlike nearest neighbour atoms observed
q_r = fraction of unlike nearest neighbour atoms that would be present if the solid-solution were completely random
q_m = fraction of unlike nearest neighbour atoms that would be present under the condition of maximum possible order.

Two important features of ordered intermetallic compounds are antisite defects and antiphase (domain) boundaries (APBs or APDBs). Consider a notional intermetallic AB. In this case, an antisite defect would be an A atom on a B site, or vice versa. An APB would be formed, as illustrated in Figure 38.2 (for early work on the observations of antiphase domains, see [26, 27]).

The domains at the top and bottom of the figure are both perfectly ordered. However, there is an antiphase displacement between the ordering of these two domains. As a result, AA and BB bonds are formed at the boundary between the domains (i.e. the APB).

In the event that the intermetallic is strongly ordered, the creation of an antisite defect will carry a large energy penalty and the APB energy (APBE) will be high, in some cases to the point where APBs can not be produced. Note, however, in intermetallics with a wide compositional range, the presence of *structural* antisite defects provides a possible mechanism for accommodating deviations
Figure 38.2   *Schematic representation of an APB (the plane of the APB corresponds to the dashed line at the centre of the figure)*

from stoichiometry, as an alternative to the formation of structural vacancies. Such structural antisite defects can be a normal part of the structure of a non-stoichiometric intermetallic and can form even in strongly ordered alloys (this is discussed further, with respect to NiAl, in Section 38.3.6 below).

In long period superlattice structures, such as those that form in the Au–Cu system, regularly spaced APBs form an integral part of the structure of the intermetallic (a concise discussion of these and other superlattice structures is contained in [28]). However, in the case of intermetallics of interest as structural materials, APBs are of the greatest importance with respect to their role in the behaviour of dislocations. Issues related to both antisite defects and APBE values are discussed further in the next section and in more detail (again with respect to NiAl) in Section 38.3.6.

38.3.4   The effect of ordering on the properties of intermetallics

In cases where there is a strong affinity between the constituent species, the melting point of an intermetallic can be significantly higher than that of any of its constituent elements. For example, as can be seem from the Ni–Al phase diagram in Chapter 11, the melting point of stoichiometric NiAl is nearly 200°C higher than that of nickel and far exceeds the melting temperature of aluminium. In a very strongly ordered intermetallic:

- Diffusion of the constituents of the intermetallic will be impeded, when vacancy—atom interchanges lead to the creation of antisite defects. The simplest example of this phenomenon* is B2 compounds (as shown in Figure 38.3), such as NiAl. In NiAl, strong ordering forces diffusion to occur via cyclic mechanisms requiring a series of co-ordinated vacancy—atom interchanges.[29] Diffusion is a random walk process and so coordinated cyclic jumps have a much lower probability than a single vacancy—atom interchange event. Thus, ordering will significantly reduce

---

* The effect of ordering on diffusion can be seen most clearly by looking at the effect of temperature on diffusion coefficients in reversibly ordered intermetallics.
Figure 38.3   *The* B2 *structure, showing that a single vacancy—atom interchange event will result in the formation of an antisite defect*

Table 38.2   THE EFFECT OF DEVIATIONS FROM STOICHIOMETRY ON THE SELF DIFFUSION COEFFICIENT OF NICKEL (D_{Ni}) IN NiAl, AT A TEMPERATURE OF 1 000°C [33]

Ni (at. %)	D_{Ni} (m^2 s^{-1})
50	$\sim 1 \times 10^{-16}$
48.5	7×10^{-16}
58	5×10^{-14}

the observed diffusion coefficients* Non-stoichiometric intermetallics can have quite different diffusion coefficients than stoichiometric compounds (see Table 38.2). This follows because deviations from stoichiometry are accommodated by constitutional point defects, These constitutional point defects can be either antisite atoms (as in nickel-rich NiAl), or structural vacancies (as in aluminium-rich NiAl—see references in the discussion of NiAl).

- The possible Burger's vectors may be restricted, to those which do not involve the formation of an APB (see Figure 38.4). Hence the number of slip systems may be severely restricted. The operation of the remaining available slip systems may be changed significantly (in some cases such that these are difficult to activate).
- Other properties may be affected, for example the rate of work hardening can increase on ordering and recrystallisation may become sluggish (for an overview of the latter, see [34]).

The formation of a high melting temperature intermetallic, in which diffusion (and possibly dislocation motion) may be difficult, raises the possibility of employing such materials under conditions

---

* Diffusion of ternary additions in B2 compounds is influenced by the extent to which the alloying addition partitions to one of the two sublattices (i.e. Ni sublattice and Al sublattice in the case of NiAl). An example of recent work on diffusion in B2 compounds with ternary additions can be found in [30]. See [31] for recent work on site occupancy in NiAl and FeAl with ternary additions.

The exact character of the intermetallic is very important in determining the extent to which ordering influences diffusion. For example, in the case of L1$_2$ type Ni$_3$Al, diffusion on the Al sublattice might be expected to be much more difficult than diffusion on the Ni sublattices, since only the former would disrupt local order. However, in recent work on Ni$_3$Al, the intrinsic diffusion coefficients of Ni and Al were found to be almost the same,[32] which suggests that Al can diffuse readily by an antisite mechanism.

In discussing diffusion in an intermetallic A$_X$B$_y$, it is especially important to distinguish between the interdiffusion coefficient ($\bar{D}$) and the self diffusion coefficients (D_A and D_B). These are related to the atom fractions of A and B (X_A and X_B) by

$$\bar{D} = (X_B\,D_A + X_A\,D_B)\,F$$

The value of the parameter F depends on the character of the intermetallic and in some cases can actually be larger than unity.[33]
Figure 38.4   *Some possible Burgers vectors in the* B2 *and* L1$_2$ *systems. Notice that* 1/2 <111>$_{B2}$ *and* 1/2 <110>$_{L1_2}$ *lead to the creation of an APB, whereas* <001>$_{B2}$ *does not*

where creep resistance is required (see [35] for an overview of creep in structural intermetallic compounds). However, it must be cautioned that in cases where dislocation motion is difficult and/or an inadequate number of slip systems operate, problems are experienced with loss of low-temperature ductility. As will be discussed below, the lack of room-temperature ductility is perhaps the largest single obstacle impeding the widespread commercial application of structural intermetallics. An overview of plastic deformation in intermetallic compounds is available in [36].

38.3.5   Overview of aluminide intermetallics

Much of the work on monolithic intermetallic compounds has aimed at enabling the use of these materials in high-temperature structural applications, typically as an alternative to nickel-base superalloys. The driving force behind this work has largely been the relatively low densities of nickel and titanium aluminide intermetallics, when compared with those of typical nickel-base superalloys (Table 38.3). Given the low density of these materials, some specific properties of aluminide intermetallics, such as specific stiffness, are attractive. However, it should be cautioned that the creep and environmental resistance of these materials do not necessarily rival those of single crystal γ/γ' superalloys, as can be seen in Table 38.4 (an overview of oxidation and corrosion of intermetallics can be found in [37]). Note also the wide variation in fracture toughness between these different alloys. These various points will be discussed further in subsequent sections.

38.3.6   Nickel aluminides

The Ni–Al binary system contains several intermetallic phases. However engineering interest has focused on Ni$_3$Al and NiAl. The aluminium-rich phases in this system have relatively low melting

Table 38.3   THE DENSITY (ρ), ROOM-TEMPERATURE YOUNG'S MODULUS (E) AND SPECIFIC STIFFNESS (E/ρ) OF SOME COMMON INTERMETALLIC COMPOUNDS, IN COMPARISON WITH THOSE OF NICKEL-BASE SUPERALLOYS AND TITANIUM ALLOYS

points (and are very brittle) and so are not candidates for structural applications. The structure and properties of Ni$_3$Al and NiAl diverge considerably.

Ni$_3$Al

The primitive cubic L1$_2$ type structure of γ'–Ni$_3$Al phase is the same as that of the similar phase in γ/γ' superalloys, although the latter has a composition that is usually closer to Ni$_3$(Al,Ti), as has already been remarked. In the binary Ni–Al system, Ni$_3$Al has quite a narrow range of composition. However, ternary alloying of this phase is possible (for an overview of partitioning behaviour and phase stabilisation in the $\gamma/\gamma'/\beta$ system see [42]).

Dislocations in γ' travel in the form of pairs.[13] Each dislocation in such a pair is of the 1/2 <110> type (but see discussion below on further dissociation). This Burgers vector is the same as that observed in disordered FCC metals and alloys—see e.g. [43] for a concise overview of dislocations in FCC metals). A dislocation with a Burger's vector of 1/2 <110> is a perfect dislocation in the disordered γ phase. However, with respect to the superlattice of γ', 1/2 <110> is a partial dislocation, since this displacement places Al onto Ni sites (Figure 38.4). The terminology describing such dislocations is far from standardised, but the term 'superlattice partial' dislocation will be used here (superpartial is another common term).

Given that 1/2 <110> is a superlattice partial, the first dislocation in the pair creates an APB, which is then removed by the second dislocation. Hence, the two 1/2 <110> dislocations in a pair are separated by a ribbon of APB, the formation of which is opposed by the APBE. The spacing between the superlattice partials is determined by equilibrium of the tension, induced by the APB, and the elastic repulsion of the like 1/2 <110> dislocations. Such pairs of dislocations, bound together by APBs, are often referred to as 'superdislocations'.

The APBE in γ' is relatively low. Measured and calculated values of the APBE in γ' have been summarised in [46]. These lie in the range of 90–196 mJ m^{-2} for APBs on {100} and 110–283 mJ m^{-2} for APBs on {111} (compared with stacking fault energies in the range of 5–40 mJ m^{-2} in the same system). Given the relatively low APBE, the spacing between the 1/2 <110> dislocations can be quite large. Just as in disordered FCC metals and alloys, the 1/2 <110> dislocations dissociate into pairs of 1/6 <112> partial dislocations (these are partials with respect to the fundamental FCC structure and not just to the primitive cubic superlattice). Each pair of 1/6 <112> partials is separated by a ribbon of stacking fault (SF), so that the spacing of these partials is influenced by the SF energy (SFE) in the same fashion as in an FCC metal or alloy. Note, in the case of ordered γ', the result

Table 38.4 STRUCTURES AND REPRESENTATIVE PROPERTIES OF NICKEL AND TITANIUM ALUMINIDES, IN COMPARISON WITH NICKEL-BASE SUPERALLOYS

See the footnotes to the table for the sources of these data. It should be noted that, within these general classes of material, there are very significant variations in properties depending on the alloy and processing route chosen. Also, some information on the current generation of alloys remains proprietary at the time of writing. Thus, these data should be treated only as a general guide.

| Type of alloy | Usual notation for major phase | Structure of major phase(s)[1] | Likely maximum operational temperature of alloys based on this phase (°C) | | Representative room temperature properties (polycrystals unless otherwise stated) | | | | |
			Due to creep	Due to oxidation[2]	Type of alloy (see text for details)	Yield stress (MPa)	Ultimate tensile strength (MPa)	Tensile ductility (%)	Fracture toughness (MPa $\sqrt{m}$)
Ni_3Al	γ'	$L1_2$	1 000	>1 100	Microalloyed with B[5] Single crystal[5]	$\sim$240–$\sim$700 <100–$\sim$300	$\sim$700–$\sim$1 200 $\sim$200–$\sim$900	20–30 10–50	$\geq$60 (alloyed with Cr)

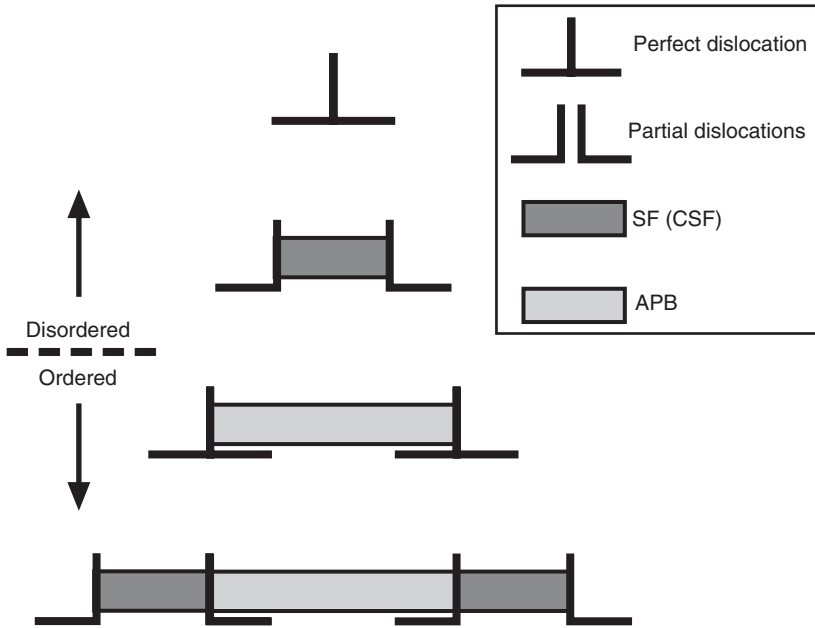
[9] In this alloy, β indicates a B2 phase, typically stabilised by Nb additions.
[10] The best ductility is produced by duplex alloys (equiaxed γ + lamellar γ/α_2), whereas fully lamellar (γ/α_2) materials offer the maximum fracture toughness and creep resistance.


Figure 38.5   *Schematic representation of the dislocation configuration in γ (disordered) and γ′ (ordered)*

Table 38.5   THE EFFECT OF TEMPERATURE (T) ON THE YIELD STRESS (σ_y) OF Ni$_3$Al (PEAK INDICATES THE HIGHEST FLOW STRESS OBSERVED)

These values are from evaluated data in [17] for <001> oriented Ni–24.9 at. % Al. Both the yield stress at any given temperature and the temperature at which the yield stress reaches a maximum are sensitive to both composition and orientation.

T (K)	σ_y (MPa)
300	151
700 ($\sim$ peak)	534
1 000	407

is a complex stacking fault (CSF). Thus, dislocation motion in γ′ involves a train of four partial dislocations, arranged in two pairs, with the partials in each pair bound together by CSFs and the pairs held together by an APB, as shown in Figure 38.5.

Unalloyed single crystal Ni$_3$Al is quite ductile, even at room temperature. In contrast, polycrystalline binary Ni$_3$Al suffers from brittle grain boundaries. Fortunately, however, microalloying with boron[47] overcomes this problem for hypostoichiometric, i.e. Ni-rich, Ni$_3$Al. Modelling work suggests that the grain boundaries in Ni$_3$Al are intrinsically weak and so the boron may be acting as a grain boundary strengthener. However, it has also been found that boron-free Ni$_3$Al suffers from grain boundary environmental embrittlement under normal conditions and that good ductility can be produced in very dry environments even without the addition of boron.[48,49] Environmental embrittlement mechanisms for Ni$_3$Al and other intermetallics are discussed in [50].

Ni$_3$Al exhibits an anomalous increase in yield and flow stresses with increasing temperature, as can be seen in Table 38.5. The yield stress anomaly in γ′ is the result of thermally activated cross-slip from the usual {111} slip plane (the same as in disordered FCC metals and alloys) to {100}. Once screw dislocations cross slip to {100} their mobility is reduced and so the flow stress increases. The driving force for cross-slip from {111} to {100} may come from anisotropy in the APBE; as can be seen in the data above, the APBE may be somewhat lower for APBs on {100} than on {111}. Anisotropic elastic properties may also produce a driving force for cross-slip. A detailed discussion

of the mechanisms underlying the yield stress anomaly is beyond the scope of the present work. However, such a discussion can be found in [51], along with numerous references to the original work in this area.

Although high creep resistance γ/γ' superalloys[52] contain at least 60 vol. % γ' (in some cases considerably more than this), this does not imply that a 100 vol. % γ' material will have superior creep resistance. There are a number of mechanisms that contribute to the high creep resistance of superalloys (see for example [1] for a useful summary). Unfortunately, many of these are not applicable to single phase γ'. Thus, in comparison with a high γ' volume fraction single crystal γ/γ' superalloy, the creep resistance of single phase γ' is quite poor. An elegant demonstration of this problem may be found in [53] which compares the creep behaviour of a superalloy with single phase γ' of the same composition as that in the superalloy.

In summary, the density of Ni_3Al is only a little lower than that of a superalloy and the creep resistance is markedly inferior to that of the best superalloys. Hence, there is little hope that Ni_3Al will find application in aerospace, or other cases where high specific creep resistance is a key requirement. However, suitably alloyed Ni_3Al is much more 'forgiving' than more brittle intermetallics. Also, this material does possess some intriguing properties in terms of strong environmental resistance. For example, Ni_3Al has as excellent resistance to carburising atmospheres.[54] Hence, there has been interest[54] in using this material in applications such as belts, pans, rollers and other heat treatment furnace furniture, for high volume production in the automotive and other industries. Likewise, the diesel engine industry has expressed interest in the selective application of Ni_3Al.[55]

NiAl

Unlike Ni_3Al, the B2 compound β-NiAl occupies a significant range of composition in the Ni–Al binary system. As has already been remarked, nickel-rich NiAl forms Ni antisite defects. When aluminium-rich, this phase has nickel vacancies. A discussion of site occupancy and point defects in non-stoichiometric and alloyed NiAl may be found in [56–61]. As has already been remarked, stoichiometric NiAl has quite a high melting point (around 300°C above that of current superalloys). Also, the relatively low density of NiAl (approximately 2/3 that of modern superalloys) offers the possibility of good specific properties. Overviews of NiAl may be found in [62–67] and comparison with other B2 Compounds in [68–71].

NiAl has a high thermal conductivity (at around 80 W m^{-1} K^{-1} some 4–8 times those of typical superalloys).[62] This property is important with respect to the potential application of NiAl as an aero gas turbine blade material. Replacement of superalloy blades by NiAl would result in a highly significant 50°C reduction in blade temperatures.[62] Furthermore, NiAl offers a good match with superalloy thermal expansion coefficients.[62]

Given the high aluminium content of this phase, NiAl is an unequivocal Al_2O_3 former. NiAl therefore provides excellent oxidation resistance.[72–75] Indeed NiAl offers an enhancement in oxidation resistance over that available with alloyed Ni_3Al (see [76] for a an example of work on the oxidation of Ni_3Al alloys).

NiAl has markedly better specific creep resistance than Ni_3Al (see [77] for a discussion of the creep resistance of (Fe, Ni) Al alloys). Furthermore, the creep resistance of NiAl can be markedly enhanced through alloying, to produce a suitable two phase microstructure (see e.g. [53, 78–88] for a selection of the literature relevant to this topic). This approach to creep resistance has some similarities with that employed in γ/γ' superalloys. However, in the case of creep resistant NiAl alloys, both the matrix (which retains the B2 structure) and the second phase, are ordered. A common choice of second phase, in the references listed above, is an $L2_1$ type Heusler phase, with a composition Ni_2AlX, where X is titanium, hafnium or a range of other elements. In NiAl alloys, phases of this type are commonly known* as β'. The use of other ternary intermetallic phases to enhance creep resistance is also possible. Figure 38.6 provides an overview of the various microstructural modifications to NiAl alloys discussed in the text.

NiAl also offers good chemical compatibility with common ceramic phases. NiAl is therefore suitable for use as the matrix of intermetallic matrix composites and can also be dispersion strengthened (these topics are discussed further in Section 38.3.8).

There is currently a major problem with NiAl. The usual slip systems in this phase are <001>{110} or {001} and NiAl shows great reluctance to undergo non <001> slip at room-temperature, except under unusual circumstances. With only <001> Burgers vectors available at room-temperature, there are insufficient slip systems for polycrystalline NiAl to satisfy the Von Mises yielding criterion. Hence, polycrystalline NiAl is exceedingly brittle (although textured materials can show some

---

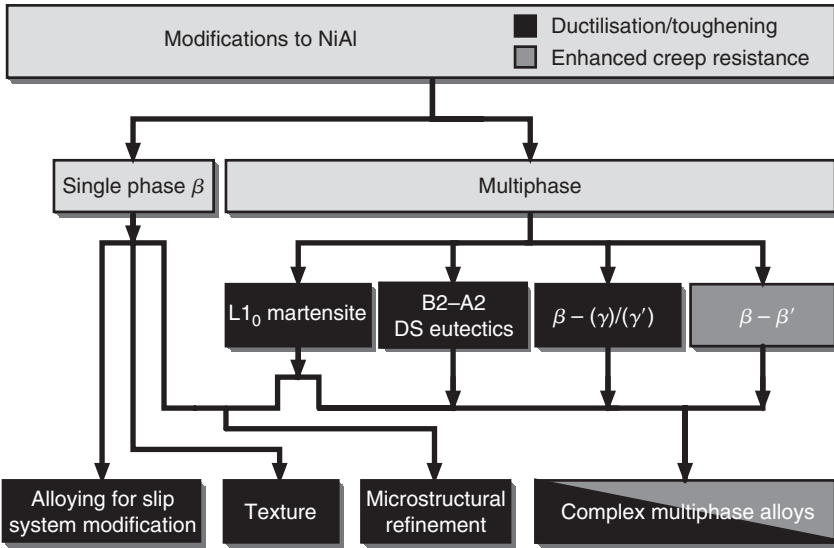
* β' is also used sometimes to indicate the $L1_0$ type martensite that forms from nickel-rich NiAl. However, in the present work, this symbol will be used exclusively to represent the Heusler phase.


Figure 38.6   *An overview of* NiAl *alloys. For details of specific microstructures and references, see text*

ductility).[89] Likewise, the ductility of single-crystal NiAl becomes very sensitive to the loading axis (and can be quite poor even with soft orientations).

A key problem with NiAl is that ordering of this phase is very strong and consequently there is a large energy penalty associated with the formation of APBs. Calculated APBEs for NiAl are in the range of 240 to 1 000 mJ m^{-2} (see references below). The upper end of this predicted APBE range is very high (comparable in magnitude, for example, to high angle grain boundary energies—see [90] for a compilation of interfacial energy data).

In cases where non <001> slip is produced, e.g. because a single crystal is tested on the hard <001> axis, <111> dislocations are observed, but these remain perfect with respect to the superlattice* and dissociation into 1/2 <111> superlattice partials is not observed.[91] There has been quite an intense effort to model bonding and its effects for example on cleavage fracture, APBE, grain boundary properties and dislocation core structures (see e.g. [92–99]) in NiAl.

NiAl also appears to suffer from problems with embrittlement as a result of strain ageing.[100–103] In recent work, it has been suggested that phosphorus-induced softening of polycrystalline NiAl is the result of gettering or trapping of interstitials by this element.[104]

NiAl also has unusual fracture behaviour,[105,106] involving cleavage on {115} and {117}. In this case, the fracture path involves alternating {115} or {117} planes so that the fracture surface has a 'rooftop' appearance. Cleavage on these high index planes is very unusual. Instead, as a strongly ordered B2 compound, NiAl might be expected to cleave on {110}, thus preserving the Ni:Al ratio at the fracture surface. More weakly ordered B2 compounds cleave on {100}, as for disordered body centred cubic metals.

Various approaches have been investigated in an attempt to enhance the low-temperature ductility and/or fracture toughness of NiAl (see for example [45, 89, 107–109] and Figure 38.6). These approaches are discussed below.

Although mixed results have been claimed, solid-solution alloying (to reduce the APBE) does not seem to offer a clear solution to the problem of enhancing the low-temperature ductility of NiAl. A few examples (covering a wide time span) of the extensive body of literature on the topic of slip and slip system modification in NiAl may be found in [110–117] (for some early work on slip in B2 compounds, see [118]).

A possible solution to the poor fracture toughness of NiAl is composite type toughening using *in-situ* composites (e.g. [119–127]) consisting of, usually directionally solidified, eutectics of NiAl–Z. In this case, Z is typically a disordered body centred cubic solid solution, based for example

---

* Within the capabilities of weak-beam dark field transmission electron microscopy, no dissociation of <111> dislocations is observed and this restricts the maximum dissociation (if any) to ~1.5 nm. See the overviews of B2 compounds mentioned elsewhere in this section for comparison of NiAl with less strongly ordered FeAl or (Fe, Ni) Al.

on Cr, Mo or W, although other additions have been investigated. In this fashion, significant increases in room temperature fracture toughness can be produced (>10 MPa $\sqrt{m}$, compared to about 5–6 MPa $\sqrt{m}$ for binary NiAl).

The poor room temperature ductility of NiAl can be addressed by the addition of a significant volume fraction of a ductile second phase, for example γ' or a number of disordered FCC solid solution γ phases (see e.g. [128–139] for a representative selection of the research that has been conducted on this topic). In this case, the second phase serves two functions. Firstly, the ductile phase serves as an 'adhesive' that bonds the NiAl together, so that the limited number of slip systems in the latter ceases to be a problem. Secondly, glissile dislocations are 'injected' into the β-phase, so that the available slip systems in the β-phase work more efficiently (additional slip systems are not necessarily activated). In these circumstances, it is very important to have a morphology that removes the high angle β–β grain boundaries, that would initiate cracks in the absence of non $\langle 001 \rangle$ slip in the β-phase. Also the occurrence of a suitable orientation relationship (i.e. Kurdjumov–Sachs or Nishiyama–Wasserman between β and γ or γ') facilitates slip transfer to the β-phase. Two phase β–γ' alloys can of course be formed in the binary Ni–Al binary system. However, the formation of a β–γ alloy requires ternary alloying, for example with iron.

Although useful toughening or ductilisation of NiAl can be achieved by the use of multiphase microstructures of the two types discussed above, there is a price to be paid. Increases in density result from the use of alloys that are nickel-rich and/or have extensive additions of heavy alloying elements. Thus, there is reason to question the extent to which these multiphase alloys would be useful in density critical applications (e.g. aerospace). Furthermore, creep resistance may be compromised as a result of:

- the presence of significant volume fractions of low creep resistance second phases, in the form of contiguous regions.
- moving the β-phase away from stoichiometry.

An additional problem (see e.g. [140–146]) is that the microstructures developed in complex multiphase NiAl alloys can be quite complex and in some cases show limited stability. Those alloys that attempt to combine ductilisation and/or toughening (through the addition of γ or γ' or an eutectic involving a body centred cubic metal), with creep resistance (via the formation of β'), can be especially problematical with regard to the stability of the desired microstructure.

There have been a number of studies (e.g. [147–151]) on micro- and nanostructured NiAl alloys. The intent of these studies was to enhance the fracture toughness of this alloy. In some cases, this work avoided sacrificing the low density of stoichiometric NiAl, whereas a significant portion of this effort focused on nickel-rich materials. In the latter case, there are overlaps with work on γ' and martensite-containing NiAl-derived materials, as discussed elsewhere in this section. Although these efforts have met with at least some success, the microstructural stability of these materials at high-temperature and their likely creep resistance remain concerns. For a general overview of grain size effects in intermetallics see [152].

As with much of the work on structural intermetallics, the intended applications of NiAl as a structural material are mostly in aerospace (e.g. gas turbine stators and rotors). However, unless the low temperature ductility/toughness of this phase can be improved, without compromising its low density, it is difficult to envisage large scale structural application of this material.

Nickel-rich NiAl will undergo a martensitic transformation,* by twinning, to an $L1_0$ type martensite. This transformation is thermoelastic and is capable of showing shape memory. The martensite start (M_s) temperature of NiAl is strongly dependent on composition and ranges from 30 K (–243°C) for a 60 at. % Ni alloy to 1 146 K (873°C) for 69 at. % Ni material.[161] Thus NiAl offers M_s temperatures that are far higher than for a commercial shape memory alloy (SMA), such as NiTi (Nitinol). Hence, there has been some interest in using NiAl as a high-temperature SMA.[162–166] However, the maximum recoverable strain from the shape memory effect (SME) in NiAl is very low ($\ll 1$ %). Also both the diffusional and diffusionless phase transformations in nickel-rich NiAl are quite complex (see [167–200] for some of the literature on this topic) and many of the possible product phases do not show the SME. The $L1_0$ martensite does have somewhat better fracture toughness ($K_{IC} > 10$ MPa $\sqrt{m}$ versus around 5–6 MPa $\sqrt{m}$) than stoichiometric NiAl. Indeed, the formation of

---

* In common with many other phases based on the B2 type β CuZn structure (see e.g. [153, 154,]), even stoichiometric NiAl possesses a modulated 'tweed' microstructure. This microstructure involves small displacements from the nominal lattice of the β-phase (not to be confused with spinodal decomposition, which can occur in some NiAl-derived alloys). An important cause of this modulation is that the β phase is intrinsically unstable with respect to $\{110\} \langle 1\bar{1}0 \rangle$ shear. In NiAl (and some other β phases), this instability is manifested in the formation of shear displacement waves, with propagation vectors of $\langle 110 \rangle$ and polarisation vectors of $\langle 1\bar{1}0 \rangle$. Notwithstanding the shear displacements, there have been suggestions that the tweed microstructure is not necessarily a precursor of the martensitic transformation of β. Some of the literature on the tweed microstructure can be found in [155–160]. Information on the elastic properties of NiAl is available in [160].

martensite been considered as a possible toughening route for NiAl (see references in the discussion of micro- and nanostructured NiAl alloys). Nonetheless, the addition of a significant volume fraction of non-shape-memory ductilising second phase is still likely to be needed. This will further dilute the already low recoverable strain obtainable with NiAl.

38.3.7   Titanium aluminides

The intermetallic phases in the Ti–Al system that have attracted major interest as structural materials are D0$_{19}$ type α_2–Ti$_3$Al and L1$_0$ type γ–TiAl, both of which have a significant range of composition in the Ti–Al binary system (see Chapter 11). TiAl$_3$ is D0$_{22}$ in the Ti–Al system, but an L1$_2$ structure can be stabilised by ternary alloying (see e.g. [201]). The use of TiAl$_3$ would be attractive from the standpoint of both density (3.37 Mg m^{-3}) and oxidation resistance (since this phase contains enough aluminium to be a reliable alumina former). However, alloys based on TiAl$_3$ are very brittle (and seem likely to remain brittle for the foreseeable future) and so will not be discussed here. See for example [202] for work on dislocations in L1$_2$ stabilised TiAl$_3$.

The interest in the titanium aluminides has primarily been driven by potential applications in aerospace, both as engine components and airframe materials. Unlike the nickel aluminides, the titanium aluminides do not offer a sufficiently high operating temperature to compete with nickel-base superalloys in applications such as aero gas turbine blades and guide vanes. Instead, the titanium aluminides are largely intended to serve in applications at intermediate temperatures (<900°C even for TiAl alloys). These applications exceed the operating-temperature limits of conventional titanium alloys, thus forcing currently the use of superalloys. Section 38.3.10 provides further discussion of the potential applications of structural intermetallics.

Ti$_3$Al

The density of Ti$_3$Al and its alloys is somewhat higher than for TiAl-based materials, as can be seen from the data given in Table 38.3. However, Ti$_3$Al alloys offer a significantly lower density than for stoichiometric NiAl. Indeed, the density of Ti$_3$Al alloys (in the low to mid 4 000 kg m^{-3} range), is comparable to those of typical titanium alloys (data on the latter may be found in Section 7 of Chapter 14).

Ti$_3$Al alloys of potential commercial interest invariably contain ternary alloying additions. Most commonly, significant additions of niobium (as for example in the alloy Ti–24 at. % Al–11 at. % Nb) are made to stabilise the B2 type β-phase (see e.g. [203, 204]). Note, the high-temperature β phase in the Ti–Al binary system is disordered and of the A2 type (i.e. body centred cubic), as can be seen from the relevant phase diagram in Chapter 11. In some Ti$_3$Al alloys with β stabilised by ternary additions, the β-phase may not be fully ordered.

The orthorhombic 'O' phase forms in high niobium materials.[205] Detailed discussion of this phase is beyond the scope of the present work. Instead, for structure–property relationships in alloys containing the O phase, see [206, 207]. Comparison of β and O alloys can be found in [208]. Phases of the ω type can also form in some cases (e.g. [209]; for discussion of ω formation in conventional titanium alloys see [210–212]).

The relationship between the processing and the microstructure of these α_2–β alloys is quite complex (although these do form a logical extension of the physical metallurgy of conventional titanium alloys) and will not be discussed here. Instead, readers interested in composition/processing–structure–property relationships are referred to an overview of Ti$_3$Al alloys.[203]

The ductility and fracture toughness of two phase Ti$_3$Al alloys are far superior to those of stoichiometric NiAl, for example, and the use of Ti$_3$Al alloys would be attractive if it were not for the relatively poor high-temperature creep and oxidation resistance of these alloys. Low oxidation resistance is only to be expected in a material of low aluminium content, although additions of niobium are helpful in this regard. With any intermetallic, the extent to which ordering impedes diffusion is a key consideration in determining creep resistance (see Section 38.3.4) and recent work on diffusion in Ti$_3$Al and TiAl can be found in [213–218].

In recent years, interest has tended to switch from Ti$_3$Al to TiAl-based materials, given the superior creep and oxidation resistance of the latter.

TiAl alloys

Of the materials discussed in this section, alloys derived from TiAl perhaps offer the best hope of seeing commercial application within a reasonable timeframe. Although both the oxidation and creep resistance of TiAl alloys (see e.g. [219] for an example of recent work on creep in TiAl alloys) lag noticeably behind those of NiAl, the former offers considerably lower density and much higher

Table 38.6 THE CHARACTERISTICS ASSOCIATED WITH VARIOUS MICROSTRUCTURES OF TiAl ALLOYS

For an overview of the effects of microstructure on deformation and fracture of TiAl alloys see [261]. Numerical data in this table is from [262], except for data marked *, which is from [263].

Microstructure	Typical characteristics (all properties shown are at room-temperature)
Near single phase and single phase (γ)	Can be fine grained ($< 20\,\mu$m) Ductility depends strongly on composition (0% elongation for high Al alloys*) Worst fracture toughness (~ 12 MPa $\sqrt{m}$)
Fully lamellar (γ/α_2)	Coarse grained ($\sim 300\,\mu$m, often coarser) Poor tensile ductility ($< 1\%$ elongation*) Best fracture toughness (> 20 MPa $\sqrt{m}$) Best creep resistance
Duplex ($\gamma + \gamma/\alpha_2$)	Can be fine grained ($\sim 20\,\mu$m) Best ductility ($\sim 4\%$ elongation*) Poor fracture toughness (~ 15 MPa $\sqrt{m}$) Poor creep resistance

room-temperature fracture toughness (see data in Table 38.4). Indeed, the fracture behaviour of TiAl alloys can be regarded as somewhere in between brittle and ductile[220] (although the properties of TiAl alloys have been claimed to be amenable to analysis by Weibull statistics;[221] for a recent example of work on the fracture of TiAl alloys see [222]).

Single phase TiAl is of no potential value as a structural material, as this material lacks both ductility and fracture toughness, especially when aluminium-rich (which is unfortunate, given the benefits this would have for oxidation resistance). Instead, interest focuses on materials that are titanium-rich and consequently have a two phase lamellar microstructure comprised of γ and α_2 (useful overviews of TiAl alloys can be found in [223–228] and [229] provides a comparison with Ti_3Al alloys). A noticeable feature of the lamellar γ/α_2 microstructure is that γ forms a number of twin variants when the α_2 second phase is present. This microstructure is described as being 'polysynthetically twinned' (PST). Details of the PST γ/α_2 microstructure are available elsewhere (microstructural features are described in references [230–237]; for discussions of mechanical twinning in TiAl alloys and the stability of the PST microstructure during creep deformation see [238] and [239] respectively). Recent work suggests that interstitials can have an effect on the lamellar spacing (and hence the properties) of PST alloys.[240]

Two microstructures are of particular interest. The first of these is fully-lamellar (FL), or in some cases near-fully-lamellar (NFL), γ/α_2. The second is a duplex (DP) microstructure containing γ grains plus lamellar γ/α_2. Note, the formation of these microstructures does not necessarily occur in the fashion that might be expected from perusal of the Ti–Al phase diagram. In any case this phase diagram has been subject to revision and controversy. A discussion of the various transformation sequences involved in the formation of lamellar and duplex microstructures is beyond the scope of the present work. However, such a discussion may be found, for example, in [241] or [242] (there has been recent interest in the occurrence of massive transformations in these alloys, as can be seen in [243, 244]).

The key features of various TiAl-alloy microstructures and their properties are summarised in Table 38.6. Notice that it is necessary to make a compromise between fracture toughness and creep resistance on the one hand and ductility on the other (for an example of recent work on an integrated study of tensile, creep and fatigue behaviour in these materials see [245]). A discussion of the toughening mechanism in multiphase intermetallics, including γ/α_2 can be found in [246]. As with other intermetallics, TiAl alloys can suffer from strain ageing and it has been suggested recently that antisite defects play a role in this problem.[247]

TiAl alloys of potential commercial interest invariably contain ternary alloying additions. A large number of alloying additions have been investigated and so only some examples will be included here (a more detailed summary of the effects of ternary alloying can be found in [248]). The titanium-rich TiAl alloys (i.e. the alloys that are of potential commercial interest), greatly benefit from alloying to promote oxidation resistance, since these alloys are at best only borderline alumina formers. For some examples of work, and overviews, on oxidation of TiAl alloys see [249–257]. A common example of alloying to promote oxidation resistance is the addition of Nb. However, it must be cautioned that the effect on oxidation resistance of alloying additions can be strongly influenced by concentration. For

example, chromium is added in small quantities (as in the well established alloy Ti–48 at. % Al–2 at. % Cr–2 at. % Nb) for control of mechanical properties. In contrast, much larger chromium levels (∼8 at. % [248]) than those used typically in TiAl alloys would be needed for this element to have a beneficial effect on oxidation resistance.

Although most attention on TiAl alloys has focused on γ/α_2 microstructures, there has also been interest in the addition of elements such as W to stabilise the formation of B2 type β phases. In some alloys (e.g. those containing Mn), disordered body centred cubic β can play an important role in their processing.[258] There has also been some work on the formation of ω and other phases—see e.g. [259, 260]. As with other intermetallics, considerable interest has been shown in dispersion strengthened TiAl alloys and TiAl matrix composites (see next section).

Although the creep and oxidation resistance of TiAl alloys are noticeably better than those of Ti$_3$Al alloys, they can not compete with NiAl, for example. Thus, as has already been discussed, likely applications of TiAl alloys are expected to involve relatively low temperatures (below 900°C).

38.3.8 Dispersion strengthened intermetallics and intermetallic matrix composites (IMCs)

There has been considerable interest in dispersion strengthening of structural intermetallics.[264] The driving force behind work on dispersion strengthening has been the potential for enhanced creep resistance. An overview of dispersion strengthened intermetallics may be found in [264]. With conventional alloys, interest has focused principally on oxide dispersion strengthening (e.g. Y_2O_3 for nickel-base and ferritic ODS alloys; see [265] for an overview of these materials). However, with intermetallics there has been consideration of a wider range of dispersoids, for example phases such as AlN, HfC and TiB$_2$ have been considered (see references below), in addition to oxide dispersions, such as Y_2O_3.[266]

There has been a fairly large body of work on intermetallic matrix composites (IMCs). A significant portion of the work conducted on IMCs has focused on *in-situ* composites (as discussed above for NiAl), primarily for enhanced fracture toughness. However, there has also been considerable interest in IMCs with a variety of ceramic reinforcing phases, such as TiB$_2$, AlN and sapphire. An overview of fibres and fibre coatings for IMCs can be found in [267].

Some examples of work on IMCs and dispersion strengthened intermetallics can be found in [268–278]. A good source of overview information on the topic of IMCs is the proceedings of the MRS symposium series 'Intermetallic Matrix Composites'.[279] In particular, for a concise overview of application-related issues for IMCs, see [280].

For conventional alloys, there is a clear distinction between ODS alloys, with low volume fraction of fine dispersoids, and particulate metal matrix composites (MMCs), with a much higher volume fraction of coarse reinforcements. In ODS alloys, the dispersion serves to strengthen the matrix (by controlling the motion of grain boundaries and/or impeding Orowan bypass by dislocations), whereas MMCs show true composite properties. In contrast, in some of the work on intermetallic matrix materials, this distinction is less well defined, due to the use of intermediate volume fractions and particle sizes.

38.3.9 Processing and fabrication of structural intermetallics

Structural intermetallics can be (and often are) processed via a cast, or wrought route, much as in the case of conventional alloys. There has also been extensive interest in the powder metallurgical processing and mechanical alloying of intermetallics (see [281] for an overview of processing of intermetallics). However, some special features of intermetallic compounds do need to be borne in mind when processing these materials:

- The melting temperature of structural intermetallics, such as NiAl for example, is considerably higher than for nickel base superalloys. Thus existing processing technologies (e.g. mould cores for casting[67]) may need modification for use with intermetallics.
- Properties such as fracture toughness can be very sensitive to even very minor changes in the composition and/or microstructure of the intermetallic. Therefore, compositional and process tolerances may have to be considerably tighter than for more 'forgiving' materials. Furthermore, balancing ease of processing and optimum properties in service can be an issue.[282] For a review of phase stability during processing of intermetallics see [283].
- The poor low temperature ductility and fracture toughness of structural intermetallics must be allowed for in selecting a processing route.

- The potential for environmental embrittlement of some intermetallics (as discussed above) must be allowed for, as this can be a problem during processing.[284]
- With the aluminide intermetallics, evaporation of aluminium can be a major problem during processing and needs to be controlled.[285,286]

In some cases, the intrinsic characteristics of intermetallics provide opportunities for processing, as for example in the self-heating synthesis (SHS) of a number of intermetallic materials ([287–291] provide some recent examples). Some intermetallics show superplastic behaviour (see e.g. [292]) and so offer opportunities for superplastic forming (and also hybrid process routes such as diffusion bonding—superplastic forming).

With regard to both primary fabrication and pre/post-service repair, a number of joining processes have at least some applicability to intermetallics. There has been a body of research on the fusion welding of intermetallics (e.g. [293, 294]). This work has shown that fusion welding by electron beam or gas-tungsten-arc processes is quite attractive for alloys such as Ni_3Al with good intrinsic ductility and reasonably practicable even with materials such as TiAl. In contrast, with materials such as NiAl that possess poor intrinsic ductility/toughness, fusion welding would be far less suitable. Furthermore, the fusion welding of aluminide intermetallics to nickel-base superalloys would present a major challenge. Friction welding offers a means of fabricating a variety of difficult to join materials. Indeed, friction welding of TiAl appears promising.[294] However, with intermetallics such as NiAl that are extremely brittle at low-temperatures, initial attempts at friction welding[295] have not met with success.

Diffusion bonding provides a means of joining a wide range of materials and (in cases where an interlayer is not required) offers the possibility of a relatively low degree of microstructural disruption. In the case of TiAl, diffusion bonded components can maintain the strength of the parent material.[296] The major limitation of diffusion bonding is that the presence of continuous oxide layers on the faying surfaces has a strongly detrimental effect on the ability to produce sound bonds. Thus, the diffusion bonding of strongly alumina forming intermetallics (such as NiAl) is not attractive.

In common with brazing, the transient liquid phase (TLP) bonding process is tolerant of the presence of stable oxide layers on the faying surfaces. TLP bonding is therefore well suited to the joining of strongly alumina forming intermetallics (such as NiAl), unlike diffusion bonding. The TLP bonding process is conducted under isothermal conditions and requires (at most) only a small applied load for fixturing. Thus, TLP bonding is well suited to the joining of non-weldable brittle materials, such as many intermetallics. An overview of TLP bonding, including details of the issues related to the application of this technique to intermetallic compounds (and numerous references) can be found in [297].

TLP bonding of intermetallics can involve non-conventional processes. For example, in the case of NiAl substrates,[298] a high-temperature vacuum treatment of the faying surfaces produces a nickel-rich layer, due to evaporation of aluminium. This nickel-rich layer has a lower melting-point than stoichiometric NiAl and can be used as a liquid-former. In some cases, TLP bonding starts to resemble self-heating synthesis (SHS). There has also been investigation of the joining of intermetallics alloys by other techniques, such as reactive casting.[299]

38.3.10 Current and potential applications of intermetallics

The current applications of intermetallic compounds are largely non-structural. For example, pack aluminide diffusion coatings (in some cases with platinum modification [300,301]) have been employed for many years to enhance the oxidation resistance of nickel-base superalloys. Details of aluminide coatings can be found in [302–305]. Many of the microstructural features observed in aluminide coatings (see e.g. [306–311]) are similar to those of multiphase structural NiAl alloys. However, it should be cautioned that (especially due to incorporation of alloying elements from the superalloy) aluminide diffusion coatings have very complex microstructures. These contain numerous phases of varying stability and are influenced strongly by thermal/environmental exposure.

Overlay coatings of the MCrAlY type (where M is usually nickel and/or cobalt, although iron is used in some cases), find extensive industrial application. The coatings can be deposited, for example by low pressure plasma spraying (see Chapter 35 for details of thermal spray technologies). The MCrAlY system is used both to form oxidation resistant coatings and as the bond-coat [312] for thermal barrier coatings (TBCs). For details of MCrAlY coatings, see [313, 314], whilst information on TBCs can be found in [315]. Overviews of intermetallic-based protective coatings for superalloys can be found in [316–318]. There has also been some interest in employing powder eutectic coating, involving $TiAl_3$, FeAl and other phases, to protect steels.[319]

Bulk intermetallic compounds have found successful commercial application as functional (as opposed to structural) alloys. A major commercial application (see e.g. [320]) of intermetallic

compounds is in the form of shape memory alloys (SMAs), most commonly based on NiTi ('Nitinol'). Applications of SMAs can involve the shape memory effect (SME), superelasticity, or vibration damping. The commercial uses of SMAs are widespread. However, some examples include:

- medical (stents to reinforce blood vessels, surgical guide wires etc.) and consumer applications (spectacle frames, underwires for brassieres);
- self clamping pipe couplings, especially for aerospace;
- a wide variety of actuators (e.g. on the NASA Mars lander) and thermal control systems (thermostats, thermal cut-outs, anti-scald valves etc.).

Further details of SMAs may be found in Chapter 15. Overviews of SMAs are available in [321–323] and the following provide details of NiTi.[324–327]

A further major commercial application of intermetallics is the use of $MoSi_2$ in heating elements for a range of commercial applications. Intermetallic (A15 type) superconducting materials continue to be widely used, notwithstanding the development of high-temperature ceramic superconductors (see Chapter 19 for a discussion of superconducting materials). Intermetallic compounds are also important as hard magnetic materials (as discussed in Chapter 20).

A major structural application of intermetallic compounds, although clearly not involving their use at high-temperatures, is in the form of dental alloys (e.g. [328, 329]. In contrast, high-temperature structural applications of intermetallic compounds are typically still at the experimental stage. Interest in these materials focuses mostly on aerospace applications in gas turbines and airframe components for advanced air and spacecraft,[40,330–332] although use in terrestrial transportation (e.g. turbocharger rotors) has also attracted interest.[333,334] An overview of the high-temperature applications of structural intermetallics can be found in [335] and other papers in the same volume include information on non-structural applications of intermetallics. Comments on the application status of individual intermetallic systems may be found in the relevant sections above. For an overview of the requirements imposed on structural intermetallics by potential aerospace applications, see [38].

Work continues on materials development for a wide range of intermetallic systems. In some cases, research on intermetallics has advanced to the point of examining end-application specific issues, such as damage due to particle impact in gas turbine engines [336] and shock loading, as would be experienced in a bird strike.[337] Fatigue resistance of intermetallics has not been discussed here, but a review of this topic may be found in [338].

38.4 Metallic foams

Metallic foams have attracted considerable interest in recent years and have a variety of commercial applications (some current and potential uses of metallic foams are summarised in Table 38.7). Foams have been produced in a variety of other materials (Table 38.8 provides some commercial examples), such as magnesium, titanium, austenitic stainless steels and nickel-base superalloys, see e.g. [339, 340]. However, there has been particular interest in foamed aluminium alloys. For representative properties of aluminium alloy foams, see Table 38.9. As can be seen from this table, metallic foams offer a very low density and can provide high specific properties.

References [341, 342] provide a useful introduction to the properties of foamed materials, whilst an overview of both biological and engineered foams can be found in [343]. Extensive information

Table 38.7   SOME APPLICATIONS OF METALLIC FOAMS AND FEATURES OF THESE MATERIALS THAT ARE RELEVANT TO END APPLICATIONS

This information is abstracted from a much more detailed table in [344].

Application	Relevant features of metallic foams
Lightweight structures (sandwich panels etc.)	High specific stiffness and specific yield stress.
Mechanical damping, vibration control and acoustic absorption	Damping capacity is an order of magnitude higher than for solid metals. Vibration control and acoustic absorption characteristics are attractive on a specific basis.
Impact absorption	High energy absorption capability.
Thermal management and flame arrest	High surface area for heat transfer, combined with high thermal conductivity cell edges.
Filters	Controlled pores sizes can be produced in open cell foams.
Electrodes and catalyst supports	High surface area per unit volume in open cell foams.

on metallic foams is available in [344] and the papers in [345, 346]. For an analysis of the economics of metallic foams, see [347].

Both open and closed-cell foams are available. The choice of which type of foam to employ depends on the intended application. For applications where fluid access to the walls of the foam is required (electrodes or filters for example) an open cell foam is needed. In contrast, many foams for load-bearing applications have closed cells.

Metal foams can be produced by a wide variety of routes, as can be seen from the examples shown in Figure 38.7 and an extensive discussion of foam production methods is beyond the scope of the present work (a summary of foam processing methods can be found in [349]). However, the following are representative examples of process routes for foamed products:

- Inco offers an open cell nickel foam, produced by a chemical vapour deposition route,[350] for applications in batteries, fuel cells, catalysis and filtration.
- A commercial example of a closed cell aluminium foam is produced Shinko Wire,[351] using a batch casting process. This process employs 1.5 wt. % Ca as a thickening agent (which operates through the formation of metal oxides). This addition is followed by 1.6 wt. % TiH_2 which decomposes to liberate hydrogen gas, thus producing a foaming effect. The thickening agent is needed to ensure a viscous enough melt to prevent gas escape.

In contrast to the Shinko process, Al–SiC particulate metal matrix composites (MMCs) can be produced with a foamed matrix,[352] since the ceramic particulate makes the melt sufficiently viscous to prevent escape of the foaming gas phase. Regardless of the processing route, it is important that gas release occurs at the appropriate moment during processing and this can be challenging to achieve (see e.g. [353]). There is continuing work on production techniques (for an example of recent work on open cell foams see [354]).

Table 38.8 SOME COMMERCIALLY AVAILABLE FOAM MATERIALS AND A COMPARISON OF THEIR DENSITY, WHEN IN THE FORM OF FOAMS PRODUCED NOMINALLY AT 5% OF THE FULL DENSITY OF THE MATERIAL CONCERNED

The materials shown are selected from the list available in [348].

Material	ρ_f (kg m^{-3})
MCrAlY (M = Fe or Ni–Co)	360–420
Cu/60–40 Brass	450/420
Steel (Eutectoid and 316 Austenitic Stainless)	390
Nickel	450
Silver	530
Titanium	230

Table 38.9 REPRESENTATIVE CHARACTERISTICS AND PROPERTIES OF SOME COMMERCIALLY AVAILABLE ALUMINIUM FOAMS

This information is abstracted from a much more detailed table in [344].

Property (*units*)	*Type or value*
Material	Pure Al or Al–SiC$_{particulate}$ composite
Available morphologies	Open and closed cell
ρ_f (kg m^{-3})	70–1 000
ρ_f/ρ_s	0.02–0.35
E (MPa)	20–12 000
σ_c (kPa)	40–14 000
σ_y (kPa)	40–20 000
σ_t (kPa)	50–30 000
MOR (kPa)	40–25 000
K_{IC} (kPa $\sqrt{m}$)	30–1 600
C_p (J kg^{-1} K^{-1})	830–950
λ (mW m^{-1} K^{-1})	300–35 000

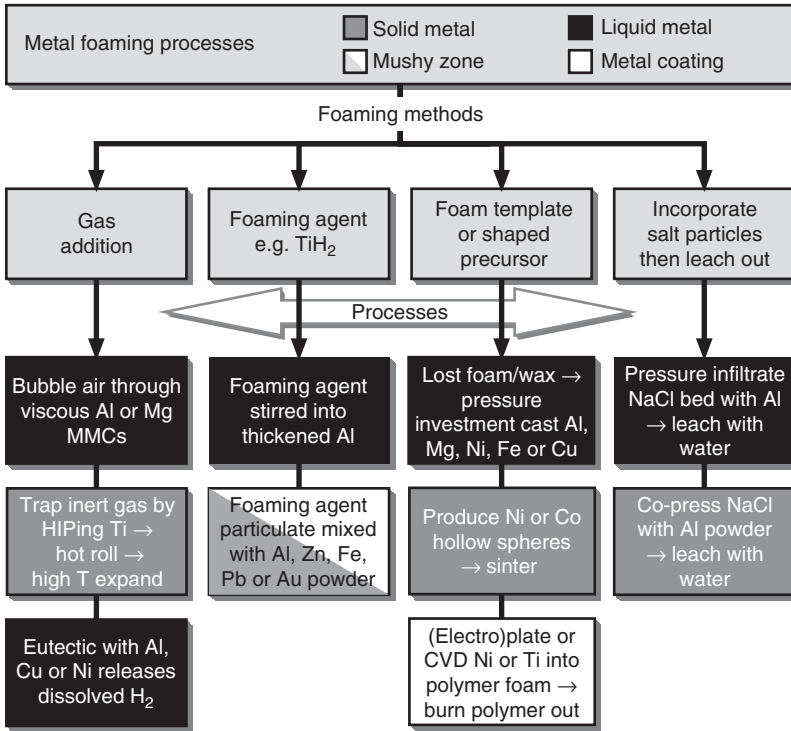
ρ_f = density of foam, ρ_s = density of equivalent fully dense material, E = Young's modulus, σ_c = compressive strength, σ_y = tensile yield stress, σ_t = tensile strength, MOR = modulus of rupture, K_{IC} = mode I fracture toughness, C_p = specific heat capacity, λ = thermal conductivity.


Figure 38.7   *Some methods for the production of metal foams. The methods are applicable to the metals shown and certain of their alloys. Some of the methods listed in this figure are appropriate only for laboratory batch production and are unsuitable for commercial use. For more detail on these methods, see* [344, 349].

Given the interest in using foams for structural applications (and hybrid applications with both structural and functional aspects) there is quite an extensive body of literature on structure—mechanical property relationships for metal foams. Detailed discussion of these is beyond the scope of the present work, but some representative examples of research in this area can be found in [355–365]. An overview of creep in foams and other cellular materials can be found in [366].

When foams are used in sandwich structures, bonding of the face sheets to the foam is required (in some applications, foam—foam joining may also be needed). Foams can be joined by a variety of methods, including brazing (and the braze itself can be made foaming),[367] spot welding,[368] laser welding [369] and diffusion bonding.[370]

Foams are not the only type of non-fully-dense metallic structures. Other examples include:

- honeycombs, as employed widely in aerospace;
- wire mesh products ranging from the macroscopic scale down to sintered microfibrous materials for catalyst supports and filters;
- felt metals for abradable seals in gas turbine engines.

38.5   Metallic glasses

Metallic materials are crystalline in their equilibrium state and solidification is a crystallisation process. with a distinct transition from liquid to solid. Most metals and alloys are able to crystallise, even when cooled very rapidly. However, in some alloy systems, when a sufficiently high cooling rate is employed the solidification phase transformation does not occur.[371] Instead, the liquid congeals, resulting in a metallic glass. The amorphous structure and hence the properties of metallic glasses are quite different from those of crystalline metallic solids. Nonetheless, it should be noted that metallic glasses are still metallically bonded. Indeed, metallic glasses are not transparent and have a reflective appearance that is similar to a crystalline metallic solid! The underlying science of amorphous alloys

is beyond the scope of the present work, which concentrates on applications. Instead, readers are referred to a detailed discussion in [372].

Metals and alloys generally crystallise much more readily than many ceramic materials and only a subset of metallic alloys are glass forming. Even then, high cooling rates (commonly of the order of 10^5–10^6 K s^{-1}),[371,372] may be needed to suppress nucleation of solid grains. Thus, rapid solidification processing (RSP), for example melt-spinning, has traditionally been required for metallic glasses.* An important exception to this situation is what are known as bulk metallic glass (BMG) materials. BMGs will amorphatise when cooled at moderate rates (<100 K s^{-1} in some cases far lower), which are within the capabilities of conventional metals processing routes.

38.5.1   Metallic glasses requiring rapid quenching

A wide range of metallic-glass-forming alloys exist.[373–375] However, of particular commercial interest are those involving late transition metals and metalloids, such as Ni–(Cr)–(Si)–B, Ni–(Cr)–P and Fe–(Si)–B. These materials are commercially available in the form of melt-spun foils, as in the examples shown in Table 38.10 and Table 38.11.

An important application of metallic glasses is as a soft magnetic material. Since amorphous materials lack microstructural features, such as dislocations and grain boundaries, they allow easy motion of magnetic domain walls (see e.g. [377] for an overview of magnetic metallic glasses and their applications). The characteristics of metallic glasses as magnetic materials are discussed in Chapter 20 and so will not be repeated here. Applications of these materials include: transformers for electric power distribution and electronics, security tags for retailing and components for pulsed power systems.

A further major commercial application of metallic glasses is as interlayer foils for brazing or transient liquid phase (TLP) bonding of nickel-base and other alloys. Many of the alloys in the American Welding Society's BNi series of nickel-base brazes contain boron or phosphorus.[378] These materials are too brittle to produce in the form of rolled foils (due to the formation of phases such as Ni_3B or Ni_3P) and so conventional brazing alloys are powder-based. Use of brazes in powder form both complicates handling and compromises wettability. Thus, the ability to produce a boride-free (and hence flexible) foil by rapid solidification is very attractive (see [379] for a recent detailed overview of metallic glass brazing alloys; some additional literature on amorphous brazing foils and their applications can be found in [380–384]). Amorphous brazing foils do crystallise during heating

---

* It is important to note that RSP can be used both to produce metallic glasses and micro/nanomaterials (the latter are discussed in the next section). In the event that solidification is not suppressed entirely by RSP (due either to the use of a non-glass forming alloy or an insufficient cooling rate) then the result will be solidification at a very high undercooling. Solidification at a high undercooling implies very rapid nucleation, but slow diffusional growth and hence an extremely fine (sometimes nanoscale) grain size.

to the brazing temperature, but this does not present a problem, as by that time the foil has already been placed into the desired location.

38.5.2   Bulk metallic glasses

The requirement that conventional metallic glass forming alloys undergo very rapid cooling limits the production of these materials to thin foils. In contrast, BMG materials can be produced, for example, by centrifugal casting[385] or water quenching.[386] BMGs form in a variety of systems based on Pd,[387–389] Au,[390] La,[391] Mg,[392] Zr,[393,394] Ti,[395] Fe,[396] Ni,[397] Co,[398] and Cu.[399–401] Typically, these systems contain three to five constituents, with a large atomic size mismatch and a composition close to a deep eutectic. For an overview of BMG materials, see [402].

In some cases, BMGs can be generated [403] by mechanical alloying (MA) at room-temperature. Examples of recent work in this area can be found in [404–407]. However, the duration of the MA process is crucial and as this is increased, the metastable glass can be replaced by nanocrsystalline phases, that can also be metastable (e.g. [408]).

BMGs offer the possibility of producing thick sections and have therefore attracted much recent interest. Some representative examples of the large body of recent work in this area can be found in [409–413]. Unlike conventional metallic glasses, which are mature materials with long-established commercial applications, the field of BMGs is evolving rapidly.

A key requirement for a BMG is that the material shall have a high glass forming ability (GFA). A variety of work has been conducted recently on the fundamentals of BMGs. Recent work on the theory of bulk metallic glass formation,[414,415] involves both electron concentration and size factor rules, as was the case for earlier studies of metallic glasses.[416–418] Indeed, it is interesting to compare the rules (*anti-Hume-Rothery rules*) for a lack of crystallisation with the Hume-Rothery rules for intermetallic formation,[19,20] as discussed in Section 38.3.3. An example of recent research on the GFA of BMGs can be found in [419]. In addition to the GFA, the thermal conductivity of bulk metallic glass formers is clearly a key practical issue in achieving amorphatisation on cooling (and is also important in the deformation of these materials). For an example of recent work on thermal conduction in BMG alloys, see [420].

There has been interest recently in employing amorphous bulk Mg–Ni based alloys as an electrode material for Ni-metal hydride batteries (see e.g. [421–425]). The use of amorphous and quasicrystalline Ti–Zr–Ni has also been considered for hydrogen storage.[426] For recent work on diffusible hydrogen in amorphous alloys, see [427]. Soft magnetic applications of iron-based bulk metallic glasses have also attracted attention (see e.g. [428–430]), as has the production of corrosion-resistant BMGs.[431]

The mechanical properties of BMGs (see Table 38.12) have attracted very considerable interest, since these properties are important both in structural and functional applications. Metallic glasses do not have a lattice and so can not form dislocations. Instead, plastic deformation of metallic glasses[433] involves the rapid propagation of intense shear bands (for an example of recent work on this topic, see [434]). However, it should be cautioned that BMGs behave differently in tension and compression. In cases where plasticity is observed, this may only occur in compression.[435] The plastic flow characteristics of these materials are also strain rate sensitive.[436]

There has been much recent interest in enhancing the mechanical properties of bulk metallic glasses through the formation of nanocrystals, produced by partial devitrification, so that an amorphous–nanocrsystalline composite results. In some of these composites, plasticity is observed.

Table 38.12   REPRESENTATIVE MECHANICAL PROPERTIES OF BULK METALLIC GLASSES

Based on data provided in [401, 432] and various references given in the text.

Property (units)	Value
E (GPa)	~100–140
σ_{yc} (GPa)	~1.8–2
σ_c (GPa)	>2
σ_t (GPa)	~2–2.1
ε_e (%)	>2
ε_{p_c} (%)	~0.8–2

E = Young's modulus, σ_{yc} = compressive yield stress, σ_c = compressive strength, σ_t = tensile strength, ε_e = elastic elongation to failure, ε_{p_c} = compressive plastic strain to failure.

These materials can also have unusual magnetic properties.[437] For some recent examples of work in the area of amorphous–nanocrsystalline composites, see.[438–443] Research has also been conducted[444] on composites with a BMG matrix, plus high volume fractions (up to ∼50 vol. %) of coarse crystalline metallic particles (with particle sizes up to 200 μm). There has also been interest in metal fibre reinforced BMG matrix composites.[445]

As with any metallic glass, BMGs are metastable and will crystallise if heated to a suitable temperature. Depending on the intended application, this can be a problem (if unwanted devitrification occurs during processing or service), or a benefit (as in controlled devitrification to produce the composite materials discussed above). Some recent research on crystallisation and the thermal stability of BMGs can be found in [446–452]. In addition to thermally-induced devitrification, it is also possible to precipitate metastable nanocrsystalline phases under electron irradiation.[453]

It should be cautioned that low-temperature annealing, below the glass transition temperature (T_g) can lead to embrittlement in some cases.[454] For work on the effect of heat treatment on the mechanical properties of BMGs, see for example [455].

38.6   Mechanical behaviour of micro and nanoscale materials

Until recently, the field of mechanics of materials has dealt mainly with how solids behave when acted upon by static and dynamic forces. The resulting interplay of stress and strain in controlling how materials deform is organised into a continuum describing material behaviour. However, with the advent of microelectronics and micro-electro-mechanical systems (MEMS), traditional continuum mechanics has been unable to explain the deleterious effects that stresses cause in thin film devices. Consequently, considerable work has been carried out towards investigating and understanding the origin of distinctive thin film behaviour as well as determining means to minimise and control its effects. In addition to stresses in thin films, recent advances in nanotechnology and the arrival of carbon nanotubes have again challenged traditional theories describing material behaviour. In these systems, typically one or more of the structure's dimensions is in the order of 1 to 100 nm in size, and so the mechanisms controlling deformation revolve around interatomic (or molecular) forces rather than defect generation, density and mobility. The study of these issues no longer lies only in the field of mechanics but has become cross-disciplinary and must borrow from other fields, such as physics and materials science. This section is focused on introducing the reader to recent advances in the micro and nanomechanics field and providing a basic understanding of the issues involved therein.

38.6.1   Mechanics of scale

It has been known for quite some time that materials and structures with small-scale dimensions do not behave mechanically in the same manner as their bulk counterparts. This aspect was first observed in thin films where stresses were found to have deleterious effects on the film's structural integrity and reliability. This occurs as one of a specimen's physical dimensions begins to approach that of the microstructural features. The material's mechanical properties then begin to exhibit a dependence on the specimen size. In metallic thin films, this translates to plastic yielding occurring at increased stresses, over their bulk counterparts. Although this phenomenon was observed as early as 1959,[456] no consensus or common basic understanding of it has yet been arrived upon. Besides plastic behaviour, other mechanical properties, such as fracture and fatigue also exhibit size effects. Each of these properties operates on a characteristic length scale that can be compared with the characteristic dimensions of microelectronics, microdevices or nanodevices. This is shown schematically in Figure 38.8, which utilises a logarithmic length scale map beginning at the atomic scale and onwards up to the macro world.

On the left of Figure 38.8 are four categories of devices and the regime where their dimensions fit on the length scale. On the right are regimes indicating where dimensional size-effects begin to affect the material's mechanical properties and theories used to predict behaviour. Elastic properties are dependent on the nature of bonding of the material and only exhibit size effects at the atomic scale. In contrast, plastic, fatigue and fracture properties all exhibit size effects in the micrometre and sub-micrometre regime. These properties all depend on defect generation and evolution, the mechanisms of which operate on characteristic length scales.[457] In terms of devices, these fundamental changes in mechanical behaviour occur in the size scale of the MEMS and microelectronics regimes, and thus, a better understanding of inelastic mechanisms is required to better predict their limits of strength.

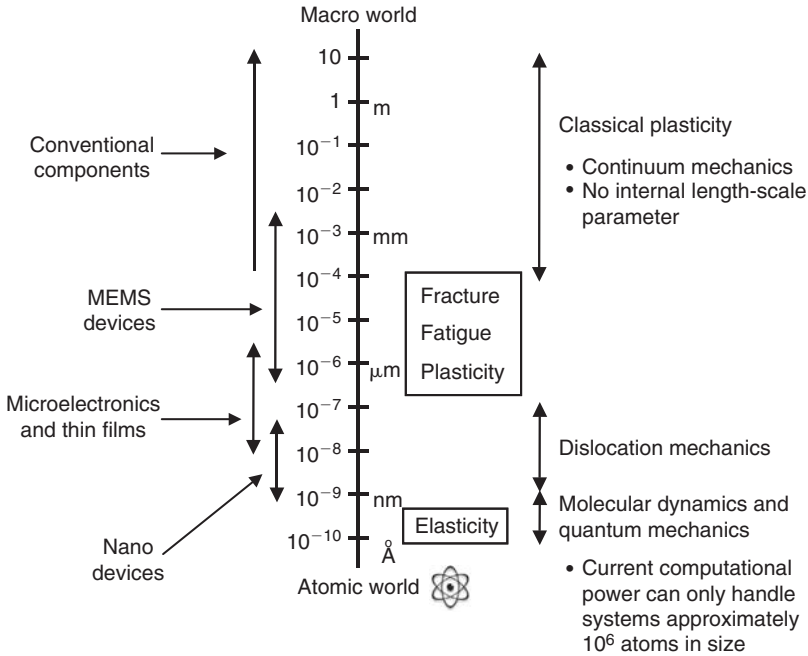
The right side of Figure 38.8 lists the theories used to predict behaviour and the regimes on the length scale where they are applicable. These include classical plasticity at the upper end of the scale and dislocation/interatomic mechanics at the lower end. Classical plasticity is described as traditional


Figure 38.8   *Illustration of length-scale effects on the mechanical properties of materials*

continuum mechanics, which uses traditional relationships describing the interplay between stress and strain and is applicable for predicting behaviour from a range of approximately 100 µm and up. Dislocation mechanics (or molecular mechanics) is at the other end of the scale and involves the generation, mobility, and interaction between individual dislocations. The latter is applicable only at the lower end of the scale since it is based on numerical simulation and is consequently limited by current computational power, i.e. systems approximately one million atoms in size. Also, at the lower end is intermolecular mechanics that deals with the interatomic potentials between bonded atoms. In the region between classical and dislocation/interatomic mechanics is a grey area that continues to elude prediction of behaviour. This is a critical region where many size effects fit on the length scale. There has been solid work in the field by a number of researchers who have developed theories and models to explain thin film behaviour.[458–463] Unfortunately, these tend to address the subject within a particular range of length scale and some with only particular geometrically induced effects. An additional issue also stems from a lack of experimentally resolved real-world phenomena in the literature. Moreover, no consensus has yet been reached on exactly how the length scale affects the mechanical properties of thin films, e.g. failure mode and fracture toughness, yield strength, etc. The higher yield point of metallic thin films mentioned above is likely the result of a combined interaction of strain hardening and constraint of dislocation motion due to specimen size [464] and/or an effect of grain boundary dislocation sources [465] and geometrically necessary dislocations.[466] Clearly, a better understanding of inelastic mechanisms is required to better predict limits of strength in this region.

Several pioneering studies have identified experimentally the existence of size effects on the plasticity of metals.[467–471] These include: nanoindentation data showing a strong size effect in finding that hardness decreased as indentation depth increased;[468,472–479] bending metal strips of varying thickness around a rigid rod of scaling diameter whereby when strained to the same degree the thinner strips required a larger bending moment[471] and applying a torque load to copper rods of varying diameter whereby an identical applied twist resulted in an increase in strength by a factor of three for the smallest wire over the largest.[470] In these pioneering studies, the size dependence of the mechanical properties has been considered to be a result of non-uniform straining.[470,475,480] It was shown that classical continuum plasticity cannot predict the size dependence under these conditions. A new theory termed *strain gradient plasticity* has been proposed to describe this behaviour, but is only applicable under particular geometrically induced effects.[461–463,470,480–483] However, a comprehensive theory that predicts behaviour in this intermediate region continues to elude researchers.
Figure 38.9   3-D *schematic view of the membrane deflection experiment* (*MDE*)

38.6.2   Thin films

Although thin films have been employed widely in protective coatings, microelectronics and micro-electro-mechanical systems, little is understood about their mechanical behaviour. This deficiency stems from difficulties in performing actual mechanical tests on these microscale structures. Since the physical dimensions of thin films are of a very small magnitude (from a few hundred μm down to as small as 1 nm), conventional mechanical testing methods have not been successful at measuring properties. Specimens in this size range are easily damaged through handling and they are difficult to position to ensure uniform loading along specimen axes. They are also difficult to attach to the testing instrument's grips, in a consistent fashion. Testing has been shown to suffer from inadequate load resolution as well as having analytical solutions that are highly sensitive to precise dimensional measurements. Several small-scale testing techniques have been employed to investigate size effects on mechanical properties. A number of reviews detail the particulars of these methods.[459,484–486]

One of the more noteworthy micro-scale tensile tests, called the membrane deflection experiment (MDE), was developed and involves the stretching of freestanding, thin-film membranes in a fixed-fixed configuration with sub-micrometre thickness.[487–490] In this technique, the membrane is attached at both ends and spans a micromachined window located beneath the membrane (see Figure 38.9). A nanoindenter applies a line-load at the centre of the span to achieve a deflection. Simultaneously, an interferometer focused on the lower side of the membrane records the deflection. The geometry of the membranes is such that they contain tapered regions to eliminate boundary-bending effects. The result is direct tension, in the absence of strain gradients, of the gauged regions of the membrane, with load and deflection being measured independently.

The MDE test has certain advantages, for instance, the simplicity of sample microfabrication and ease of handling lend confidence to repeatability. The loading procedure is straightforward and accomplished in a highly sensitive manner, while preserving the independent measurement of stress and strain. It can also test specimens of widely varying geometry, with thicknesses from sub-micrometre to several micrometres and width from one micrometre to tens of micrometres.

Recent work, employing the MDE technique, on tensile testing of thin gold films of sub-micrometre thickness has shown that size effects do indeed exist in the absence of strain gradients.[487–490] In these studies, grain size was held constant at approximately 250 nm while specimen thickness and width were varied systematically. Figure 38.10(a) consists of diagrams that show the side view of the three studied membranes with different thicknesses. Each thickness has a characteristic number of grains composing the thickness. Stress–strain plots for these films are shown in Figure 38.10(b) and show that the yield stress more than doubled when film thickness was decreased, with the thinner specimens exhibiting brittle-like failure and the thicker samples a strain softening behaviour. It is believed that these size effects stem from the limited number of grains through the thickness, which limits the number of dislocation sources and active slip systems; hence, other deformation modes such as grain rotation and grain boundary shearing accompanied by diffusion become dominant.

These data show great promise of an ability to test ever-smaller specimens, generating information that is expected to have a great impact on the development of micro and nanoscale devices. When
Figure 38.10   *Thin film size effects* (*a*) *Schematic representation of the number of grains within the film thickness* (*b*) *Stress–strain plot for gold membranes, 0.3, 0.5 and 1.0* μm *thick* [488]

coupled with finite element modelling, this information should be able to provide an accurate description of nanoscale structures and features, in order to predict behaviour. These sorts of data are important in exploiting micro and nanoscale properties in the design of more reliable devices with increased functionality. A compilation of mechanical behaviour for various thin film materials is given in [491].

38.6.3   Nanomaterials

Nanomaterials have been receiving increased attention in recent years due to the promising and unique properties that result from their distinctive structure. They are described physically as materials possessing a nominal grain size in the range of 1 to 100 nm, a condition where the interface to volume ratio, or in other words the grain boundary area, greatly increases over traditionally coarse-grained systems. These characteristics are expected to influence strongly a material's chemical and physical properties. Thus, the major focus of study in the nanomaterials field is how properties change as grain size is reduced to the nanometre scale. Recent reviews on nanomaterials can be found in the literature.[492–495]

By controlling the grain size, properties such as the hardness, wear and fatigue resistance, ductility, electric resistivity, magnetic properties, etc. can be optimised.[492–498] An example of these improvements is the yield strength increase observed with decreasing grain size in the *Hall-Petch* relationship.[499,500] This relationship which predicts realistically increases in material strength as grain size is reduced, is as follows:

$$\sigma_y = \sigma_0 + \frac{k}{\sqrt{d}} \tag{1}$$

where σ_y is the yield strength, σ_0 is a friction stress below which dislocations will not move, d is the grain diameter and k is an experimental constant. A similar relationship exists for material hardness. This expression predicts, that as the grain size is reduced, the yield strength will increase. This behaviour has indeed been demonstrated experimentally in many material systems. Extrapolation of the *Hall-Petch* relationship to the nanometre scale predicts an enormous increase in strength and hardness. However, experimental measurements of these properties actually fall well below the extrapolation. The understanding of relationships between nanostructure and mechanical properties of nanocrystalline materials is in its infancy however, and much research remains to be accomplished.

Several models have been developed to account for *Hall-Petch* behaviour;[501–504] graphical representations of three leading models are given in Figure 38.11. The first is a traditional approach and involves the pile-up of dislocations at the boundary of a grain.[501] A grain boundary is considered the ultimate obstacle for a dislocation to overcome. Thus dislocations generated in a grain, in response to an applied stress, will travel along slip planes until a boundary is met, whereby, the dislocations then arrest and begin piling-up. After a critical number of dislocations pile-up, a number dependent on the misorientation of the neighbouring grain sharing the boundary, stress in the boundary causes dislocations to arise in the neighbouring grain. This allows yielding to propagate across the boundary. This theory is applicable only when the grain size is large enough to support the generation of at least two dislocations. Further grain refinement would then result in a plateau of strength or
Figure 38.11 *Schematic representations of models proposed to explain* Hall-Petch *behaviour,* (*a*) *Cottrell,*[501] (*b*) Li[502,503] *and* (*c*) *Meyers*[504]
Figure 38.12 *Compilation of yield stress data on nanocrystalline copper on a* Hall-Petch *plot. Note that the references given in the plot are from* [506]

even a reduction,[505] the so-called *negative Hall-Petch behaviour*. Other theories include dislocation generation at grain boundary ledges[502,503] or as a consequence of stress concentrations at grain boundaries resulting from elastic anisotropy.[504]

It has not yet been agreed upon as to whether dislocation based deformation processes are active in the nanosized grain size regime or are merely suppressed because of the difficulty in activating sources. In moving from coarse-grained to nano-grained materials three types of deformation, based upon the *Hall-Petch gradient* $d\sigma/d(d^{-1/2})$, have been documented experimentally. These include: coarse-grained materials exhibiting a constant positive *Hall-Petch gradient*, a reduction in the positive gradient when a critical grain size is reached and finally the so-called *negative Hall-Petch behaviour* with a negative gradient.[492,494,495] Masumura et al.[506] have collected data on the yield stress of nanocrystalline copper from various sources and summarised them on a *Hall-Petch* plot (see Figure 38.12). The plot shows a continued increase in strength, with decrease in grain size down to a critical size of approximately 15–25 nm. Here, the transition to *negative Hall-Petch behaviour* is distinct where the difference in strength between the grain sizes can readily be seen. Recent work in molecular dynamics (MD) simulations have also predicted that, at very small grain sizes, further grain refinement would lead to a decrease in strength.[507–509]

Beyond hardness and strength, other additional aspects of nanocrystalline materials are affected by their distinctive structure. These include elasticity, ductility and toughness, and superplastic behaviour. In terms of material elastic response, the first documented evidence showed that the elastic moduli of nanocrystalline materials can sometimes be only a fraction of their coarse-grained counterparts.[510–514] The agreed upon explanation of this is rooted in extrinsic defects such as pores

and cracks that result from the compaction of powders. Experimental results on pore-free Ni–P, produced by electroplating, have verified that modulus does return to coarse-grained levels with the removal of pores,[515] also confirmed by other studies.[513,516]

Ductility and toughness of coarse-grained materials has been shown to depend on dislocations and cracks, both their interplay or competition, the effect of which are determined by grain size, whereby a reduction in grain size limits the propagation of each and results in a corresponding increase in fracture toughness.[517,518] In nanocrystalline materials, one would then expect further grain refinement to be a simple extrapolation of coarse-grained behaviour. However, experimental results have been inconclusive in this respect, a consequence of specimen inconsistencies such as porosity, flaws, and surface conditions as well as the testing methodology.[519] This may be the case for metallic materials, however, ductility has been observed in nanocrystalline ceramic materials such as CaF_2 and TiO_2 at temperatures as low as 80 to 180°C.[520,521]

Superplasticity is the ability of a material to withstand elongations in excess of 1000% without the occurrence of necking or fracture. Traditionally this occurs in materials at elevated temperatures, $T > 0.5\,T_m$, containing a second phase that inhibits grain growth, and possessing a fine grain size, on the order of 10 μm.[522,523] Microscopic examination of these materials has concluded that grain boundary sliding accompanied by considerable grain rotation is the incipient mechanism. As grain size is further refined, so is the temperature where superplasticity occurs. However, superplasticity in nanocrystalline materials has not been observed much below $0.5\,T_m$, most likely a result of nanocrystalline creep being comparable to coarse grained creep as exhibited by creep measurements in this regime.[524] Nevertheless, several experimental investigations have found enhancements in superplastic behaviour of nanocrystalline materials above $0.5\,T_m$.[525–527]

38.6.4   Nanostructures

As structures move beyond the sub-micrometre to the nanometre scale, description of mechanical behaviour will be focused on concerns other than the traditional ensemble of defects. For instance, the length scale of a typical dislocation and the volume of material required for it to have significant influence on deformation is large compared with the typical nanovolume. Therefore, it can be argued that beyond a certain point, other types of defects, surface forces, and intermolecular processes will control behaviour.

Nanostructures can be described as either a grain structure with a nominal size in the range of 1 to 100 nm or structures with one or more dimensions on the same order. An example of a nanostructure is a carbon nanotube, which is a molecular scale fibrous structure made of carbon. Carbon nanotubes, discovered by Sumio Iijima in 1991, are a subset of the family of fullerene structures.[528] Note that fullerenes were originally discovered by Curl, Kroto and Smalley, for which they were awarded the 1996 Nobel Prize in Chemistry. The simplest description of their structure would be to imagine a flat plane of carbon graphite rolled into a tube, much the same as a piece of paper (see Figure 38.13).
Figure 38.13   *Schematic drawings of a* 2-D *graphene sheet* (*a*) *rolled-up sheet* (*b*) *armchair* (*c*) *zigzag* (*d*) *chiral* (*e*) *nanotubes* [(*c*), (*d*), and (*e*) *from reference* [536]]

Like the paper, the graphene plane can be rolled in several directions to achieve varying structures. Since their discovery, many scientists have been fascinated by their ensemble of unique properties.

A dominant characteristic of nanostructures is that they possess a rather large surface area to volume ratio. As this ratio increases, interfaces and interfacial energy as well as surface topography, are expected to acquire a commanding role in deformation and failure processes. The picture of nanoscale behaviour can be viewed as the following. At the larger end of the length scale, i.e. 50 to 100 nm, dislocation generation and motion will continue to dictate behaviour. As the grain size or structural dimensions proceed below this, behaviour control will transition to surface and intermolecular mechanisms.

A few experimental studies detail the tensile testing of carbon nanotubes.[529–535] The main difficulties that have to be overcome in the testing of these nanoscale structures are similar to those for thin films; specimen handling, position, gripping and alignment. Young's modulus was found to be in the TPa regime and the tensile strength was found to be in the 11–63 GPa range, depending on the technique. These rather large numbers are reflective of the nanotubes' very low defect density.

Clearly there are many things still to be learned about materials at small scales. Understanding the mechanics of these materials and structures and the competition and interplay between their deformation mechanisms will be essential to predicting their behaviour. Such knowledge is essential to their application in nanoscale electronics and devices. These types of concerns compose the field of nanomechanics, the foundation of which is currently being laid out.

39   Modelling and simulation

39.1   Introduction

The design of useful materials generally involves the simultaneous optimisation of large numbers of parameters, often in circumstances where the interactions between the parameters are ill-defined. This chapter describes some of the methods by which the task can be enhanced using quantitative models which cover a range of disciplines and which include both rigour and empiricism. From the scientific point of view, modelling can lead to the creation of new theory capable of dealing with complexity; the practical goal is to accelerate the design process and to minimise the use of resources. Each of the following sections is intended to communicate the concepts associated with a particular method; appropriate references are provided where the details can be sought.

39.2   Electron theory

A metal is created when the atoms are brought sufficiently close together so that the electrostatic repulsion in transferring a valency electron between adjacent atoms is offset by the gain due to delocalisation of the electron.[1] This enables the valency electrons to move within the metal.

The essential characteristics of the metallic state can be understood in terms of a single-electron wave function which in one-dimension (x) and for the description of stationary states takes the time-independent form:

$$\psi\{x\} = C \exp\{\mathrm{i}kx\}$$

where k is the wave number, C is a constant. All such wave functions must become zero at the boundaries of the metal so that allowed values of k are discrete, each of which defines a quantum state. The Pauli exclusion principle permits only two electrons with opposite spins to occupy each state. The energy of each state scales with k^2 and the highest occupied state at $0\,\mathrm{K}$ is said to have the Fermi energy.

The delocalised electrons feel only a weak electrostatic field ('pseudopotential'), from the positively charged atomic cores. This is because the attraction of the valence electrons to the positive cores is greatly reduced by the repulsion from the core electrons. The delocalised electrons are also partly screened from each other by small exclusion zones (positive holes).

It is useful to understand why the electrons are able to move within the potential of the screened positive ion cores without being scattered. Bloch showed that the effect of the periodic potential $u\{x\}$ is simply to modulate the free-electron wave function by a term $u\{x\}$:

$$\psi\{x\} = u\{x\} \exp\{\mathrm{i}kx\}$$

Difficulties only arise when the wave vector **k** is such that the wave satisfies the Bragg condition; the electron cannot then, on average, move forward or backward through the reflecting planes. In wave theory this is represented by using two functions corresponding to $\pm k$, one of which places the maximum electron density where the positive potential is lowest, giving a solution with an energy that is lower than that of a completely free electron. Similarly the other solution has an energy higher than that of a free electron. This introduces *band gaps* in the distribution of electron energies. Electrons are able to move, and hence the metallic state is able to exist, if the valency bands are only partly filled.

We have so far considered the metallic state in terms of a single-electron wave function; this fails to account for the vast numbers of electrons that are interacting within the metal. There will be Coulomb correlations between the electrons. Their spins may also correlate. The density functional method which is the basis of much of the modern theory of metals, provides an expression of these effects whilst at the same time exploiting the one-electron equation. The energy E of an electron gas is written as a function of a function (i.e. a functional) in terms of the electron density n and a radial coordinate r:

$$E\{n\} = \int V\{r\}n\{r\}\,\mathrm{d}r + \frac{1}{2}\int\int \frac{e^2}{r_{12}}n\{r_1\}n\{r_2\}\,\mathrm{d}r_1\,\mathrm{d}r_2 + T\{n\} + E_{xc}\{n\}$$

where the first term is the pseudopotential due to the ionic cores, the second term is the classical Coulomb interaction energy (e is the electronic charge), the third term is the kinetic energy (i.e. Fermi energy) and the fourth term accounts for the exchange and correlation effects. The use of this equation, and the adaptations necessary to account for various complications (e.g. to take account of partly covalent characteristics), represents the skill in using electron theory. The most rigorous application of the theory requires the largest amount of computing power and hence is limited to circumstances where there is strict periodicity in the atomic structure so that only small numbers of atoms need to be considered with periodic boundary conditions. It is then possible to calculate, for example, the cohesive energy of arbitrary crystal structures, the elastic properties and surface energies.

Some calculations for iron are illustrated in Figure 39.1, which shows the cohesive energy as a function of the density and crystal structure. Of all the test structures, hexagonal close-packed iron (h.c.p.) is found to show the highest cohesion and therefore should represent the most stable form. This contradicts experience, because body-centred cubic iron (b.c.c.) is the equilibrium form at low temperatures. This discrepancy arises because the model ignores magnetic effects—it is ferromagnetism which stabilises b.c.c. iron over the h.c.p. form.

The example illustrates how all models begin with intentional or unintentional simplifying assumptions and yet can be useful. The electron theory not only highlights the importance of magnetic terms, but in addition makes it possible to study crystal structures of iron which have yet to be achieved in practice. The diamond form of iron would have a density of only $5\,\mathrm{g\,cm}^{-3}$. Unfortunately, the calculations show that the difference in energy between the diamond and b.c.c. forms is so large that it is improbable for the b.c.c. $\rightarrow$ diamond transformation to be induced by alloying. The methodology has been used to see whether certain intermetallic compounds can be forced to occur into desirable crystal structures.[3]
Figure 39.1   *Plot of cohesive energy* (0 K) *versus the normalised volume per atom for a variety of crystal structures of iron. Hexagonal–P and Cubic–P are primitive structures*[2]

One application of the theory is to derive empirical potentials representing pairwise or higher order interactions between neighbouring atoms. Such potentials are used in molecular dynamics simulations in which the motion of hundreds of thousands of atoms can be followed simultaneously.[4]

39.3 Thermodynamics and equilibrium phase diagrams

Electron theory is not yet able to give sufficiently accurate calculations of phase diagrams; thermo-dynamic models which exploit experimental databases are much more suited for this purpose.[5–7] The basic information to be gained from a binary phase diagram in which temperature is plotted against concentration, is the chemical composition and proportion of each phase at a specified temperature and average composition. Plotting such diagrams becomes tedious for ternary alloys, and ceases to be useful for higher order alloys. This is not a problem in practice because the information to be gained from a multicomponent, multiphase diagram is identical to that expressed for a binary system. The volume fractions and chemical compositions can readily be communicated numerically instead of using complicated diagrams, as in Table 39.1.

Given thermodynamic data, calculations such as those presented in Table 39.1 are based on the simple requirement that the chemical potential must be uniform at equilibrium:

$$\mu_i^\alpha = \mu_i^\beta = \ldots \quad \text{for } i = 1, 2, 3, \ldots \quad \text{and} \quad \text{phase} = \alpha, \beta \ldots \tag{1}$$

where μ_i^j represents the chemical potential of component i. There are many thermodynamic models for expressing the chemical potential as a function of the mixing the solutes. Each model will have a contribution from the entropy of mixing (ΔS_M) and enthalpy of mixing (ΔH_M) to derive a free energy of mixing (ΔG_M). The equations defining these quantities depend on the assumptions: in ideal mixing the solutes are dispersed at random and $\Delta H_M = 0$; the regular solution model has $\Delta H_M \neq 0$ but it is still assumed that ΔS_M can be calculated assuming random mixing; quasichemical theory also has a finite enthalpy of mixing but does a better estimation of ΔS_M. The method adopted for generalised computation of phase diagrams recognises that in practice it is necessary to implement calculations over a wide range of concentrations, parameters and phases. The molar free energy of mixing in a binary solution is often written as:

$$\Delta G_M = \Delta_e G + N_a kT[(1 - x)\ln\{1 - x\} + x\ln\{x\}] \tag{2}$$

where N_a is Avogadro's number, k is the Boltzmann constant, x is the mole fraction of solute, T is the absolute temperature. The last term in equation 2 comes from the ideal entropy of mixing. The excess Gibbs free energy $\Delta_e G$ expresses the deviation from an ideal solution and is written empirically for a binary solution with components A and B as:

$$\Delta_e G_{AB} = x_A x_B \sum_i L_{AB,i}(x_A - x_B)^i \tag{3}$$

The excess free energy of a ternary solution can as a first approximation be expressed in terms of purely binary interactions:

$$\begin{aligned}
\Delta_e G_{ABC} = {} & x_A x_B \sum_i L_{AB,i}(x_A - x_B)^i \\
& + x_B x_C \sum_i L_{BC,i}(x_B - x_C)^i \\
& + x_C x_A \sum_i L_{CA,i}(x_C - x_A)^i
\end{aligned} \tag{4}$$

Table 39.1 EQUILIBRIUM PHASE MIXTURE FOR Fe–0.1C–0.2Si–0.5Mn–9Cr–1W wt%, AT 873 K

Phase fractions and concentrations are as mole fractions

Phase	Fraction	C	Si	Mn	Cr	W
Ferrite	0.976 9	0.000 001 9	0.006 067 5	0.005 124 6	0.083 947 3	0.001 998 7
M$_{23}$C$_6$	0.022 3	0.206 896 6	0.000 000 0	0.001 977 6	0.624 445 9	0.036 302 9
Laves	0.000 8	0.000 000 0	0.000 000 0	0.000 000 0	0.134 653 0	0.333 333 3

The advantage of the representation embodied in equation 4 is that for the ternary case, the relation reduces to the binary problem when one of the components is set to be identical to another, e.g. $B \equiv C$.

There might exist ternary interactions, in which case a term $x_A x_B x_C L_{ABC,0}$ is added to the excess free energy. If this does not adequately represent the deviation from the binary summation, then it can be converted into a series which properly reduces to a binary formulation when there are only two components:

$$
x_A x_B x_C \Big[L_{ABC,0} + \frac{1}{3}(1 + 2x_A - x_B - x_C)L_{ABC,1}
$$

$$
+ \frac{1}{3}(1 + 2x_B - x_C - x_A)L_{BCA,1}
$$

$$
+ \frac{1}{3}(1 + 2x_C - x_A - x_B)L_{CAB,1} \Big]
$$

The method can clearly be extended to deal with any number of components, with the great advantage that few coefficients have to be changed when the data due to one component are improved. The experimental thermodynamic data necessary to derive the coefficients may not be available for systems higher than ternary so high order interactions are often set to zero.

39.4   Thermodynamics of irreversible processes

Equilibrium as described above represents a state in which there is no perceptible change no matter how long one observes the state. A process of change (i.e. an irreversible process) is by contrast associated with the dissipation of free energy and is best described using kinetic theory. Before dealing with full-blown kinetic theory, it is possible to study a compromise model in which thermodynamics is used to represent systems in which there is *apparently* no change but free energy is nevertheless being dissipated. This is the case of the *steady state*, for example, diffusion across a constant gradient; neither the flux nor the concentration at any point changes with time, and yet the free energy of the system is decreasing since diffusion occurs to minimise free energy. The rate at which energy is dissipated is the product of the temperature and the rate of entropy production (i.e. $T\sigma$) with:[8,9]

$$
T\sigma = JX \tag{5}
$$

where J is a generalised flux of some kind, and X a generalised force. In the case of an electrical current, the heat dissipation is the product of the current (J) and the electromotive force (X).

Provided the flux–force sets can be expressed as in equation 5, the flux must naturally depend in some way on the force. It may then be written as a function $J\{X\}$ of the force X. It is found that for small deviations from equilibrium, the flux is proportional to force, Table 39.2.

There are many circumstances where a number of irreversible processes occur together. In a ternary Fe–Mn–C alloy, the diffusion flux of carbon depends not only on the gradient of carbon, but also on that of manganese. Thus, a uniform distribution of carbon will tend to become inhomogeneous in the presence of a manganese concentration gradient. Similarly, the flux of heat may not depend on the temperature gradient alone; heat can be driven also by an electromotive force. Electromigration

Table 39.2   EXAMPLES OF FORCES AND THEIR CONJUGATE FLUXES

z is distance, ϕ is the electrical potential in volts, and μ is a chemical potential

Force	*Flux*
Electromotive force (e.m.f.) $= \dfrac{\partial \phi}{\partial z}$	Electrical current
$-\dfrac{1}{T}\dfrac{\partial T}{\partial z}$	Heat flux
$-\dfrac{\partial \mu_i}{\partial z}$	Diffusion flux

involves diffusion driven by an electromotive force. When there is more than one dissipative process, the total energy dissipation rate can still be written.

$$T\sigma = \sum_i J_i X_i. \tag{6}$$

For multiple irreversible processes, it is found experimentally that each flow J_i is related not only to its conjugate force X_i, but also is related linearly to all other forces present. Thus,

$$J_i = M_{ij} X_j \tag{7}$$

with $i, j = 1, 2, 3, \ldots$. Therefore, a given flux depends on all the forces causing the dissipation of energy. Onsager has shown that to maintain dynamic equilibrium, and provided that the forces and fluxes are chosen from the dissipation equation and are independent, $M_{ij} = M_{ji}$. An exception occurs with magnetic fields in which case there is a sign difference $M_{ij} = -M_{ji}$.

39.5 Kinetics

Many kinetic processes are not consistent with the steady-state. The vast majority of such processes in metals involve aspects of nucleation and growth; the theory for nucleation and growth is standard and is assumed here, in order to focus on the estimation of the volume fraction, which requires *impingement* between particles to be taken into account.

This is done using the extended volume concept of Kolmogorov, Johnson, Mehl and Avrami.[10] Suppose that two particles (Fig. 39.2) exist at time t; a small interval δt later, new regions marked a, b, c & d are formed assuming that they are able to grow unrestricted in extended space whether or not the region into which they grow is already transformed. However, only those components of a, b, c & d which lie in previously untransformed matrix can contribute to a change in the real volume of the product phase (α):

$$dV^\alpha = \left(1 - \frac{V^\alpha}{V}\right) dV_e^\alpha \tag{8}$$

where it is assumed that the microstructure develops at random. The subscript e refers to extended volume, V^α is the volume of α and V is the total volume. Multiplying the change in extended volume by the probability of finding untransformed regions has the effect of excluding regions such as b, which clearly cannot contribute to the real change in volume of the product. For a random distribution of precipitated particles, this equation can easily be integrated to obtain the real volume fraction,

$$\frac{V^\alpha}{V} = 1 - \exp\left\{-\frac{V_e^\alpha}{V}\right\} \tag{9}$$

Time $= t$ Time $= t + \Delta t$
Figure 39.2 *An illustration of the concept of extended volume. Two precipitate particles have nucleated together and grown to a finite size in the time t. New regions c and d are formed as the original particles grow, but a & b are new particles, of which b has formed in a region which is already transformed*
Figure 39.3   *The Scheil method for converting between isothermal and anisothermal transformation data*

The extended volume V_e^α is straightforward to calculate using nucleation and growth models and neglecting any impingement effects. Solutions typically take the form:

$$\xi = 1 - \exp\{-k_A t^n\} \tag{10}$$

where k_A and n characterise the reaction as a function of mechanism of transformation, time, temperature and other variables.

Reactions sometimes do not happen in isolation. For example, a steel designed to serve at 600°C over a period of 30 years may contain more than six different kinds of precipitates so that it can sustain a load without creeping. A simple modification for the simultaneous formation of two precipitates (α and β) is that the relation between extended and real space becomes a coupled set of two equations,[11,12]

$$dV^\alpha = \left(1 - \frac{V^\alpha + V^\beta}{V}\right) dV_e^\alpha \quad \text{and} \quad dV^\beta = \left(1 - \frac{V^\alpha + V^\beta}{V}\right) dV_e^\beta \tag{11}$$

This can be done for any number of reactions happening together. The resulting set of equations must in general be solved numerically.

A popular method of converting between isothermal and anisothermal transformation data is the *additive reaction rule* of Scheil.[10] A cooling curve is treated as a combination of a sufficiently large number of isothermal reaction steps. Referring to Figure 39.3, a fraction $\xi = 0.05$ of transformation is achieved during continuous cooling when

$$\sum_i \frac{\Delta t_i}{t_i} = 1 \tag{12}$$

with the summation beginning as soon as the parent phase cools below the equilibrium temperature.

The rule can be justified if the reaction rate depends solely on ξ and T. Although this is unlikely, there are many examples where the rule has been empirically applied with success. Reactions for which the additivity rule is justified are called isokinetic, implying that the fraction transformed at any temperature depends only on time and a single function of temperature.

39.6   Monte Carlo simulations

The complete description of microstructure requires both field and feature parameters; the former describes averaged quantities such as volume fraction and the amount of surface per unit volume;

1	1	2	2	2	2	3	3	3

Figure 39.4 *Mapping of variable defining crystallographic orientation; the orientation domains are separated by grain boundaries. In this example, the elements within each grain are arranged in a square pattern*

the latter includes for example, size distributions. One disadvantage of the Avrami method is that it yields only the field parameters since information about individual particles is lost during the conversion from extended to real space. Methods such as Monte Carlo and phase field simulations permit the visualisation of microstructural development and can therefore reveal feature parameters.

The simulation of microstructure using the Monte Carlo method begins with the definition of domains using an appropriate variable which can take on discrete values out of a set of possible values.[4] A case where the variable is used to represent crystallographic orientation is illustrated in Figure 39.4, with grain boundaries located wherever the variable changes value.

We shall consider isothermal grain coarsening to illustrate the method. Having defined the starting grain structure as in Figure 39.4, the elements located at the grain boundaries are identified and are the only ones considered in further calculations. Each of these grain boundary variables is then randomly perturbed. If the perturbation leads to an overall reduction in energy, it is accepted. If it leads to an increase ΔE in energy, then it is accepted only if the term $\exp\{-\Delta E/kT\} \leq p$ where p is a random, computer-generated number between 0 and 1.

The accepted perturbations lead to a new grain structure once all the elements have been sampled. The process of sampling of all of the elements defined in the model corresponds to one Monte Carlo step, equivalent to the progress of time. Since each of the elements illustrated in Figure 39.4 is much coarser than an atom, care must be taken to investigate the effect of this 'coarse-graining'; indeed, the symmetry of the pattern in which the elements are arranged within each grain is known to influence the outcome.[4]

39.7 Phase field method

Consider the growth of a precipitate which is separated from the matrix by an interface. There are then three distinct quantities: the precipitate, matrix and interface. The interface is described as an evolving surface whose motion is controlled according to the boundary conditions imposed to describe the physical mechanisms which lead to the growth of one phase at the expense of the other. This mathematical description categorises the boundary as a two-dimensional surface with no width or structure, a *sharp interface*.

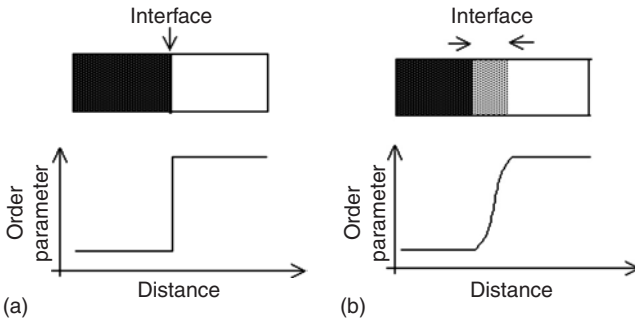
By contrast, the phase-field method[13] begins with a description of the entire microstructure, including the interface, in terms of a single variable known as the *order parameter*. The precipitate and matrix each have a particular value of the order parameter. Likewise, the interface is located by the position where the order parameter changes from its precipitate-value to its matrix-value. The order parameter is thus continuous as one traverses the precipitate and enters the matrix (Fig. 39.5).


Figure 39.5   *(a) Sharp interface. (b) Diffuse interface*

The range over which it changes is the *width* of the interface. The set of values of the order parameter over the whole microstructure is the *phase field*.

The order parameter changes smoothly through the interfacial region from one limiting value to the other, in a phase-field model. A theory which tracks the dynamics of the order parameter across the entire phase field, would allow the evolution of the microstructure to be calculated without the need to track the interface. Such a theory would require the free energy as a function of the order parameter so that the field can follow a path which leads to a maximisation of entropy production.

Two examples of phase-field modelling are as follows: the first is that of grain growth, where the order parameter is not conserved since the amount of grain surface per unit volume decreases with grain coarsening. The second conserves the order parameter. When composition fluctuations evolve into precipitates, it is the average chemical composition which is conserved. We now consider this second example in a little more detail.

In solutions that tend to exhibit the clustering of atoms, it is possible for a homogeneous phase to become unstable to infinitesimal perturbations of chemical composition. The free energy of a solid solution which is chemically heterogeneous can be factorised into three components.[14] First, there is the free energy of a small region of the solution in isolation, given by the usual plot of the free energy of a homogeneous solution as a function of chemical composition. The second term comes about because the small region is surrounded by others which have different chemical compositions. This *gradient term* is an additional free energy in a heterogeneous system, and is regarded as an interfacial energy describing a 'soft interface' of the type illustrated in Figure 39.5b. In this example, the soft-interface is due to chemical composition variations, but it could equally well represent a structural change. The third term arises because a variation in chemical composition also causes lattice strains in the solid-state. We shall neglect these coherency strains.

The free energy per atom of an inhomogeneous solution is then given by:

$$g_{ih} = \int [g\{c_0\} + \upsilon^3 \kappa (\nabla c)^2]\mathrm{d}V \tag{13}$$

where $g\{c\}$ is the free energy per atom in a homogeneous solution of concentration c_0, υ is the volume per atom and κ is called the *gradient energy coefficient*. g_{ih} is often referred to as a free energy *functional* since as in density functional theory, it is a function of a function.

Equilibrium in a heterogeneous system is obtained by minimising the functional, subject to the requirement that the average concentration is maintained constant:

$$\int (c - c_0)\mathrm{d}V = 0$$

where c_0 is the average concentration. Spinodal decomposition can therefore be simulated using the functional defined in equation 13. The system would initially be set to be homogeneous but with some compositional noise. It would then be perturbed, allowing those perturbations which reduce free energy to survive. In this way, the whole decomposition process can be modelled without explicitly introducing an interface. The interface is instead represented by the gradient energy coefficient.
Figure 39.6 *Finite difference representation of diffusion*

39.8 Finite difference method

The finite difference method is useful in the numerical solution of second order boundary value problems.[15] Consider one-dimensional diffusion in a concentration gradient along a coordinate z (Fig. 39.6). The concentration profile is divided into slices, each of thickness h. The matter entering a unit area of the face at a in a time increment τ is given approximately by $J_a = -D\tau(C_1 - C_0)/h$. That leaving the face at b is $J_b = -D\tau(C_2 - C_1)/h$. If C_1' is the new concentration in slice 1, then the net gain in solute is $(C_1' - C_1)h$ so that

$$C_1' - C_1 = \frac{D\tau}{h^2}(C_0 - 2C_1 + C_2) \tag{14}$$

This allows the concentration at a point to be calculated as a function of that at the two neighbouring points. By successively applying this relation at each slice, and advancing the time τ, the entire concentration profile can be estimated as a function of time.

The approximation here is that we have applied Fick's first law to each slice, i.e. assumed that the concentration gradient within each slice is constant. Since the profile is in fact a curve, the approximation will be better for smaller values of h, but the computation times will be correspondingly longer. Considerations of numerical accuracy are vital in such methods; the accuracy can be assessed by changing h and seeing whether it makes a significant difference to the calculated profile.

39.9 Finite element method

In finite element analysis, continuous functions are replaced by piecewise approximations. Thus, a finite element representation of a circle would be a circumscribed polygon, with each edge being a finite element. We shall discuss this in terms of the forces involved in the deflection of springs.[16]

It is assumed that for any spring, the force varies linearly with displacement: $F = k\delta$ where k is the stiffness of the spring. Consider the forces at the nodes of a spring in a system of springs at equilibrium, as illustrated in Figure 39.7a. Since $F_1 = -F_2$,

$$\begin{bmatrix} F_1 \\ F_2 \end{bmatrix} = \begin{pmatrix} k & -k \\ -k & k \end{pmatrix} \begin{bmatrix} \delta_1 \\ \delta_2 \end{bmatrix}$$

The forces at the nodes of the springs illustrated in Figure 39.7b are therefore

$$\begin{bmatrix} F_1 \\ F_2 \\ 0 \end{bmatrix} = \begin{pmatrix} k_1 & -k_1 & 0 \\ -k_1 & k_1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \end{bmatrix} \qquad \begin{bmatrix} 0 \\ F_2 \\ F_3 \end{bmatrix} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & k_2 & -k_2 \\ 0 & -k_2 & k_2 \end{pmatrix} \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \end{bmatrix}$$

$$\begin{bmatrix} F_1 \\ F_2 \\ F_3 \end{bmatrix} = \underbrace{\begin{pmatrix} k_1 & -k_1 & 0 \\ -k_1 & k_1 & 0 \\ 0 & 0 & 0 \end{pmatrix} + \begin{pmatrix} 0 & 0 & 0 \\ 0 & k_2 & -k_2 \\ 0 & -k_2 & k_2 \end{pmatrix}}_{\text{component stiffnesses}} \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \end{bmatrix} \equiv \underbrace{\begin{pmatrix} k_1 & -k_1 & 0 \\ -k_1 & k_1 + k_2 & -k_1 \\ 0 & -k_2 & k_2 \end{pmatrix}}_{\text{overall stiffness}} \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \end{bmatrix}$$
Figure 39.7   *Forces on springs*
Figure 39.8   *(a) A neural network representation of linear regression. (b) A non-linear network representation*

This simple case illustrates how the properties of the elements can be combined to yield an overall response function.

39.10   Empirical modelling: neural networks

There are problems in materials science where the concepts might be understood but which are not amenable to thorough scientific treatment. Empirical regression then becomes useful. By fitting data to a specified relationship, an equation is obtained which relates the inputs x_j via weights w_j and a constant θ to obtain an estimate of the output $y = \sum_j w_j x_j + \theta$. Because the variables are assumed to be independent, this equation can be stated to apply over a certain range of the inputs.

This linear regression method can be represented as a neural network (Fig. 39.8a). The inputs x_i define the *input nodes*, and there is an *output node*. Each input is multiplied by a random weight w_i and the products are summed together with a constant θ to give the output $y = \sum_i w_i x_i + \theta$. The summation is an operation which is hidden at the *hidden node*. Since the weights and the constant θ were chosen at random, the value of the output will not match with experimental data. The weights are changed systematically until a best-fit description of the output is obtained as a function of the inputs; this operation is known as *training* the network.

The network can be made non-linear as shown in Figure 39.8b. As before, the input data x_j are multiplied by weights $(w_j^{(1)})$, but the sum of all these products forms the argument of a hyperbolic tangent:

$$h = \tanh\left(\sum_j w_j^{(1)} x_j + \theta\right) \quad \text{with} \quad y = w^{(2)} h + \theta^{(2)} \tag{15}$$

where $w^{(2)}$ is a weight and $\theta^{(2)}$ another constant. The strength of the hyperbolic tangent *transfer function* is determined by the weight w_j. The output y is therefore a non-linear function of x_j, the
Figure 39.9 *(a) Three different hyperbolic tangent functions; the 'strength' of each depends on the weights. (b) A combination of two hyperbolic tangents to produce a more complex model. (c) A two hidden-unit network*

function usually chosen being the hyperbolic tangent because of its flexibility. The exact shape of the hyperbolic tangent can be varied by altering the weights (Fig. 39.9a).

A one hidden-unit model may not be sufficiently flexible. Further degrees of non-linearity can be introduced by combining several of the hyperbolic tangents (Fig. 39.9b), permitting the neural network method to capture almost arbitrarily non-linear relationships. The number of tanh functions per input is the number of hidden units; the structure of a two hidden unit network is shown in Figure 39.9c.

The function for a network with i hidden units is given by

$$y = \sum_i w_i^{(2)} h_i + \theta^{(2)} \quad \text{where} \quad h_i = \tanh\left(\sum_j w_{ij}^{(1)} x_j + \theta_i^{(1)}\right) \tag{16}$$

Notice that the complexity of the function is related to the number of hidden units. A neural network like this can capture interactions between the inputs because the hidden units are nonlinear. Appropriate measures must be taken to avoid overfitting. With complex networks it is not possible to easily specify a range of applicability. MacKay has developed a particularly useful treatment of neural networks in a Bayesian framework;[18] instead of calculating a unique set of weights, a probability distribution of sets of weights is used to define the fitting uncertainty. The error bars therefore become large when data are sparse or locally noisy.

40 Supporting technologies for the processing of metals and alloys

40.1 Introduction and cross-references

This chapter brings together three topics that support the processing of metals and alloys, namely: the design of metallurgical furnaces, vacuum technology and the control of metallurgical processes.
  Material in this chapter relates to the following:

- The statistical basis of process control is discussed in Chapter 2.
- Thermocouple-based temperature measurement and information on emissivity relevant to pyrometry are outlined respectively in Chapters 16 and 17.
- Foundry practice and heat-treatment are considered respectively in Chapters 26 and 29.
- Refractory materials form the topic of Chapter 27.
- For a discussion of fuels, *see* Chapter 28.

40.2 Furnace design

40.2.1 Introduction

There are many considerations to be made when designing a metallurgical processing furnace. A furnace is not just simply a box of bricks; it is a unit which encompasses many engineering aspects including:

- Furnace safety
- Energy input
- Temperature measurement
- Temperature control
- Temperature uniformity
- Temperature recording
- Mechanical handling
- Door mechanisms
- Heat loss
- Batch or continuous operation
- Pre-cleaning
- Post-cleaning
- Method of quenching
- Quench media
- Quench agitation
- Heat transfer from quench medium
- Furnace atmosphere
- Generation of furnace atmosphere
- Control of furnace atmosphere
- Mass (load weight) of work pieces
- Heat transfer to load.

The above are just a few of the considerations that are necessary in the design of the metallurgical processing furnace. Furnace design requires the engineer to have, or to have access to, multiple disciplines which range from:

– Mechanical engineering
– Electrical engineering
– Metallurgical engineering
– Physics
– Chemistry.

These disciplines will assist the engineer in designing a cost-effective, functioning, metallurgical processing furnace that will process the necessary work in an efficient and safe manner to the benefit of both the furnace operator and the resulting product's end user.

Metallurgical processing furnaces can be categorised into two main groups, which relate to the types of materials to be processed.

– Ferrous materials
– Non-ferrous materials

Within the above two groups, further subdivisions can be made in relation to heating methods. These subdivisions are:

Electrical heating

The electrical heating methods and techniques can be further subdivided into elemental type heating systems and other electrical methods of heating such as laser, radio frequency, electron beam, infrared. The latter four types of heating will not be considered in this section.

Gas heating

Furnaces can be further categorised into three distinctive groupings which relate to the general types of application. These distinctive groupings are:

Ovens: An oven is considered to be a low operating temperature system. This means that the unit will operate from room temperature up to approximately 300°C (600°F).

Heat treatment furnaces: A heat treatment furnace will operate over a temperature range from 150°C (300°F) up to (as in the case of vacuum furnaces) 1 650°C (3 000°F), although specialist furnaces can reach far higher temperatures.

Melting and holding furnaces: These furnaces will melt both ferrous and non-ferrous materials ranging from lead to aluminium, brasses, cast irons and steels.

The focus of the discussion in this section will be on the design of heat treatment furnaces only, i.e. this means furnaces that are capable of heat treating aluminium alloys and various types of steels, whose only function is to accomplish phase changes within the selected metal.

40.2.2 Types of furnaces

There are three simple furnace configurations, which are as follows:

– Horizontal furnaces
– Pit furnaces
– Bottom load elevator hearth furnaces.

The first group of furnaces to be considered will be the horizontal furnace configuration.

40.2.2.1 *Box furnaces*

The box furnace is perhaps the most simple of all of the heat treatment furnaces. This is usually of a rugged and simple construction. The furnace will literally be a box which will contain insulation material (refractory insulation or thermal blanket insulation). The furnace usually has a range of operating temperatures from 150°C (300°F) up to 1 200°C (2 200°F). Some high-temperature box furnaces that are heated by silicon carbide elements are capable of reaching temperatures above 1 300°C (2 400°F). Heating methods, such as the use of MoSi$_2$ elements, for higher temperature

vertical furnaces are not discussed here. The furnace can have either a single access door or an entry and exit door at each end of the furnace. The furnace heating system can be:

Direct heating

In this instance, the products of combustion (if gas-fired) can provide an atmosphere. This atmosphere can be either oxidising, carburising or decarburising. If the furnace is heated electrically, then heat transfer will be either by convection, conduction or both, depending on the furnace's maximum operating temperature, with radiant heat transfer becoming important at high temperature.

Indirect heating

A furnace heated by indirect methods can have its heat source located in an external heating chamber, and the heated air driven by an air blower which will distribute the heated air into the work processing chamber through a series of dampers, which are set to distribute the heated air and ensure good temperature uniformity.

40.2.2.2 *Integral quench furnaces*

The integral quench furnace is perhaps the 'workhorse' of the heat treatment furnaces. The design of the integral quench furnace dates back to the late 1940s. The original aim of this type of furnace was to transform a box type (batch) furnace into a continuous/semi continuous type furnace. The design of the furnace integrates the use of two separate process chambers, the first chamber being the entry vestibule which contains the quench tank and is separated by an intermediate insulated door. Behind the intermediate door is the high heat chamber in which the heat treatment procedure could be carried out. The high heat chamber contains the furnace heating system and the furnace atmosphere system, as well as the mechanical handling equipment which enables the workload to be transferred into the furnace from an external load table, through the entry vestibule and on into the heating chamber. Upon completion of the heat treatment procedure, the workload is transferred back into the front entry vestibule and on to an elevator table which will lower the workload into the quench medium (if required). If the process is, for example, an annealing process, then the workload can sit on the elevator table without being immersed into the quench medium. This will allow a slow cool.

The integral quench furnace is used for many different heat treatment processes, such as:

– Annealing
– Carburising
– Carbonitriding
– Ferritic nitrocarburising
– Solutionising
– Neutral hardening.

The limiting factors of the integral quench furnaces can be both the volume of quench medium in the quench tank and size limitations of the heating chamber. Generally, these types of furnaces will have a temperature limitation of 950°C (1 750°F).

Many advances have been made since the late 1940s in terms of heating efficiency, operating costs, work load handling and most importantly, process control in terms of atmosphere control, temperature control, temperature uniformity and minimal heat losses.

40.2.2.3 *Pit furnaces*

As the name implies, this type of furnace can be installed into a pit or be mounted on the shop floor. It will be the size of the furnace, height clearance above the furnace, and foundation/floor conditions that will determine the positioning of the furnace.

These furnaces are also known as vertical air circulation furnaces. This means that the heated air/atmosphere within the furnace is circulated throughout the heating chamber, which provides good temperature uniformity. The air circulation is accomplished by the use of a fan, located either in the base of the furnace or in the furnace lid. This type of furnace is used typically for the following heat treatment processes:

– Tempering
– Stress relieving
– Normalising
– Annealing

– Nitriding
– Ferritic nitrocarburising
– Carbonitriding
– Carburising.

The furnace construction is very simple, once again, and offers excellent uniformity of both temperature and atmosphere (if used). Improved temperature uniformity is a result of the shape of the furnace chamber, which is circular.

40.2.2.4   *Horizontal car bottom furnaces*

The car bottom furnace is designed usually to process large products such as fabrications, pressure vessels, ingots, forgings and castings. The heat treatment procedures usually carried out in these furnaces are:

– Annealing
– Normalising
– Stress relieving
– Hardening
– Tempering.

The furnace consists of a static steel framework into which is installed the heating system (gas or electric), insulation (refractory brick or low thermal mass fibre), entry door (which can be a single entry door, or two doors i.e. one front, one rear) and finally the car bottom. If the furnace is of the single door entry type, then it is supplied usually with one insulated refractory brick/castable transportable base on wheels. The drive mechanism of the hearth can be an external steel rope and pulley system, or a motorised drive system located on the underside of the hearth. If the furnace has a two-door system, then a single hearth can still be used on a straight through basis or two load transportation cars can be utilised i.e. one for processing and one for loading/unloading.

If the furnace is to be used for hardening followed by quenching, then a lifting or tilting mechanism will be necessary to discharge the load into the quench tank.

Another variation of the car bottom type of furnace is the lift off bell furnace. The bell can be circular and cylindrical, or a box type furnace. The circular/cylindrical bell furnace can be heated by electrical methods or by gas firing. The heating system is generally on the external side of the bell. The box type furnace is usually fired within the insulated box and can be fired by either electrical or gaseous heating methods.

40.2.2.5   *Continuous furnaces*

The continuous type of furnace is used normally for high-volume production of manufactured parts. The mechanical handling of the work piece within this type of furnace can be designed for the particular product that the furnace is to handle, such as:

Ingots, slabs bars: These products can be handled within the furnace grouping known as walking beam furnaces. This work handling method is managed by two sets of beams within the furnace heating chamber. The first group of beams are static beams, which are fixed to the hearth of the furnace. A second group of beams is able to move. This group of beams manipulates the products through the furnace. This type of furnace is generally fired internally by gas and air mixtures.

Smaller components (*e.g. small billets*)*:*   These can be heated inside a rotary hearth furnace. This type of furnace is round in shape and is of a static type. The only moving parts of this furnace being the entry/exit doors and the rotary hearth upon which the work is placed. The furnace can be heated either by gaseous means or electrically. The furnace atmosphere can either be generated from the products of combustion, from direct gas firing, or by any generated atmosphere such as an endothermic atmosphere or a nitrogen/methanol atmosphere. If these types of atmospheres are used, then the firing method will be encapsulated in the burner combustion tubes.

Mass production: The continuous type of furnace for this application can be a roller hearth furnace. In this type of furnace, the heating method can be either direct or indirect heating, using gas or electrical heating. The work is transported through the furnace on specially designed work load trays that are placed (with the work) on to driven rollers. Each of these

rollers are driven from a master drive system and each roller is supported on either side of the roller with water cooled bearings. The furnaces are usually long and have an entry and exit door at each end of the furnace.

Where the integrity of the atmosphere is vital, the choice of furnace would be a pusher type furnace. This type of furnace is usually heated indirectly and the heating method (gas or electrical) is encapsulated in the heating tubes. Generally, the furnaces are designed for atmosphere conditions using either endothermic or nitrogen/methanol atmospheres. Because of these types of atmospheres, a front and rear vestibule is generally fitted to the furnace. Generally these furnaces are fitted with an atmosphere circulation system compromising of multiple fans located either in the roof or side walls of the furnace. This type of furnace can maintain a very accurate atmosphere for a variety of processes.

When small components are required to be heat-treated, the furnace of choice would be a shaker hearth furnace or a continuous mesh belt furnace. A shaker hearth furnace (a.k.a. a shuffle hearth furnace) comprised of a long horizontal tetragonal furnace with a single hearth that moves rapidly forwards and backwards over a distance of approximately 150 mm (6 in). This causes the work load to move forward through the heating chamber. A variety of processes can be accomplished in this type of furnace, such as hardening, tempering, carbonitriding and carburising. Usually, at the end of the table, the work is allowed to free fall into a vertical chute which is immediately above the quench tank. The disadvantage of this type of furnace is that there is no control of the presentation of the work to the quench medium, therefore the problem of distortion becomes quite high. A mesh belt furnace is a long horizontal tetragonal type of furnace that is capable of holding the furnace atmosphere as it is with the shaker hearth furnace. The difference between the two furnaces is simply in the method of transportation of the work. In the mesh belt furnace, the mesh belt is a woven belt of heat resistant stainless-steel which transports the work through the heating chamber and discharges it either into a quench tank or into a controlled cooling area. The mesh belt can be returned to the driven end of the furnace either externally or internally. If the belt is returned externally, it means that the belt has to be reheated. These furnaces can be heated either electrically or by gaseous methods. The heat source is usually encapsulated, irrespective of which method is chosen.

Rotary barrel furnaces contain a heat resisting process barrel which is fitted internally with a screw drive mechanism. The work is loaded, on a continuous basis, through an external sealed feeding system. The barrel is rotated by an external drive system which can be either a direct chain drive or a roller drive system. Sometimes, the whole furnace will tilt to discharge the workload into the quench medium, or the parts will be screw driven out of the furnace through a sealed discharge aperture and into the quench medium.

The single most important problem with any of the above furnaces is that of the potential for distortion to occur, simply because the work is allowed to free fall into the quench medium, without any control of how the component is presented to the quench medium.

40.2.3   Heat calculations

Irrespective of the type of furnace selected, it is necessary to calculate the amount of energy that is required to raise the temperature of the workload from ambient up to the metallurgical processing temperature. Such calculations can range from simple 'back of the envelope' methods (*e.g.* energy requirement = specific heat capacity × gross load mass × [target temperature – ambient temperature]) to sophisticated heat transfer models. The former type of calculation will be familiar to readers, whilst the latter forms an entire branch of the technical literature and hence cannot be discussed here.

Once the heating requirement calculations have been accomplished, then it is necessary to calculate the hearth length.

The furnace length will be determined by considering the following parameters and factors which are in relation to the operation process parameters. Note that load support fixtures as well as furnace support and carrier trays must be considered in the heating calculation. The process parameters to be considered are listed below:

– Total work throughput (mass per hour)
– Number of trays per hour
– Trays and support mass per hour
– Number of trays per hour required for the desired rate of production
– Method of heating
– Process time at temperature.

It is necessary to consider the heating method to determine if there is space to equip the furnace with either heating elements or burners and burner tubes.

40.2.4 Refractory design

The choice of insulation materials are wide and varied (*see* Chapter 27 for more detail).

REFRACTORY BRICKS VERSUS CERAMIC FIBRE BLANKETS

The maximum operating temperature of the furnace will determine the primary choice of insulation material, in addition to which air velocity and atmosphere movement within the process chamber must be considered. On this basis, a choice must be made between refractory brick and a low mass ceramic fibre material. It cannot be stated that one type of material is universally better or worse than the other. Instead, the choice of insulating material is application specific and depends upon the heat up and cool down rate required, maximum furnace operating temperature and the amount of wind abrasion that will occur within the furnace process chamber.

Another consideration in regard to temperature, will be the cold face temperature. That is the temperature that will occur on the external steel walls of the furnace. The accepted safe outside wall temperature is 65°C (150°F) maximum. However, if the furnace maximum operating temperatures is say, 1 000°C (1 800°F), then the external wall temperature will be determined by:

The hot face insulation of the furnace wall is made up of refractory material (in the form of bricks or a fibre blanket as discussed above). Behind the hot face insulation material will be another course of lower temperature heat resistance material, followed by possibly a third or fourth layer, to reduce the transfer of the heat that is generated at the hot face, in order to maintain a safe external wall temperature.

The disadvantage of using refractory brick is that the insulating wall thickness is generally quite high, which means additional weight within the furnace construction. A further disadvantage of all refractory bricks (which is probably the primary disadvantage) is the thermal energy necessary to heat the furnace chamber up to its operating temperature. The major advantage of refractory brick however, is that it has good heat retention and storage capacity. Generally (excluding fire brick) the brick is very porous. The degree of porosity will determine the bricks' heat storage capacity. The high porosity bricks can work against the heat treatment practitioner, in so much as, if the work load requires a controlled carbon atmosphere, or a carburising atmosphere, then the brick will begin to soak up the carbon atmosphere (depending of course on the carbon potential of the furnace atmosphere). This will mean a frequent burnout of the process chamber. Another consideration when using refractory brick, is the iron content. Generally when firing the furnace electrically, one should choose a brick with a low iron content. Excess iron can lead to 'tracking' or small arcs occurring at the point of mounting the element onto the wall. If the furnace is gas fired, then the iron content is not as critical to the refractory selection process.

Low mass ceramic fibre blanket is not very capable of heat storage. However, it has the ability to heat up to the operating temperature very quickly when compared with refractory brick. The blanket is very easy to install, and in order to reduce the effects of wind erosion, due to air movement within the process chamber, a surface hardener can be applied to the surface of the blanket. Periodic inspections must be made to assess the condition of the surface hardener. The surface can also be enhanced for longer life by the application of wire mesh with a hardener painted over the mesh. The mesh is generally made of stainless steel.

The low mass ceramic fibre blanket is not very good for use with controlled carbon atmosphere potentials. The blanket has a far greater porosity than the brick. Thus the blanket will also take carbon away from the furnace atmosphere, making it difficult to control the atmosphere accurately.

MODULES

When contemplating the use of low mass fibre, consideration can be given to the use of preformed square blanket modules. This will reduce the installation time dramatically as a result of increased ease of application.

PREFORMS

Another insulation material to consider, particularly when designing and building repeat types of furnaces and sometimes with complex designs, are pre-formed/vacuum formed insulation modules.

MORTAR

Careful consideration should be given to the selection of mortar used to install and cement the brick together. The mortar should be applied:

– Uniformly
– Thinly
– With a small joint clearance.

The mortar should have similar insulating characteristics to those of the refractory brick. When mixing the mortar, the consistency of the mortar will be determined by the amount of water added. The mixed mortar should have a firm consistency.

DRYOUT

Any new or re-bricked furnace must be dried out before commencing heat treatment operations. This is not as critical when the furnace has been relined with, for example, a low mass thermal insulation blanket, simply because the fibre is flexible and can accommodate any moisture that might be present within the blanket.

A furnace that is insulated with refractory brick will absorb atmospheric moisture as well as moisture contained in the mortar. If the furnace is raised from room temperature to operating temperature immediately after bricking or re-bricking, the residual moisture present in the brick will expand very rapidly and will have the potential to crack the brick. Therefore the furnace should be raised to a temperature of say, 105°C (220°F), and held at this temperature for up to 12 hours. This should be done with the furnace doors open, to allow the moisture bearing air to disperse from the furnace process chamber.

The next step in the dry out procedure will be to raise the furnace temperature up to say 260°C (500°F) and hold it for approximately 12 hours, again with the doors open. After this segment is completed, the furnace can be heated up to perhaps 535°C (1 000°F) and held for approximately six hours. At this point the furnace doors can be closed.

The furnace temperature can then be ramped up to say 750°C (1 400°F) then the furnace can be heated up to its process temperature with a ramp rate of no more than typically 35°C per hour (100°F per hour). This is to reduce the risk of thermal shock to the refractory brick, thus minimising the potential to crack the refractory, which might occur if the temperature is raised too quickly.

In the case of a new furnace, then it is most important to adhere to the manufacturer's dry out procedure. The above description of dry out, gives both the furnace engineer and the service technician an idea of the potential for cracking the refractory, if the furnace is raised to temperature too quickly.

40.2.5   Vacuum furnaces (see also section 40.3 on vacuum technology)

The dry out procedure of a vacuum furnace is somewhat different to that of a refractory lined furnace. Vacuum furnaces can be both heated and insulated in two different fashions:

All metal   This means refractory metals and stainless steels for both heat shield and elements.
Graphite   Graphite or carbon reinforced carbon can be used as the heating elements. The insulation can be manufactured from pure graphite or graphite fibres with a sealed reflective surface on the hot face of the insulation material.

Both oxygen and moisture can be detrimental to each of the above insulating materials, insomuch as oxygen contamination of a metallic heat shield will disturb the reflective surface of the insulating metal by oxidising the metal surface.

If graphite or fibrous graphitic material is used as an insulator or a heating element, and is left exposed to atmosphere, it will absorb moisture. The presence of moisture within the vacuum chamber will make it increasingly difficult to pump down to the appropriate pressure level, due to the evaporation of moisture. Moisture can be a technician's enemy in terms of vacuum operation, due to its ability to migrate anywhere within the vacuum process chamber. Once moisture is in the chamber, and in particular within the fibrous insulation materials, the moisture will 'stick' to the insulating fibres and will be difficult to remove on pump down.

Therefore, when a new vacuum furnace is shipped to its end-user, it is usually shipped with the door clamped down and the interior under vacuum conditions. Once the furnace is in position at the installation site, the vacuum will be broken, and the door opened. Once the installation is complete, the door is closed and the vacuum pump started to take the furnace down to its ultimate vacuum level. The temperature of the furnace is raised to its maximum operating temperature and allowed to hold at this temperature for a short period of time. After the outgassing period of time has expired, the furnace is allowed to cool down to ambient temperature. The vacuum pump is then turned off and the leak up rate of the process chamber is noted. The normal leak up rate of any type of commercial-scale vacuum furnace that is cold, clean and empty should be in the range of 0.7 Pa (5 mtorr) per hour maximum.

The act of pumping down the vessel and raising the furnace up to its maximum operating temperature is designed to ensure that not only the insulating material, but also all other materials of construction within the heating chamber, have completely outgassed. If the vessel then leaks up at a rate greater than 0.7 Pa (5 mtorr) per hour, it means that there is a potential leak within the process chamber. It is then necessary to begin to establish the nature of the problem.

There are two types of problems that produce the appearance of leaks, namely:

– Real leak (actual physical leak)
– Apparent leak (internal or virtual leak or outgassing)

REAL LEAK

A real leak is a leak through a hole in the furnace wall. This means that somewhere within the construction of the furnace vessel there is a passage which will allow air, or moisture to leak into the process chamber, thus steadily raising the furnace chamber vacuum pressure. The leak can be at any vacuum sealing point, such as the main door, power feedthroughs, the thermocouple feedthroughs, recirculation fan seal, or any other aperture into the furnace.

APPARENT LEAK

An apparent leak is a situation where there is a rate of rise in pressure, but after leak detection procedures are completed, no leak is visible, yet the pressure continues to rise. This is the most difficult type of vacuum problem to handle, simply because it has no external cause. The apparent leak up rate is being caused by something within the process chamber that is outgassing. This can be caused, of course, by a pin hole leak within a weldment on the inner wall of the chamber. This allows water from the water jacket to migrate into and vaporise in the process chamber. Another cause of this condition can be oxides on furnace support fixtures that are outgassing, or the components being processed outgassing. This last type of apparent 'leak' is the most difficult to locate. Poorly designed vacuum systems can include constrictions that make pump down of some regions difficult, thus producing the appearance of a leak (i.e. a virtual leak).

Assuming that the vacuum furnace is tight and that there are no apparent or real leaks in the furnace system, then the vacuum furnace should be kept closed and under partial vacuum when not in use.

40.2.6   Cooling

Once the work has been processed, it needs to be cooled. The cooling rate of the work piece will be determined by the desired metallurgy necessary to impart the required mechanical properties to the material. Cooling can be accomplished (see Chapter 29 for more detail) as follows:

Rapidly   (by a variety of quenching processes)

Slowly   The word 'slowly' in this instance, is relative. The work piece can be cooled down in still air or forced air (fan cooling). It can also be cooled down in air with a specially designed cooling chamber which would be surrounded by a water jacket. The work piece could be cooled down in a specially designed cooling chamber but insulated with a low mass ceramic fibre blanket. The work piece could further be cooled down by quenching into a liquid salt bath at a predetermined temperature. The physical act of cooling can be accomplished in either the batch type operation or a continuous operation.

40.3   Vacuum technology

40.3.1   Introduction

In recent years, the field of vacuum technology has expanded greatly in terms of volume production of equipment and in the diversity of equipment available. To a large extent, this has been driven by the semiconductor industry with its requirements for many large scale wafer fabs operating at high vacuum levels, although other industrial uses of vacuum have also burgeoned. These cover such diverse applications as coating window glass with reflective films, plasma processing of baby's disposable diapers, freeze drying, etc. Figure 40.1 shows some typical industrial processes using vacuum and the range of pressures over which they tend to operate. Despite this growth, the underlying technologies of pumping and measurement of vacuum have changed little. Such advances as there have been have tended to be better implementations of existing technologies.
Figure 40.1   *Some industrial processes using vacuum*

Table 40.1   UNITS OF PRESSURE

Unit	Common area of usage	Equivalent in mbar	Comment
Inches of water	Industry where a 'negative' pressure is required e.g. vacuum forming	2.49	Widely used, but definitely 'non-standard'
Torr	Very widely used in industry	0.752	Non-standard but refuses to die!
mbar	Widely used in laboratories and often in industry	1.0	An alternative unit in the SI system
Pascal	Largely confined to standards laboratories	0.01	The SI unit

Table 40.2   VACUUM RANGES WITH APPROPRIATE PRESSURE MEASUREMENT TECHNIQUES

Pressure region	Pressure range (mbar)	Pressure measurement technique
Low (rough) vacuum	$1\,000$–1	Direct acting gauges—e.g. Bourdon tube
Medium (fine) vacuum	1–10^{-4}	Gas bulk properties—e.g. Pirani gauge
High vacuum	10^{-4}–10^{-9}	Molecule 'counting'—e.g. Penning gauge
Ultra high vacuum (UHV)	$<10^{-9}$	Molecule 'counting'—e.g. Bayard Alpert gauge

In this section, a short review will be given which should enable the practicing technologist to understand some of the aspects to be considered when choosing appropriate vacuum technology for the job in hand. Space limitations force this review to be highly selective.

40.3.2   Pressure units and vacuum regions

Table 40.1 lists the most common units in which the pressure in a vacuum system is measured and their relationship. Table 40.2 lists a common set of terminology for different pressure regimes, although it should be noted that there is no universally agreed way of doing this.

40.3.3   Pressure measurement

There is no single way of measuring sub atmospheric pressure over the entire range. Broadly, the measurement techniques used fall into three categories: direct; those which use bulk properties of
Figure 40.2   *Operating ranges of some vacuum gauges*

a gas; and those which essentially 'count' gas molecules. Here we only discuss types of pressure measurement devices (i.e. gauges) which are widely available and are commonly used in industrial applications. More specialist gauges are described in the references to be found in the bibliography. Figure 40.2 shows the operating pressure ranges of some gauges.

40.3.3.1   *Direct measurement gauges*

These use the difference in forces exerted by the gas in the vacuum system at a given pressure and a reference pressure—usually atmosphere. In a sense, they are exactly analogous to gauges measuring pressures above atmosphere. Such gauges are insensitive to the gas species being measured.

Occasionally, one will still see a *water column* being used to measure 'negative' pressures of an inch or two of water. This is usually a simple U-tube with one side open to atmosphere and the other connected to the vacuum and the U-bend filled with water. The pressure difference is then the difference in height between the surfaces of the water in the two arms of the U.

More common is a *diaphragm gauge*, where the deflection under the differential force of a thin diaphragm or a capsule like an aneroid barometer is measured. Often a system of levers and gears causes a pointer to move over a dial to give an indication of the pressure. Modern gauges may use a strain gauge to measure the deflection and display it electrically. The *capacitance manometer* is a sophisticated implementation of such a device. An equivalent type of gauge uses a *Bourdon tube*—a thin metal or glass spiral which curls or uncurls as the pressure inside changes. Similar display techniques to diaphragm gauges are used.

40.3.3.2   *Gas bulk property gauges*

These gauges measure some physical property of the gas which is pressure dependent. The most common property used is heat conduction, although some specialist gauges measure viscosity changes (e.g. *spinning rotor gauges*). *Thermocouple gauges* measure the temperature of a filament which is heated by a constant electrical current. *Pirani gauges* measure the electrical resistance of a filament wire whose resistance varies with temperature. In each case as the pressure changes, heat conduction through the gas changes and so the temperature of the filament changes. Some forms of Pirani gauge keep the filament temperature (and hence resistance) constant by varying the current flowing through the wire.

Gauges of these types are clearly only useful when the property actually varies with pressure. Those relying on thermal conductivity are therefore limited to measuring pressures between about 1 mbar and 10^{-3} mbar. The upper range may be extended to above atmospheric pressures by taking convection into account.

There are two main drawbacks to bulk property gauges. In general, they are gas species sensitive—so the gas composition must be known if accurate pressure measurement is required. This is very important when safety issues need to be considered. Thermal conductivity gauges are also dependent on the state of the filament—surface contamination changes its thermal transfer properties. The hot filament itself may interact with the gas which may be explosive, or may 'crack' to leave e.g. carbon deposits on the filament.

40.3.3.3 *Molecular counting techniques*

Below about 10^{-3} mbar, physical properties of gases vary little with pressure, so the only readily accessible technique to measure pressure is to count gas molecules in some way. Such techniques of course do not actually measure the real physical pressure of the gas, but provide a measure of the number density of gas molecules. Calibration is therefore required to convert this to an equivalent pressure and the gauge sensitivity will be gas species dependent.

A simple way to count gas molecules is to ionise the gas and collect the resultant ions—this ion current is a good measure over many decades of pressure. Two ionisation techniques are commonly employed. *Cold cathode gauges* generate a plasma which is confined by electrical and magnetic fields and ions are extracted to a cathode plate of some sort. *Hot cathode gauges* use a beam of electrons extracted from a hot filament to directly ionise the gas. Classical implementations of these techniques are *Penning gauges* and *Bayard-Alpert gauges* respectively. Both are useful and relatively stable, although the sensitivity of each type of gauge is dependent on its history. It can vary somewhat unpredictably by factors of 50% or more in use. Both types of gauge are prone to contamination changing sensitivity, the Penning gauge being somewhat less so. However, this gauge is subject to random fluctuations in the plasma discharge conditions which change the sensitivity. The Penning gauge requires a strong magnetic field at the gauge head, which can be a problem in some applications and the gauge head generates some particulates. The Bayard-Alpert gauge has a hot filament with similar drawbacks to those noted above for thermal conductivity gauges. It is also susceptible to external magnetic fields which can change the indicated pressure dramatically. At low pressures, it can release a surprising quantity of gas from the walls of its housing.

Penning gauges are reliable down to about 10^{-8} mbar and Bayard-Alpert gauges to 10^{-11} mbar, in both cases the lower limit being dependent on detailed gauge design. A variant on the cold cathode gauge is the *Inverted Magnetron gauge* which is somewhat more stable in sensitivity and can work down to 10^{-11} mbar. It is also more expensive. All of these gauges can measure pressures up to 10^{-3} mbar.

40.3.3.4 *Control and measurement units*

All gauges which use indirect methods to indicate pressure—and indeed some direct measurement gauges also—require electronic control and measurement units to drive the gauge head, to measure currents, to display the pressure, etc. Nowadays, all of these can readily interface to computer systems to provide gauge control, plant interlocking and data logging for process control or monitoring.

A recent trend in control units is the development of so called compact gauges where the electronics to drive the head and to measure the appropriate analogue of pressure is contained in a miniaturised unit fixed directly to the gauge head. This unit usually requires only a dc electrical supply (often $+24$ V) and a computer connection (e.g. RS232 or Ethernet). This is an economical solution where many gauges have to be integrated into a process control system, or where long distances are involved. However, where vacuum systems operate at high temperatures or generate radiation, such close-coupled units may not be reliable.

40.3.3.5 *Can gauge readings be believed?*

All vacuum gauges in common use in industry require calibration. As discussed above, the indicated pressure often depends on the gas species being measured, so the effects of this must be understood. In some cases, such differences can be calculated from the kinetic theory of gases, etc., but more often gauges must be specifically calibrated for the gas species of interest.

Most of the vacuum gauges described above—certainly all the indirect gauges—exhibit variations in sensitivity dependent on their history—even a simple exposure to atmosphere during a system vent can change gauge sensitivity in an unpredictable way. Such variations may be of the order of a few percent, although in the worst cases much larger factors are not unknown. Thus, unless a gauge is calibrated in situ against a standard of some sort, then it is wise to treat pressure indications as a guide rather than a precise measurement.

When accurate and repeatable measurements are required, specially built gauges whose repeatability is much better are available at correspondingly increased cost. Manufacturers should be consulted for further information.

40.3.4   Pumping technologies

40.3.4.1   *Low and medium vacuum pumps*

The classic workhorse pump in this range is the oil sealed *rotary vane pump* often supplemented by a *Roots blower* to achieve lower pressures or higher gas throughput. Newer technologies in this area have sought to eliminate the problems of contamination of the work system with pump oil by using clean, 'oil free' techniques. In some processes, pumping of particulate contaminated gas streams is required—in others generation of particulates which can get back to the process must be minimised. In any pumping situation, care must be taken to ensure that the gases being pumped do not attack the pump structure or react adversely with oils and greases in the pump. A classic example is pumping oxygen-rich gases with a mineral oil sealed pump. This might well result in an explosion. Chemically inert pumps with passivated surfaces and using inert synthetic oils and greases are available. Pump manufacturers should always be consulted about appropriate pumps and fluids for particular situations. When pumping large quantities of water vapour or other condensable gases, pumps may need to be heated to prevent the gas condensing in the pump, possibly diluting the lubricant.

Table 40.3 summarises some of the more widely available low vacuum pumping techniques.

40.3.4.2   *Medium and high vacuum pumps*

At one time, the *diffusion pump* reigned supreme in this region. It still does when either very high pumping speeds or extreme economy is required. It can also handle particulate laden gas streams. For many applications, the diffusion pump has been largely superseded by the *turbomolecular pump*. Although initially more expensive to purchase, the turbomolecular pump is much cleaner, is more reliable, more suited to unattended running since it (and the process) can be protected against many failure modes. It requires less down time for servicing with modern pump bearings being lubricated for life and having lifetimes in excess of 15 000 hrs dependent on application. Versions where a molecular drag pump is combined on the same drive shaft as the turbine stage are available, so that backing pumps which are capable of reaching only a few mbar may be used, resulting in cost savings. Versions of turbomolecular pumps are available which use magnetic bearings and are therefore completely clean. Most modern lubricated pumps use only very small quantities of bearing lubricant, often in the form of a grease, so the possibility of contamination is much reduced. Indeed most contamination is likely to come from the backing pump unless a clean or dry pump is used.
Figure 40.3   *Operating ranges of some vacuum pumps*

Turbomolecular pumps can handle modest quantities of small particulates. They must be protected (by means of a simple mesh in the pump throat) against larger items falling into them. Particulate generation is low.

Modern synthetic diffusion pump oils are available which are much less prone to cracking when exposed to atmosphere and therefore down time to service the pumps can be reduced. These oils are relatively inert, so the pumps can be made to be chemically inert. The safety problems associated with having a hot boiler remain however and they are difficult to protect adequately.

Pumps in this pressure range do not exhaust directly to atmosphere and require a backing pump with a matched throughput.

40.3.4.3 *Ultra high vacuum pumps*

Pumps for this pressure range are more specialised. In addition to *turbomolecular pumps* where pressures below 10^{-9} mbar are reasonably easily achieved, most pumps in this range work by trapping gas molecules in some way. Further details on their operation can be found in the references of the bibliography, but Table 40.5 lists some pumps and their main characteristics. Rather than using backing pumps, gas trapping pumps rely on the system being pumped down to a reasonable pressure

Table 40.3   LOW VACUUM PUMPS

(Note $1\,m^3\,hr^{-1} = 0.59\,cu.\,ft\,min^{-1}$)

Pumping technology	Typical lowest pressure (mbar)	Typical throughputs available (m³ hr⁻¹)	Comments
Diaphragm pump	10	5	Clean. Pumping and generation of particulates can be a problem.
Piston pump	10^{-2}	50	Modern versions clean (oil free). Low particulate
Claw pump	10^{-2}	500	generation possible. Possible problems when pumping particulates. Can be chemically 'inert'.
Scroll pump	10^{-2}	35	Modern versions clean (oil free). Possible problems with pumping particulates and particulate generation.
Rotary vane (single stage)	10^{-3}	1 200	Oil sealed so difficult to remove backstreaming
Rotary vane (two stage)	10^{-4}	350	contamination. Can use inert synthetic oils.
Roots blower	10^{-5}	15 000	Can generate particulates. Can be reasonably clean with care. Only operates below about 100 mbar.

Table 40.4   MEDIUM–HIGH VACUUM PUMPS

Pumping technology	Typical pressure range (mbar)	Backing pump max pressure (mbar)	Typical throughput (pumping speed) available (1 sec⁻¹)	Comments
Diffusion pump	10^{-2}–10^{-8}	0.1	50 000	Can have very high throughputs. Can be chemically inert. Can handle particulates. Relatively cheap.
Turbomolecular pump	10^{-3}–10^{-9}	10^{-3}	2 000	Good throughput. Reliable. Low particulate generation. Can handle modest particulate load. Can be chemically inert.
Wide-range turbomolecular pump	10–10^{-10}	10	1 500	Throughput at high pressure restricted. More sensitive to particulates.
Magnetic bearing turbomolecular pump	10^{-3}–10^{-9}	10^{-3}	2 000	Inherently clean. Quite expensive.

Table 40.5   UHV PUMPS

Pumping technology	Starting pressure (mbar)	Ultimate pressure (mbar)	Typical max pumping speed available (1 sec^{-1})	Comment
Sputter ion pump	10^{-3}	10^{-10}	500	Pump lifetime depends on amount of gas pumped. The pump can be unstable against air leaks. Speed depends on gas species being pumped. Can generate particulates.
Evaporable getter pumps	10^{-5}	10^{-12}	Limited by area of evaporated film	Typical example uses titanium. Only pumps active gases. Can generate particulates.
Non evaporable getter pump	10^{-5}	10^{-14}	Limited by surface area of carrier	Requires high temperature (200–450°C) activation. Does not pump inert gases.
Cryogenic pump	10^{-4}	10^{-14}	Limited by area of cold surface	Requires provision of liquid cryogens (helium or nitrogen) or a refrigerator system.

(listed here as starting pressure) by an auxiliary pump. This is then usually valved off from the system being pumped. For UHV pumps, pumping speed is usually limited by the rate at which gas molecules arrive at the pump.

40.3.4.4   *Control units and power supplies*

Vacuum pumps in all pressure ranges can be provided with controllers or power supplies which may be interfaced directly to computer control systems for monitoring and control. As with gauges, there is a trend towards integrating these controllers with the pump body, attached to, or even inside, the pump housing.

40.3.5   Vacuum systems

The design of vacuum systems is of course a very wide topic, since a vacuum system will in general be tailored to meet the requirements of the job in hand. Nevertheless a few general points can be made.

Good engineering practice will be required in order to ensure that the system will be able to work satisfactorily. For example, deflections of walls when the system is evacuated may be important.

In most cases, the vacuum performance of a vacuum system will be defined in terms of the base pressure required and the time taken to pump down to that pressure. In designing a vacuum system to meet such requirements, the designer will have to take into account the gas load to be removed. This will consist of three main parts:

- the gas inside the system from its exposure to atmosphere
- the gas load generated from the things inside the system (evaporation from any liquids present, offgassing from work pieces, outgassing from walls, wires and any contamination present)
- the removal of gas flowing into the system from process gases or leaks (some of which may be internal leaks from trapped volumes).

Many of these will not be known to any great accuracy but reasonable estimates can be made by an experienced vacuum designer. Some can be eliminated or minimised by good design and careful operation. In general, it is easier to minimise gas load than to increase pump throughput or speed. For the low to high vacuum regions, there are computer packages commercially available from the major vacuum equipment manufacturers that can be used to calculate necessary pump sizes and pump down times so that an optimum economic result can be achieved.

As the required pressure becomes lower, design becomes more complicated and specialist techniques may be required to calculate system performance.

Design of systems to work in the UHV region is an involved subject, requiring much attention to detail and the advice of an experienced specialist designer should normally be sought. Most of the vacuum equipment manufacturers who supply equipment to work in this range will be able to provide this as a service.

Table 40.6   SOME IMPORTANT PARAMETERS FOR A RESIDUAL GAS ANALYZER

Parameter	What it means	Typical value	Comment
Mass range	Maximum and minimum masses which will pass through the filter	1–100 amu	Some process gases or oils may have higher masses
Resolution	How well species with masses close to each other can be separated	1 amu at 10% peak height (equivalent to 20% valley)	Most instruments are adjusted so that peak widths are the same across the mass range. This means that gauge sensitivity will vary across the mass range
Mass discrimination	The variation in transmission of the mass filter for different masses of ion	Rarely specified!	Important if quantitative or semi-quantitative analysis is required. Software packages should automatically compensate for this
Sensitivity	Usually specified as the minimum detectable partial pressure of nitrogen (often at a signal-noise ratio of 2)	Without electron multiplier detector: 10^{-9} mbar. With electron multiplier detector: 10^{-14} mbar	Sensitivity for different gas species depends not only on mass discrimination (above) but also on ionisation cross sections. Again, software packages should automatically compensate for this
Abundance sensitivity or tailing contribution	The smallest peak which can be detected as a 'bump' on the shoulder of a peak at an adjacent mass. Usually expressed as a percentage of the large peak	0.01%	In practice, only important for trace analysis or isotopic analysis. It will be different 'above' and 'below' the large peak—usually only the low mass side value (which will be worse than the high side value) is quoted

40.3.6   Residual gas analysis

It is probably fair to say that most processes which involve vacuum require one of two things—a simple sub atmospheric pressure so that something can be moved or removed (vacuum forming or freeze drying for instance) or the production of an inert atmosphere. The latter may be for something as simple as vacuum packing where removing the oxygen delays the onset of decay processes in food or as 'high tech' as controlling surface processes in a semiconductor fabrication facility.

There are many occasions when the vacuum system user will want to know what is left in the vacuum system—and the last example above may well be one such case. This is relatively easily achieved using a *residual gas analyzer*. These devices, the most common of which are based on a simple form of mass spectrometer known as a radio frequency quadrupole analyzer, are readily available at modest cost. Such systems comprise an ion source (usually a hot filament source akin to a Bayard-Alpert gauge), a mass filter and an ion detector.

Modern residual gas analyzers are computer driven by dedicated software packages and are simple and easy to operate. Results can be displayed in terms of a spectrum, a tabulated set of masses present, trends with time of selected masses and so on. Process control can be achieved and instruments can be set to generate alarms if gas compositions go outside preset limits. Unknown peaks in a spectrum can be compared to built-in libraries of 'fingerprint' spectra of many molecular species.

Important points to note in selecting and using such analysers include those shown in Table 40.6. In this table are listed some of the key parameters and their definition with typical values for a modestly priced class of instrument. Such an instrument will suffice for most routine vacuum applications and semi-quantitative analysis will be possible. A more highly specified (and more expensive) system will be required for accurate quantitative analysis and such a device will need frequent calibration. Modestly priced equipment can provide the trained user with a wealth of information about the 'health' of a vacuum system or a process.

One very important point to note in using residual gas analyzers is that there is usually a hot filament in the ion source of the instrument so that especially at low pressures the measured residual gas spectrum may differ considerably from the actual spectrum of gases present. Experienced users will be able to assess the effect of this on the results.

40.3.7   Safety

Safety is a major consideration in the design and operation of vacuum systems. An understanding of how the vacuum system is to be used is important in this. For example in the above discussion of vacuum pumps, some emphasis has been placed on the importance of understanding the possible chemical interaction between process gases and lubricants and working fluids in pumps. Failure to take this into account may result not simply in seizure of the pump but possibly in explosions. A turbomolecular pump contains a turbine rotating at high speed (perhaps 50 000 rpm) and pump seizure may result in a catastrophic disintegration of the pump housing. Objects falling into such pumps will result in blades being stripped from the shaft.

Great care must be taken to ensure that gases being exhausted from vacuum pumps are dealt with safely. If they are in any way hazardous, they must not be exhausted directly to atmosphere but must be passed into properly designed gas handling plant. Where a range of different gas species is being pumped, consideration must be given to the effects of mixing these in the exhaust system. When particulates are being pumped, exhaust plumes must use filtration to remove these. Systems for safely removing and disposing of contaminated pump oils must be put in place.

Ion pumps operate at high voltages (3–7 kV) so adequate shielding and safety precautions against disconnection of leads is required. They also contain powerful magnets.

Cold cathode gauges operate at about 3 kV and hot cathode gauges get hot! Where hot filaments are present, there is the possibility of explosion when pumping flammable gases if pressures get too high. As has been mentioned, many types of gauge give pressure readings which are dependent on the gas species being measured, so when used as safety indicators must be calibrated for the appropriate gas.

Clearly, any vacuum vessel must be designed to withstand an external differential pressure of 1 bar without collapsing. However, it should also be capable of withstanding small internal overpressures if it is backfilled with piped or bottled gas before, for example, opening to atmosphere. Fragile components like viewing windows and feedthroughs should be protected against breakage.

Careful design will result in a vacuum system which meets its specifications and is safe to use.

40.3.8   Selective bibliography

The best source of information on vacuum pumps and gauges is to be obtained from the manufacturers of such equipment. A useful source of information on manufacturers is the Buyers' Guide on the AVS website http://www.avs.org

A reasonably extensive Bibliography on Vacuum is located on the website of the International Union of Vacuum Science, Technique and its Applications (IUVSTA) at http://www.iuvsta.org/vsd/biblio.htm

Some general references on vacuum are:

40.4   Metallurgical process control

40.4.1   Metals production and processing

Metals are produced through a long chain of processes. For primary resources, metals production goes through mining, mineral processing, ore smelting (oxidation or reduction) in high temperature
Figure 40.4 *Achieving sustainability*

furnaces or via low temperature hydrometallurgical processes, or a combination of both pyro- and hydrometallurgical operations. Taking ironmaking and steelmaking as an example, it normally follows a number of consecutive operations from blast furnace ironmaking, BOF or EAF steelmaking, steel refining e.g. in a ladle furnace, steel casting, to cold or hot rolling. For the secondary resources, metals are separated and recovered from metal scrap, which play an increasingly important role in the metal supply of the world. After being produced, either from primary or secondary resources, metals have to be further refined or manufactured into various types of alloys and finally shaped into different products suited to the end-users. Since the end-user will discard products eventually at the end of products' life the contained materials find their way back into the resource cycle as scraps. Therefore, controlling the metallurgical reactors also controls in an even much broader sense, the material quality in the complete metals cycle, from the production phase, to the end-use phase, up to the recycling phase. The recycling phase includes separation of materials into saleable intermediate products, which are reintroduced into the production phase as a secondary resource. Therefore, the metallurgical processes in each unit operation in the metals production and processing chain have to be controlled, so as to achieve optimal performance of high product quality, low energy and materials consumption, and low environmental impact. Symbolically these interactions are best illustrated by Figure 40.4, depicting the links between three interconnected cycles: the life cycle—the technology cycle—the resource cycle. The optimal control of all these cycles is affected substantially by good control of metal production and refining.

40.4.2   Modelling and control of metallurgical processes[2,31,32,34,35]

In view of the above, the discussion focuses on various industrial supervisory control, optimisation and modelling examples in which the goal was to recognise the above-mentioned philosophy. This is done by discussing (i) low level control, (ii) supervisory control and optimisation of metallurgical furnaces, (iii) modelling and simulation techniques ranging from 'black box' to 'grey box', and (iv) logistic control of metal flows between furnaces and processes. The objective of these control actions are very clear, i.e. they (i) optimise product quality, (ii) minimise energy consumption, (iii) minimise environmental impact, and (iv) optimise metal flows, or in other words optimise energy flows in a plant and between plants. Therefore, control should not only maximise economic benefits, but at the same time also minimise associated ecological effects.

Implicitly it should also become evident that metallurgical control and optimisation is the reason why modelling and simulation is done. All the related experimental work in the laboratory and on the plant is performed to parameterise these metallurgical models. In other words it can be argued that control is the umbrella for performing all the tasks depicted by Figure 40.5. This document will cover a number of the aspects depicted in Figure 40.5, i.e. the importance of good process data will be mentioned and a short overview to various modelling and simulation techniques, ranging from 'black box' or empirical to 'grey box' (some call them 'white box') semi-empirical approaches will be given. These will all be discussed very briefly in the context of various industrial process control examples.

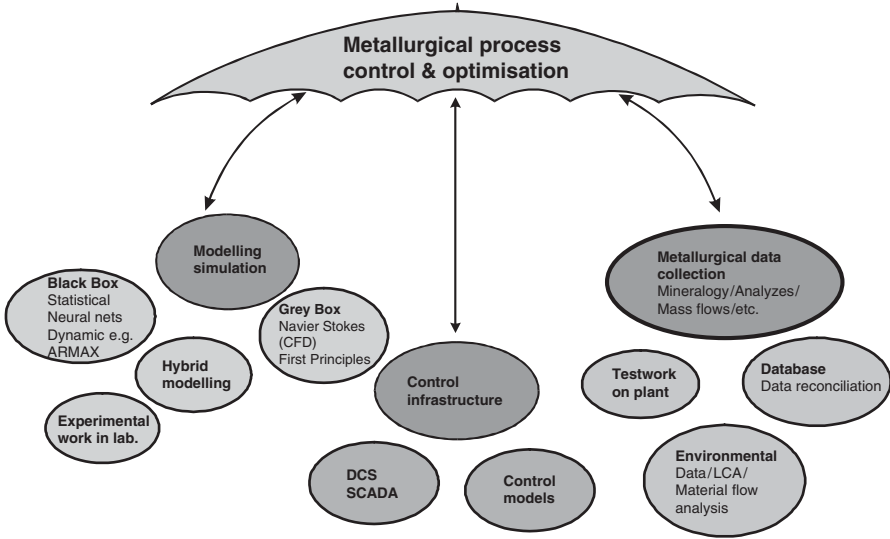
The various techniques discussed in this section will be placed in the context of modelling and controlling poorly defined industrial metallurgical reactor systems. Due to often poorly definable


Figure 40.5 *Umbrella of process control*
Figure 40.6 *Loci of fictitious data points for a furnace positioned above their respective equilibrium data (the attractor) to illustrate the effect of process dynamics, kinetics, etc.*

parameters, that include (a) the effects of changing mineralogy and distributed parameters such as density, viscosity (as a function of conditions and spatial position within the furnace), (b) the effects of different reductant types and their respective reactivities, ash contents, etc., (c) heterogeneous distributed conditions within the furnace such as temperature, that creates a distribution of properties of the system making pure thermodynamic models difficult to apply, and (d) synergetic effects created by the feed mix, it is often very difficult to create sufficiently accurate and practically useful predictive first principles metallurgical models. Furthermore, since furnaces are often not at equilibrium, the idea of a metallurgical equilibrium attractor is discussed, which is basically the equilibrium a furnace at any point in time would like to reach but finds difficult due to production constraints and process dynamics. Therefore a good process model should not only include the thermodynamic basis but also try to quantify the effects of process dynamics. Figure 40.6 suggests that in a real furnace the measured
Figure 40.7   *Change of concentration in two different lumps of ore following different paths through the furnace adjacent the mean conversion $\overline{C}$ as an integral of all trajectories*

process data points mostly lie above (or below) the equilibrium, i.e. for instance the analysis of a metal oxide in the slag would lie above the equilibrium value predicted for the same slag conditions and temperature as measured during the tap. This difference is created due to heterogeneities in the furnace created by a distribution of temperatures, mineral properties, reaction paths, and histories of each lump of ore and reductant in the reactor. In other words, the difference could also be an indication of how well the furnace is being operated. It is obvious that the fewer heterogeneities are present, such as in a well-mixed steel converter, this difference becomes much smaller. This applies also to casting and reheating operations that can be quantified and modelled in a very much more precise way than a multi-phase system such as a metallurgical furnace. In order to further explain Figure 40.6, Figure 40.7 is given which depicts the remaining concentration of an unreacted species of two different lumps of ore with different mineralogies following two different paths in the furnace, which have seen different temperatures, conditions, reductants, etc. In short, each trajectory is a fingerprint of the history of the particle. In order to establish the mean conversion it is necessary to integrate over all paths and conditions to obtain a true understanding of what is happening in the furnace.

Incorporating the distribution of all histories for all particles is defined best by the equation below. This equation defines the average concentration (average curve in Figure 40.7) as a function of the residence time distribution E, the temperature distribution ψ, reaction rate distribution χ, time t, and spatial coordinates Ω, as well as production constraints that dictate when to tap. In the equation, k is reaction rate, and T is temperature.

$$\overline{C} = C_0 \cdot \int\limits_{0}^{t_1=\text{tap time}} \int\limits_{k_1}^{k_2} \int\limits_{T_1}^{T_2} \int\limits_{\Omega} E(t) \cdot \psi(\Omega, T, t) \cdot \chi(k, T, {}_{,\text{Mineralogy}}) \cdot C(k, T, t) \cdot \mathrm{d}\Omega \cdot \mathrm{d}T \cdot \mathrm{d}k \cdot \mathrm{d}t$$

Figures 40.6 and 40.7 suggest that it is important to consider the following steps when modelling industrial metallurgical systems: (a) Assimilate reconciled plausible data for the reactor system in a real-time database and control software (see below). (b) Ensure that a reconciled mass balance produces a statistical useful mass balance from these data, from which also statistically significant recoveries, energy balances and statistically consistent analyzes are estimated. (c) For these data thermodynamic equilibrium models can be calibrated from which the equilibrium attractor of the process can be estimated (if this is at all possible). (d) The difference between the attractor and the measured (reconciled) analyzes may then be applied to estimate how far the process is from equilibrium. This difference is mostly a function of process dynamics, which also includes kinetic effects, or of mineralogy and other factors such as metal entrainment rendering the system inhomogeneous. (e) The difference between equilibrium and dynamic data should then be interpreted and investigated to obtain a true picture of what happens in the furnace. (f) Useful methods such as first principles

CFD (computational fluid-dynamics) models can be applied to estimate distribution relationships (equation above), incorporating kinetics and black box methods to further improve the understanding of the system (if this is possible).

It would be clear from the above that this suggested approach does not permit the forcing of dynamic process data into thermodynamic and/or kinetic metallurgical models at all costs by fitting with parameters. More often than not these parameters are distributed and are therefore not really suitable for inclusion in classical kinetic and thermodynamic modelling approaches. This classical modelling approach (*also followed without often passing through a data reconciliation step*) usually leads to erroneous results due to not incorporating process dynamics, leading to models that often have little or no practical value and do not lead to true furnace optimisation and control. Rather consideration of the distributed nature of the system is required, and methods should be applied to extract useful information from the data. Conversely, if the simulation becomes very difficult due to poor parameterisation, empirical methods should complement semi-empirical models to ensure good predictive control in hybrid architecture.

Although much of the discussion focuses on furnace control, the discussion is completed by providing examples on casting, reheating and milling operations, and by providing a general overview of the components of control systems.

40.4.3   Process control techniques[32,35]

Process control plays a critical role in metals production and treatment. Metallurgical processes, both in batch and in continuous operations, normally exhibit time delays with large time constants, uncertainties, non-linearities, unmodelled dynamics, etc. Taking this into account, different control techniques have been developed since 1960's. In the early days, the process control was based on mechanical, electrical or pneumatic analogue controllers. Later on, the broad use of digital computers came to the process control thanks to the rapid development of control theory, from single-input single-output linear system to a wide range of multivariable non-linear systems. Nowadays, the extensive application of expert systems, neural networks, fuzzy control, process monitoring and on-line diagnostics has become important parts of a modern process control system in metallurgical processes.

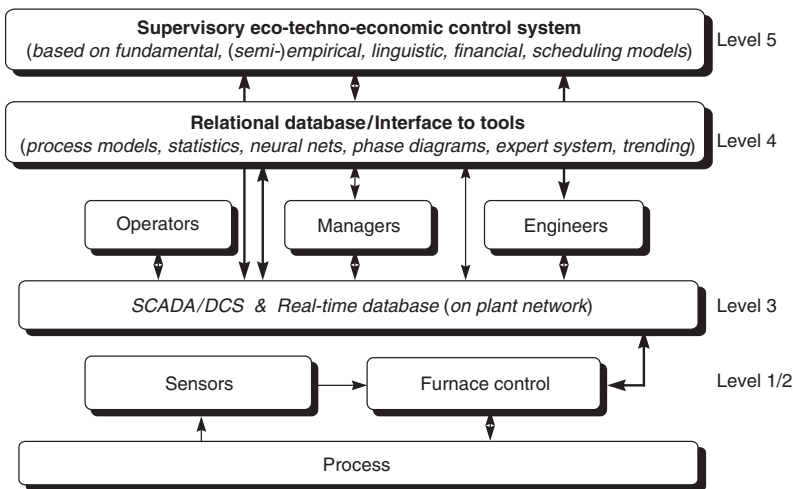
Figure 40.8 illustrates a general control structure for a typical metallurgical process,[35] which indicates different levels of a modern control system and the importance of database central to the whole system. For the benefit of the discussion below 5 levels are defined, however, various levels have been defined in the past by various vendors and providers. The figure explains the significance of each level. From Figure 40.8, discussed with reference to a submerged arc furnace for ferroalloy production, various levels can be discerned, each containing a mixed bag of the methodologies discussed above.[32] This section will dwell on the process control structure and will specifically


Figure 40.8   *Control structure for a metallurgical furnace*[35]

attempt to explain the structure and function of the database, which is central to the industrially implemented system.

Levels 1 & 2: Mintek's patented low-level control system (Minstral[TM]) for submerged-arc furnaces[31] has an international proven track record, having been implemented in various plants all over the world. This control system, packaged in different forms, i.e. from a stand-alone unit to a Windows based network version, has various proven features (a) control based on a proven resistance based algorithm, which de-couples the movement of electrodes, (b) optimisation of power input into the furnace as a function of MVA, resistance, MW and current set-points as well as a function of various dead bands and feedback loop settings, (c) differential tapping of transformers, (d) balancing of the electric circuit and hence minimisation of the asymmetry of the electric circuit, (e) the TCP/IP Windows based network version of the Minstral[TM] which permits plant wide maximum demand control, and (f) control of electrode baking. Level 3: The SCADA system creates the man-machine-interface (MMI) between the control system, the user and subsequently between all higher-level control and modelling applications. The networked SCADA system (Table 40.8) provides all the standard features of such state-of-the-art packages e.g. graphical interfaces, data logging, historical trending, and SQL-features, intelligent multiple symptom alarming e.g. through the command language, statistical process control (SPC), on-line documentation, checking of trends and setting of corresponding alarms, checking instrument readings for failure and setting alarms, and monitoring furnace pressures, temperatures, etc. and setting of alarms. In addition to the basic SCADA software customised for an application, various modular Windows utilities could also be accessed from the user-SCADA's user-interfaces. These model-based utilities provide the user with simulation tools with which various furnace modes of operation can be simulated hence providing very useful operator guidance. Level 4: A good database (for Mintek's Furnstar[TM] system[31]—MS Access® front end to SQL Server®) residing on the server of a network is the nucleus of a supervisory control system. It links databases containing data originating from different sources such as real-time data from a SCADA, production, planning and human resources data from e.g. SAP® , etc. It accommodates all furnaces in a plant and collates data in a metallurgically meaningful way in a metallurgically useful database. This structure ensures that all data can be considered simultaneously during decision making, be it by management, metallurgist, operator, fundamental process models, the control system or even an expert system. Since the furnace, its feeds and products, are only poorly defined, rather accurate process data sets are required in order to be able to calibrate (semi-)empirical models, create statistical models, or provide inputs to expert systems, etc. It can, therefore, be stated that: the more poorly a system is defined, the more heavily the (feed-forward) control system should make use of a well-structured and metallurgically useful database. Level 5: As is clear from Figure 40.8 various types of on-line models can be developed for this level, which could include fundamental models, expert systems, neural nets, process scheduling, ecological simulation and plant wide optimisation models. Level 6: Although not indicated, man (still) plays a critical part in supervisory control systems in extractive metallurgy. For submerged-arc furnaces man's involvement is still large. What this in fact also implies is that, if everyone on a plant does not buy into the control philosophy of a plant, it can be stated that optimal results will only be achieved with difficulty. Man is often still really the learning machine on an extractive metallurgical plant!

In Table 40.7 standard control techniques are summarised and listed for various operations of metals processing. For extensive applications in different minerals and metals processing industries, please read the paper by Jämsä-Jounela.[5]

40.4.4   Instrumentation for process control[1–6]

Instrumentation is an area that is currently under rapid changes as field communications move from analogue (4–20 mA) one-way to digital two-way protocols (e.g. PROFIBUS, Ethernet). Any control theory and technique have to be implemented to a process through hardware and lower level control software systems on a network. Therefore, one needs measurement devices e.g. sensors or transmitters, controllers, controlling devices, actuators and lower level control software on a plant. This constitutes levels 1 to 3 in Figure 40.8.

Control software: Control software is very important for any process control system, and it is closely associated with the controllers and the control techniques. Any good control technique needs control software to realise its functions. Along with the rapid development of control techniques, various control software have been developed and applied in different unit operations of metallurgical industry. Table 40.8 lists a few examples of commonly used modern control software.

Network: Ethernet Industrial Protocol (Ethernet/IP) is an open industrial networking standard that supports implicit messaging (real-time I/O messaging), explicit messaging (message exchange), or

Table 40.7   STANDARD CONTROL TECHNIQUES USED FOR METALS PRODUCTION AND PROCESSING[5]

Control technique	Application examples
Classical methods	
P, PI, PID control	Submerged-arc furnace (e.g. FeMn, FeCr, SiMn, SiCr, FeSi, Si), rotary kiln, hot and cold rolling mills
Feed forward control	Submerged-arc furnace
Model-based control and model predictive control	Thermal treatment, reheat furnace, extrusion, ferrosilicon production, hot and cold rolling
Multivariable control	Hot rolling mill, Al production cell,
Adaptive control	Al production cell, BOF, ingot/slab/continuous casting, reheat furnace, cold rolling
Artificial intelligence (AI) control	
Expert system	Blast furnace, BOF, hot/cold rolling
Fuzzy logic	Sintering machine, BOF, Zn roaster, continuous casting
Neural networks	Reheat furnace, EAF, BOF, ladle furnace, continuous casting, hot rolling
Genetic algorithms	
Diagnostics and monitoring	
Fault diagnostics and process monitoring	Zn hydrometallurgy plant, Outokumpu flash smelting, blast furnace, ferroalloy furnace, steelmaking, continuous casting, hot rolling
Quality monitoring	Steel surface inspection, continuous casting, hot rolling
Modelling techniques	
Thermodynamic (ChemSage, Metsim)	Equilibrium calculations for metallurgical reactors
Dynamic modelling	Various ARMAX type models to quantify the dynamics of metallurgical reactors
Statistical: Data reconciliation Neural networks Principal component analysis	Blast furnaces, converters, arc-furnaces, Sn/Cu/Zn smelters
CFD	Casting, modelling of flow in various metallurgical furnaces, off-gas systems, rotary kilns, waste incinerator

both and uses commercial off-the-shelf Ethernet communication chips and physical media. Because Ethernet technology has been used since the mid 1970s and is widely accepted throughout the world, Ethernet products serve a large community of vendors. Ethernet/IP emerged due to the high demand for using the Ethernet network for control applications. Ethernet/IP is an open network because it uses (a) IEEE 802.3 Physical and Data Link standard, (b) Ethernet TCP/IP protocol suite (Transmission Control Protocol/Internet Protocol), the Ethernet industry standard, and (c) Control and Information Protocol (CIP), the protocol that provides real-time I/O messaging and information/peer-to-peer messaging. ControlNet and DeviceNet networks also use CIP. TCP/IP is the transport and network layer protocol of the Internet and is commonly linked with Ethernet installations and the business world. TCP/IP provides a set of services that any two devices can use to share data. Because Ethernet technology and standard protocol suites such as TCP/IP have been published for public use, standardised software tools and physical media have been mass-produced and are readily available offering two benefits, established technology and accessibility. The UDP/IP (User Datagram Protocol) is also used in conjunction with the Ethernet network. UDP/IP provides the fast, efficient data transport necessary for real-time data exchange. To make Ethernet/IP successful, CIP has been added on top of TCP/UDP/IP to provide a common application layer.

Actuators: An actuator is the final driving element in a control loop, which are usually control valves, variable speed drives (pumps, etc.), and other control switches.

Sensors: Process variables in metallurgical processes are normally physical variables such as temperature, pressure, and differential pressure and flow rate. These variables are easy to measure with conventional sensors and transducers for control and monitoring purposes. For instance, thermocouples are widely used in temperature measurement and control of metallurgical processes. However, to control the chemical composition of intermediate or final products, on-line chemical analysis is also highly demanded. In reality, it is very difficult to measure directly on-line, though many on-line analyzers are used in chemical processes. Quick off-line measurements are normally taken to control the product quality, and in this case, a certain delay of the process control may happen, for instance tapping time for liquid steel in a BOF converter (2–5 minutes to sample and analyze by

Table 40.8   COMMONLY USED LOWER LEVEL (1 TO 3) CONTROL SOFTWARE FOR METALS PRODUCTION AND PROCESSING

Name of software	Functionality
PI system (OSI software) (www.osisoft.com)	PI is a universal production data acquisition system with an integrated analysis system. The data from various systems of your production plant (PCS, PLC, laboratory data, manual inputs) is stored in a long-term archive on a data server and can be visualised and evaluated on a PC within the Windows environment. In other words, a set of server and client based software programs, designed to fully automate the collection, storage and presentation of plant information, also permitting real-time data reconciliation.
G2 (Gensym) (www.gensym.com)	A graphical, object-oriented, customisable software platform for rapidly building expert manufacturing applications. G2 applications model and simulate operations, intelligently monitor and control processes and diagnose faults.
Emerson process management (www.emersonprocess.com)	Process management software.
FIX DMACS^{TM} iFIX (www.intellution.com)	SCADA (Supervisory Control and Data Acquisition) software, iFIX, the HMI/SCADA component of the Intellution Dynamics family of automationsoftware, is a Windows NT-based industrial automation solution for monitoring and controlling manufacturing operations.
Fisher-Rosemount systems (www.emersonprocess.com)	Part of Emerson Process Management. Provides software for process management; Process control, automation, and optimisation; Asset management, monitoring, maintenance, and optimisation.
Honeywell (www.honeywell.com)	Provides advanced software applications for home/building control and industrial optimisation; sensors, switches, controls systems and instruments for measuring pressure, air flow, temperature, electrical current and more.
InTouch^{TM} and FactorySuite (www.wonderware.com)	InTouch, a HMI, provides a single integrated view of all the control and information resources. InTouch enables engineers, supervisors, managers and operators to view and interact with the workings of an entire operation through graphical representations of their production processes. FactorySuite is an integrated suite of industrial automation software.
iBaan for metals (www.baan.com)	Business software for the metals industry e.g. management of inventory to optimise supply and value chain.
ABB Industrial^{IT} Solutions for Metals (www.abb.com)	ABB Industrial IT integrates diverse automation and information technologies in real time to provide better business decision support, standardisation of global processes.
Minstral^{TM} (www.mintek.ac.za)	Mintek's Submerged Arc Furnace Controller, an integrated electrode and tap-changer control system.
CSense^{TM} Crusader Systems (www.crusader.co.za)	CSense^{TM}, interfaces with SCADAs, DCSs and historians, for diagnosis of process deviations: Real-time analyzes of deviations, Alarming and messaging in HMI environment, Automatic reporting. Real-time soft sensor with a variety of artificial intelligence tools such as neural nets, fuzzy as well as classical statistics.
MDC Technology (www.mdctech.com)	MDC Technology is a major specialist provider of Production Optimisation and Performance Monitoring software solutions to the oil & gas, hydrocarbon processing, chemicals and power/utility industries. Part of Emerson Process Management.

automated robot driven XRF/XRD equipment). For some variables, which are difficult to measure, 'soft sensors' can be applied, as discussed by Reuter and Grund.[33] These use directly measurable variables to infer non-measurable data by the use of appropriate mathematical methods. The Optical Production Control (OPC) system developed by Semtech has been used for on-line production control in ferrous and non-ferrous metallurgical industry[38] e.g. copper converting and steelmaking to determine the process end point. The technology is based on the spontaneous measurement of vapour phase from molten melts by spectrometer. In addition, solid electrolytes as sensors have been used for measuring oxygen content in the molten melt of steel and copper.[37] Non-visible refractory wear and melt penetration of metallurgical furnaces has long been a difficult problem, which cause major plant damages and process shut-downs.[39] In many cases the real lining profile could only be seen when the furnace is shutdown. However, some on-line wear detecting systems are available

such as SAVEWAY described by Hopf.[39] The technique has been widely used in induction furnaces for copper or copper–nickel alloys, and ISP furnaces for zinc and lead extraction.

Controllers: A controller is the heart of a control system, where different control techniques are implemented. The simplest one is the PID controller. Conventional controllers have the advantages in small control systems. For a large-scale plant-wide control system, Distribute Control System (DCS) and a centralised operating and processing centre as well as plant-wide networking are commonly used. Fieldbus is a new generation control system: field distributed control system (FDCS), with an all-digital, high performance, multi-drop communications protocol. With bi-directional communication capabilities, the field engineers will be able to access field devices, furthermore the field devices themselves will be able to accomplish tasks as broadcasting messages over the process network and feeding other controllers with ongoing information regarding process status. These programmable logic controllers (PLC) therefore form the basis of control systems, and various types are available on the market ranging from Allen-Bradley (www.ab.com), Siemens (www.siemens.com), Bailey ABB (www.ab.com), Modicon (Schneider) (www.modicon.com), and Honeywell (www.honeywell.com), to name a few.

40.4.5   Process control examples in metals production

Various process control examples in the metals production industry have been reviewed by Jämsä-Jounela[5] from resources of IFAC MMM events. In the following paragraphs, an effort is made to include information from various sources. However, the aim is not to give a complete review of the control applications in these areas, rather to use these wide application areas to show the latest control techniques and instrumentation.

Blast furnace ironmaking:[7–11]   Blast furnace (BF) is the dominating ironmaking reactor to provide hot metal for steelmaking. As Jämsä-Jounela[5] indicated, AI methods (expert system, fuzzy control, neural networks) are applied extensively to BFs for process monitoring and fault diagnostics. Expert systems for BFs are advisory systems to support the operation of the furnace. The system monitors the heat level of the furnace, the position and shape of the cohesive zone, and forecasts abnormal conditions such as slipping, channelling, sliding and scaffolding. Warren and Harvey[11] from CORUS gave a comprehensive description on the development and implementation of a generic blast furnace expert system. G2 (Table 40.8) was selected for the BF control system, comprising data acquisition software, a comprehensive relational database, a G2 database bridge, and an expert system developed with G2. Some of the key control features include: injecting flow rate, liquid level via EMF measurement, cooling water leakage monitoring, trend analysis on hearth thermocouple readings for temperature to monitor the protective skull on the carbon blocks. Brunnbauer *et al*.[8] presented a 3rd generation close-loop expert system for a fully automatic blast furnace. Kramer and Parker described the implementation of ironmaking (level 2) supervisory control system for Dofassco's blast furnace.

Oxygen steelmaking and continuous casting:[12–18]   About 60% of the crude steel is made with BOF or LD converters, where steel scraps are melted and mixed with liquid iron from blast furnace (the hot metal). An oxygen lance is used to oxidise the impurities in the melt such as carbon, silicon, phosphorus, sulphur, etc. before further refining and casting. The blowing process takes about 15–20 minutes. Most important control parameters in BOF converter are blowing control, endpoint control of temperature and chemical composition, and exhaust gas pressure control. The converter is controlled by an operator through judgment of the state of the process based on a number of measurements such as (1) a sound level measurement with a sonicmeter to get information on the thickness of the foaming slag; (2) off-gas analysis for the information on the decarburisation rate. The operator will stop the blowing process, when the carbon content reaches the preset value based on the online or semi-online (2–3 minutes or so) measurement. Commercial systems for online estimation of metal analysis, e.g. MEFCON from MEFOS are available on the market. New development is made for carbon content control by Johansen *et al*.[13] to apply nonlinear feedback to a nonlinear process model so as to create a nonlinear observer. Superior results are obtained with real data from SSAB Oxelösund AB. Yoshida *et al*.[18] described a hybrid expert system of empirical knowledge of operators combined with a mathematical model for blowing control at Nippon Steel Corporation. The control system consists of two subsystems: (1) static control model using rule-based reasoning, based on the information available before the start of blowing, (2) dynamic control model using fuzzy reasoning, based on process signals for the state of refining during blowing. Kohl *et al*.[15] presented their development of a scheduling expert system VASE (Voest Alpine Scheduling Expert) for a LD steelmaking plant. A combined approach of expert system technology, conventional programming, and database management proved to be an adequate solution. During the blowing operation, foam level control is important. Sound signals, provided by sonic meter or microphones, are sometimes

used as control signals for static control (not for dynamic control). The sonic meter signal is estimated from off-gas flow rate and CO content in the gas. There the deviation of estimated signal from the measured signal is used to detect sloping, combining sonic meter and gas analysis[12]. Kobayashi *et al.*[14] discussed the control of slag slopping or excessive slag foaming by using a microwave gauge. Using the established prediction criterion, the sloping is predicted 30 seconds before the event with a reliability of over 80%. Then the oxygen flow rate, lance position and sub-materials addition are used for preventing the sloping. The frequency of the sloping has been reduced by four times. It has been used online at the Wakayama Works of Sumitomo Metal Industries. Various control algorithms have been developed for continuous casting, as for example by Siemens (www.siemens.com).

Electric arc furnace (EAF) steelmaking:[1]   Electric arc furnaces (both AC arc and DC arc furnaces) are used to produce about 40% of the world total crude steel. Instead of using hot metal from blast furnaces, EAF steelmaking uses almost 100% steel scrap as raw materials. The operation of modern high-powered arc furnaces is characterised by the conflict between a high power input and the limit of the thermal load of the water-cooled wall panels, as reported by Ameling from VDEh[1]. VDEh-BFI has developed a model-based on-line control system for the appropriate distribution of the power among the arcs of AC furnaces. The system was installed at a 150-t arc furnace with 150 MVA power and worked reliably with about 10% reduction in gunning materials consumption and about 8% increased productivity. There are various examples of artificial neural networks that have been applied to model arc furnaces to stabilise the power supply e.g. the Expert Furnace System Optimisation Process (EFSOP) (*www.stantec.com/efsop*), Siemens (*www.siemens.com*) and Hatch (*www.hatch.com*) to name a few.

Steel reheat furnace and rolling mill:[19–22]   Before a hot rolling operation, the steel slabs or billets have to be kept at a proper temperature so that rolling operation could be feasible. A large body of information is available on the process control of the reheating furnaces. Ameling[1] gives a comprehensive presentation about on-line control of rolling mill furnaces. Norberg[19] described practical control systems for the reheating and annealing process. The reheating furnace control systems have evolved from early control method of slab surface temperature control by adjusting fuel and air manually and then by computer based temperature measurements. Subsequently feedback and feed-forward control techniques as well as model-based technique were applied, in combination with radiation pyrometers. Presently model aided furnace control systems for reheating furnaces are state of the art especially in rolling mills[1], applied to minimisation of energy consumption, optimisation of throughput, improvement of temperature uniformity, heating and product quality, and reduction of environmental pollution. Shulkosky *et al.*[20] introduced a reheat furnace supervisory control system THERMOD for pusher, walking beam and rotary hearth furnaces. The THERMOD uses a matrix of set point and target temperature values prepared through off-line modelling and stored on hard disk for on-line retrieval keypad to scheduling information. An on-line model determines product temperature throughout the furnace and provides for priority heating of the product with the most stringent heating requirements. Indirect and direct biasing provides two stages of on-line correction to the off-line prepared set points. When stabilisation is present, THERMOD artificial intelligence modifies the set points to remove the bias for subsequent processing. Valentine *et al.*[22] described the optimisation of reheat furnace control level I and level II systems (their definition). The level I control system uses Micron P-100 single loop controllers set up in the 2-loop format. The controllers are configured to do PID control of the zone temperatures, air and gas flows using standard cross-limiting techniques, and ancillary loops such as combustion air, dilution air, and furnace pressure control. The single loop controllers also act as a conduit to pass the profile thermocouple temperature information on to the Level II supervisory computer. In the automatic mode, the zone temperature control is done via operator entered set points or the Level II supervisory computer download of set points. The control system also uses a Micon MCD-200 CRT base console for the convenient control of all the single loop controllers. The level II supervisory control system automatically regulates each furnace control zone to heat the billets to a desired temperature while minimising fuel consumption. The supervisory control software resides on a MicroVax 2000 computer and has communication links with two computers and a field device interface. A data link to the plant-tracking computer provides information on the identity and desired heating strategy for individual heats. The link to the level I system enables access of real time process variable information and downloading of set points for furnace control. The field device interface link provides the supervisory system with real time tracking signals. Siemens has also developed and implemented on various sites in the world intelligent controllers for rolling mills with the goal of obtaining closer tolerances, higher productivity, and longer service life (www.siemens.com).

Takahashi[21] gave an excellent review on the state of the art in hot rolling process control. As Takahashi summarised, since the 1960s the computer control systems have been installed in

hot strip mills. Nowadays the areas cover reheating furnace combustion control, roughing mill setup, finishing mill setup, dimensional control of thickness, width and profile, control of finishing mill and coiling temperature. Various kinds of sensors are installed and numerous data are gathered through the plant-wide network. However, increasingly severe demands for dimensional accuracy, mechanical and surface properties require further development of advanced control. The imaging processing technology combined with charge coupled device (CCD) has been applied to in-line sensors for functions such as flatness measurement by projected-fringe-method and surface defect inspection. The interstand sensors are used to improve the dimensional accuracy, such as an interstand thickness meter and width meter, and an interstand strip velocity meter. The modern high performance actuators are increasingly used such as a hydraulic roll gap control device and a hydraulic looper; AC drive of high response and reliability; profile and shape control apparatus such as pair cross, roll shifting, variable crown roll; slab sizing press; coil box or induction heater to maintain homogeneous temperature of roughed transfer bar. The rolling process at the finishing mill is a multivariable system of the rolling force, strip gauge, interstand strip tension and lopper angle. The conventional automatic gauge control (AGC) system is single-input and single-output controller. More advanced control techniques applied include least quadratic (LQ) multivariable control, H-infinity control, inverse least quadratic (ILQ) control, adaptive control, sliding mode control, observer-based multivariable control, internal model control (IMC), and the predictive feed-forward control. In the area of temperature control, the model-based feed-forward control method is used to the finisher delivery temperature and coil temperature control. In addition, rolling schedule design is very important and becomes the multi-criteria optimising problem, and the dynamic programming or the genetic algorithm has been used to solve this problem.

Aluminium reduction cell:[23–25]   In order to produce aluminium metal, aluminium oxide (alumina) is first prepared through Bayer process, and then the pure aluminium is produced in an electrolytic cell in a molten salt at high temperatures. The reduction cell is a very complicated reactor, which involves complex electromagnetic flows, and electrolytic chemical reactions. McFadden *et al.*[25] gave a good review on the advanced process control for the aluminium reduction cell. Control of the reduction cell is carried out using single input–single output (SISO) control loops that operate independently of each other. All are discrete or sampled data feedback loops, either manual or automatic/online. They are either rule-based (e.g. alumina feed control), or conventional three-term or PID controllers. In addition, there is also considerable human activity in the areas of process supervision, and fault detection and diagnostics. Normally controlled variables include cell resistance (and its noise, rise or slope), bath and metal depth, bath temperature and chemistry (AlF_3, LiF, CaF_2, MgF_2), metal purity (Fe, Si), and individual anode current. Through application of advanced control techniques, performance of aluminium electrolytic cells can be achieved. Examples include alumina feed control by application of linear and non-linear models, alumina feed control and cell resistance control using fuzzy logic control technique, online supervision of alumina feed and cell resistance control by adaptive, fuzzy logic expert and neural networks, as well as different ways to control AlF_3 concentration or bath temperature and heat balance.

Cu-flash smelting/Aussmelt Ni-Smelting/FeMn Smelting/Sn–Zn–Pb-Smelting:[26–35]   Copper metal is produced either hydrometallurgically or pyrometallurgically from its oxidic or more from its sulphide ores. Flash smelting of copper sulphide concentrates is a modern pyrometallurgical copper making process, where the sulphide concentrates are firstly smelted to copper matte in a flash furnace, and then the matte is further converted or oxidised into metallic copper either through a PS-converter or more recently through a flash converter. The control of a flash smelter has been described by Bonekamp *et al.*[27] These authors apply data reconciliation in combination with neural nets and dynamic modelling to predict future operating conditions. Lance based copper–nickel matte converters have become an established technology in the field of base metal sulphide smelting and converting. An Ausmelt® converter is currently being constructed at Anglo Platinum in South Africa to convert a nickel–copper rich matte containing platinum group metals (PGMs). The accurate prediction of the matte chemistry is required to control the composition at the endpoint which influences segregation of PGMs during the subsequent slow cooling and magnetic separation processes. Eksteen *et al.*[29] discussed a hybrid modelling approach that incorporates both the effect of thermochemistry and system dynamics. It is shown how the model relates to fundamental conservation laws, while still providing enough flexibility to adapt to changing operating conditions. It will also show how off-line modelling can be incorporated into a robust on-line model. Based on the data from many pilot plant trials, the model prediction performance is shown to be within the accuracy requirement set by industry and therefore constitutes a reliable basis for model-based control. The final generic model structure takes on the form of a thermodynamically integrated ARMAX hybrid model. The final model has the advantages of being dynamic, adaptive, robust and

it can be related to thermochemical fundamentals. Reuter and Moolman[31,32,34,35] discuss the dynamic modelling and control of ferromanganese furnaces while Aldrich and Reuter[26] discuss the use of artificial intelligence techniques to monitor the operation of a submerged arc furnace.

Process control in recycling: Pyrometallurgical reactors close all recycling chains. Dalmijn, Reuter and De Jong[28] explored the complex interrelationship between the resource cycle, recycling and metal production as a function of economics, environmental legislation, and product design. It is argued that central to optimising this resource cycle lies the control in particular of physical separation plants by the application of advanced sensor technology and sorting equipment as well suitable control and sampling algorithms supported by optimising mass balance models. The modelling and control of a furnace for the recycling of Sn/Zn/Pb containing material is discussed by Grund *et al*.[30] Furthermore, the modelling and control of a chemical waste incineration kiln by the use of computational fluid dynamics is discussed by Yang *et al*.[36]

40.4.6   Keywords in process control

Actuator, Adaptive control, Artificial Intelligence, Automation, Controller, Dynamic modelling, Expert system, Feed forward control, Feedback control, Fuzzy Logic control, Model predictive control, Model-based control, Neural networks, PLC, Process control, TCP/IP, Sensor.

41 Bibliography of some sources of metallurgical information

This chapter provides a short bibliography of some major sources of metallurgical reference. The intent is to supplement, rather than replace, the detailed references provided in each chapter of Smithells. Thus, the present chapter concentrates on works of general utility. For the convenience of readers, this bibliography is split into a limited number of categories. Inevitably, there is some overlap between categories and where this occurs, works have been assigned to the most relevant-seeming category. Within some of these categories, a distinction is drawn between works that are sources of data, those with significant narrative content and works containing both narrative and data. In the case of web-based resources, a URL has not been included, as these are subject to change, but sufficient information is provided for these items to be located easily with any standard search tool.

Title	Author(s)/ Editor(s)	Bibliographic Details	In Print	Notes
General metallurgical and related works				
Data only				
Aerospace Structural Metals Handbook	W. F. Brown, Jr., H. Mindin and C. Y. Ho	CINDAS/USAF CRDA Handbooks, 1999.	Yes	Compilation of a variety of data for common alloys used in aerospace.
Alloy Digest (1952–2000)	D. Rahoi	ASM International, Materials Park, OH, 2001.	Yes	Wide range of data on commercial alloys.
ANSI Standards	Various	American National Standards Institute, Washington, DC, various dates.	Yes	US standards.
ASM Metals Reference Book	M. Bauccio	3rd Edition, ASM International, Materials Park, OH, 1993.	Yes	Concise source of data. No index.
ASTM Standards	Various	ASTM International, West Conshohocken, PA, various dates.	Yes	Comprehensive collection of standards for materials and their testing.
British Standards	Various	BSI, London, UK, various dates.	Yes	Comprehensive collection of standards for materials, their use and testing.
Cambridge Engineering Selector	Various	Granta Design Ltd. Cambridge, UK, continuously updated.	Yes	Materials selection tool.
Control of Substances Hazardous to Health (COSHH) data sheets	Various	Provided by materials vendors, numerous on-line collections available.	Yes	Provides safety information mandated by UK law.
CRC Handbook of Chemistry and Physics	D. R. Lide	83rd Edition, CRC Press, Boca Raton, FL, 2002.	Yes	Comprehensive source of general physical science data. More for pure metals than alloys.
CRC Materials Science and Engineering Handbook	J. F. Shackelford and W. Alexander	3rd Edition, CRC Press, Boca Raton, FL, 2001.	Yes	Wide range of data on metallic and non metallic materials.
DIN Standards	Various	International Library Service, Provo, UT, various dates.	Yes	German standards (available in English).
EN Standards	Various	CEN, Brussels, Belgium, various dates	Yes	European standards.
ISO Standards	Various	International Organization for Standardization, Geneva, Switzerland, various dates.	Yes	International standards.

Japanese Standards	Various	Japanese Standards Association, Tokyo, Japan, various dates.	Yes	Japanese standards.
Material Safety Data Sheets (MSDS)	Various	Provided by materials vendors, numerous on-line collections available, various dates.	Yes	Provides safety information mandated by US Federal law.
Metals and Alloys in the Unified Numbering System	Multiple	9th Edition, ASM International, Materials Park, OH, 2001 (co-published with SAE).	Yes	Detailed cross-reference for alloy numbering systems.
MIL Standards	Various	Document Automation and Production Service, Philadelphia, PA, various dates.	Yes	US military standards.
NIST Standards Database	Various	NIST, Gaithersburg, MD, various dates.	Yes	Comprehensive database of US civil and military, plus international standards.
Physical and Chemical Constants and Some Mathematical Functions, Tables of	G. W. C. Kaye and T. H. Laby	16th Edition, Longman Science and Technology, 1995.	Yes	General physical property data.
Pure Metal Properties: A Scientific and Technical Handbook	A. Buch	Co-published by ASM International, Materials Park, OH and Freund Publishing House Ltd., 1999.	Yes	Physical and mechanical property data for pure metals.
SAE Standards	Various	SAE, Warrendale, PA, various dates.	Yes	Standards for alloys used in both ground transportation and aerospace.
Sax's Dangerous Properties of Industrial Materials	R. J. Lewis, Sr.	10th Edition, Wiley Interscience, New York, NY, 2000.	Yes	Provides detailed safety information. Complimentary to MSDS.
Science Data Book	R. M. Tennent	Oliver and Boyd, London, UK, 1971.	No	Highly concise work, yet with fairly comprehensive coverage.
Structural Alloys Handbook	J. M. Holt, H. Mindin and C.Y. Ho	CINDAS/Purdue University, 1996.	Yes	Compilation of a variety of data for common alloys.
Woldman's Engineering Alloys	J. Frick (Editor)	9th Edition, ASM International, Materials Park, OH, 2001.	Yes	Comprehensive, cross-referenced guide to commercial alloys.
Narrative only				
ASM Materials Engineering Dictionary	J. R. Davis	ASM International, Materials Park, OH, 1992.	Yes	Alphabetical listing of key materials terminology.
Atomic Theory for Students of Metallurgy	W. Hume-Rothery and B. R. Coles	6th Reprint, Institute of Metals, London, UK, 1988.	Yes	Authored by the originator of the Hume-Rothery rules.

Title	Author(s)/ Editor(s)	Bibliographic Details	In Print	Notes
Concise Chemical Thermodynamics	J. R. W. Warn and A. P. H. Peters	2nd Edition, Nelson Thornes Ltd., Cheltenham, UK, 1996.	Yes	Concise basic introduction to chemical thermodynamics.
Engineering Materials I and II	M. F. Ashby and D. R. H. Jones	Butterworth Heinemann, Oxford, UK, various dates.	Yes	Series of introductory texts. Numerous case studies.
Engineering Materials III	D. R. H. Jones	Pergamon Press, Oxford, UK, 1993.	Yes	
Materials Selection in Mechanical Design	M. F. Ashby	2nd Edition, Butterworth-Heinemann, Oxford, UK, 1999.	Yes	Introductory level text.
Metallurgy for the Non-Metallurgist	H. Chandler	ASM International, Materials Park, OH, 1998.	Yes	Introductory level text.
Metallurgy, An Introduction to	A. H. Cottrell	2nd Edition, Institute of Metals, London, UK, 1995.	Yes	Contains more advanced material than the title implies, but assumes relatively little prior knowledge.
Open University Materials in Action Series	Various	Butterworth-Heinemann, Oxford, UK, various dates.	Yes	Series of introductory texts. Numerous examples.
Selection and Use of Engineering Materials	J. A. Charles, F. A. A. Crane and J. A. G. Furness	3rd Edition, Butterworth-Heinemann, Oxford, UK, 2001.	Yes	Introductory level text.
Ternary Phase Diagrams in Materials Science	D. R. F. West and N. Saunders	3rd Edition, Institute of Metals, London, UK, 2002.	No	Guide to interpretation and use of ternary phase diagrams
Narrative and data				
ASM Handbook	Various	ASM International, Materials Park, OH, various dates.	Yes	Multivolume work (currently 21 volumes) covering most aspects of metallurgy.
ASM Metals Handbook Desk Edition	J. R. Davis	2nd Edition, ASM International, Materials Park, OH, 1998.	Yes	Single volume form of the ASM Materials Handbook (revised more recently than some volumes of the full handbook)
ASTM Standard Technical Publications (STP)	Various	ASTM International, West Conshohocken, PA, various dates.	Yes	Cover a wide variety of materials related topics.
Metallurgical Design, Handbook of	G. E. Totten, K. Funatani and L. Xie	Marcel Dekker, New York, NY, 2003.	In Press	Design with metallic materials.

Physical and chemical metallurgy

Data

ASM Alloy Phase Diagrams Collection	Depends on edition	Various editions published by ASM International, Materials Park, OH, various dates.	Yes	Comprehensive collection of evaluated binary and ternary phase diagrams. Binary phase diagrams supersede earlier series of phase diagrams collected by Hansen and Anderko, Elliott, Shunk and Moffatt. Available in a variety of editions, including volumes for specific alloy systems.
ASM Materials Property Atlases	Various	ASM International, Materials Park, OH, various dates.	Yes	Series includes atlases of stress-strain curves, fatigue curves, creep and stress-rupture curves and corrosion fatigue/stress corrosion curves.
Corrosion Data, Handbook of	D. Anderson and B. Craig	2nd Edition, ASM International, Materials Park, OH, 1995.	Yes	Detailed manual on corrosion in a wide range of media.
NIST-JANAF Thermochemical Tables	M. W. Chase, Jr.	4th Edition, American Chemical Society, Washington, DC, 1998.	Yes	Comprehensive collection of thermodynamic data.
Pearson's Handbook of Crystallographic Data for Intermetallic Phases	P. Villars and L. D. Calvert	2nd Edition, ASM International, Materials Park, OH, 1991.	Yes	Comprehensive collection of crystallographic data on pure metals and alloy phases (4 volumes).
Powder Diffraction File (formerly the Joint Center on Powder Diffraction Studies Database)	Numerous	International Center for Diffraction Data, Newtown Square, PA, updated annually.	Yes	Extremely comprehensive database of crystal structure and powder diffraction data.
Selected Values of the Thermodynamic Properties of Binary Alloys	R. Hultgren, O. D. Desai, D. T. Hawkins, M. Gleiser and K. K. Welley	ASM International, Materials Park, OH, 1973.	No	Thermodynamic data for binary alloys.
Ternary Alloys: A Comprehensive Compendium of Evaluated Constitutional Data and Phase Diagrams	G. Petzow and G. Effenberg (Editors)	John Wiley and Sons, New York, NY, various dates.	No	Currently incomplete series of volumes of ternary phase diagrams.
Thermochemical Properties of Inorganic Substances (2 Volumes)	O. Knacke, O. Kubaschewski and K. Hesselmann	2nd Edition, Springer-Verlag, Berlin, Germany, 1991.	No	Tables of thermodynamic data.

Narrative

CALPHAD (Calculation of Phase Diagrams): A Comprehensive Guide	N. Saunders and A. P. Miodownik	Elsevier Science Ltd, Oxford, UK, 1998.	Yes	Textbook on thermodynamics and calculation of phase diagrams.

Title	Author(s)/ Editor(s)	Bibliographic Details	In Print	Notes
Corrosion, The Fundamentals of (International Series on Materials Science and Technology, Vol. 44)	J. C. Scully	3rd Edition, Elsevier Science Ltd., Oxford, UK, 1990.	Yes	Introductory level textbook on aqueous corrosion and oxidation.
Crystal Chemistry	R. C. Evans	TechBooks, Herndon, VA, 1980 (originally published by Cambridge University Press, 1964).	Yes	Contains descriptions of important crystal structures.
Deformation and Fracture Mechanics of Engineering Materials	R. W. Hertzberg	4th Edition, John Wiley and Sons, New York, NY, 1995.	Yes	Introductory level textbook on mechanical properties.
Diffusion in Solids	P. G. Shewmon	2nd Edition, TMS, Warrendale, PA, 1991.	Yes	A concise work, covering both diffusion phenomena and atomic mechanisms.
Dislocations, Introduction to	D. Hull and D. J. Bacon	4th Edition, Butterworth-Heinemann, London, UK, 2001.	Yes	A comprehensive guide to dislocation theory.
Fatigue of Materials	S. Suresh	2nd Edition, Cambridge University Press, Cambridge, UK, 1999.	Yes	Comprehensive coverage of fatigue. Concentrates more on mechanisms than on testing procedures.
Fracture Mechanics, Fundamentals of	J. F. Knott	Butterworth's, London, UK, 1981.	No	Detailed discussion of fracture mechanics, including fatigue.
High Temperature Corrosion	P. Kofstad	Elsevier Science, New York, NY, 1988.	Yes	Textbook on high-temperature oxidation and corrosion.
Mathematics of Diffusion	J. Crank	2nd Edition, Oxford University Press, Oxford, UK, 1979.	Yes	Comprehensive guide to phenomenological diffusion theory, including numerous different geometries. Does not cover the atomic mechanisms of diffusion theory.
Mechanical Metallurgy	G. E. Dieter (adapted by D. Bacon)	SI Edition, McGraw-Hill, New York, NY, 1988.	Yes	Introductory text covering mechanical properties, mechanical testing and metalworking.
Modern Physical Metallurgy and Materials Engineering: Science, Process, Applications	R. E. Smallman and R. J. Bishop	6th Edition, Butterworth-Heinemann, Oxford, UK, 2000.	Yes	An expanded version of Smallman's "Modern Physical Metallurgy". Covers most major physical metallurgy principles.
Phase Transformations in Metals and Alloys	D. A. Porter and K. E. Easterling	2nd Edition, Chapman and Hall, London, UK, 1992.	No	Covers a range of topics needed to understand phase transformations.
Physical Metallurgy	P. Haasen and B. L. Mordike	3rd Edition, Cambridge University Press, Cambridge, UK, 1996.	Yes	Advanced text that assumes significant familiarity with solid-state physics.

Physical Metallurgy	R. W. Cahn and P. Haasen	4th Edition, North Holland, Amsterdam, The Netherlands, 1996.	Yes	Three volume multi-author work, offering comprehensive coverage.
Physical Metallurgy Principles	R. E. Reed-Hill and R. Abbaschian	3rd Edition, PWS Publishers, Boston, MA, 1991.	Yes	Covers general physical metallurgy at an introductory level.
Plastic deformation of Metals, The	R. W. K. Honeycombe	2nd Edition, Edward Arnold, London, 1984.	No	Introduction to plasticity and dislocation theory.
Principles and Prevention of Corrosion	D. A. Jones	2nd Edition, Prentice Hall, New York, NY, 1995.	Yes	General textbook on corrosion.
Solidification, Fundamentals of	W. Kurz; D. J. Fisher (Editor)	4th Edition, Trans Tech Publications Ltd., Aedermannsdorf, Switzerland, 1998.	Yes	Covers most aspects of solidification theory.
Structure of Metals, Crystallographic Methods, Principles and Data	C. S. Barrett and T. B. Massalski	3rd Revised Edition, Elsevier Science Ltd, Oxford, UK, 1980.	Yes	This work is part physical metallurgy, part crystallography.
Narrative and data				
Corrosion	L. L. Shreir, R. A. Jarman and G. T. Burstein (Editors)	3rd Edition, Butterworth-Heinemann, UK, 1994.	Yes	Comprehensive two volume guide to corrosion.
Interfacial Phenomena in Metals and Alloys	L. E. Murr	TechBooks, Herndon, VA (originally published by Addison-Wesley, 1975).	Yes	Primarily a narrative work, however, an extensive collection of interfacial energy data is included.
Introduction to Crystallography, An	F. C. Phillips	4th Edition, Longman, Harlow, Essex, 1971.	No	A systematic guide to point and space groups, with descriptions of their symmetry.
Materials Thermochemistry	O. Kubaschewski, C. B. Alcock and P. J. Spencer	6th Edition, Elsevier Science Ltd, Oxford, UK, 1993.	Yes	Textbook on thermochemistry with data in appendices.
Physical Chemistry of High Temperature Technology	E. T. Turkdogan	Academic Press, 1980.	Yes	Textbook on thermochemistry with table of free energy data.
Surface Wear: Analysis, Treatment and Prevention	R. Chattopadhyay	ASM International, Materials Park, OH, 2001.	Yes	Overview of tribology.
Uhlig's Corrosion Handbook	R. W. Revie (Editor)	2nd Edition, Wiley Interscience, 2000.	Yes	Comprehensive manual on corrosion.

Title	Author(s)/ Editor(s)	Bibliographic Details	In Print	Notes
Specific alloy systems and classes of materials				
Data				
Aluminum Standards and Data	Not identified	The Aluminum Association, Washington DC, 2003.	Yes	Includes alloy and temper designations, nomenclature and representative property data for commercial aluminium alloys.
ASM Specialty Handbooks	Various	ASM International, Materials Park, OH, various dates.	Yes	Handbooks on various specific classes of metals and alloys.
Atlas of Time-Temperature Diagrams	G. Vander Voort (Editor)	ASM International, Materials Park, OH, 1991.	Yes	Includes diagrams for isothermal transformation, continuous cooling, precipitation, embrittlement and ordering. Two volumes (steels and nonferrous alloys, respectively).
Properties of Aluminum Alloys	J. G. Kaufmann (Editor)	ASM International, Metals Park, OH and the Aluminum Association, Washington, DC, 1999.	Yes	Tensile, creep and fatigue data for aluminium alloys.
Properties of Intermetallic Alloys	Various	Metals Information and Analysis Center, West Lafayette, IN, 1994 onwards.	Yes	Three volume detailed collection of data on aluminide, silicide and other intermetallic compounds. Includes physical properties, mechanical properties and some information on oxidation resistance.
Steel Product Manuals and Databooks	Various	Iron and Steel Society, Warrendale PA, various dates.	Yes	Series of manuals covering major steel forms.
Worldwide Guide to Equivalent Irons and Steels	Various	4th edition, ASM International, Materials Park, OH, 2000.	Yes	Lists equivalent alloy specifications and designations.
Worldwide Guide to Equivalent Nonferrous Alloys	Various	4th edition, ASM International, Materials Park, OH, 2001.	Yes	Lists equivalent alloy specifications and designations.
Narrative				
Austenitic Stainless Steels: Microstructure and Mechanical Properties	P. Marshall (Editor)	Kluwer Academic Publishers, Dordrecht, The Netherlands, 1984.	Yes	Comprehensive discussion of structure-property relationships in austenitic stainless steels.
Light Alloys: Metallurgy of the Light Metals	I. J. Polmear	3rd Edition, John Wiley & Sons, New York, NY, 1996.	Yes	Covers aluminium, titanium and magnesium alloys.

Making, Shaping and Treating of Steel, The	R. J. Fruehan (Editor)	11th Edition, The AISE Steel Foundation, 1998.	Yes	Comprehensive guide from steelmaking to final shape.
Metal Matrix Composites, An Introduction to	T. W. Clyne and P.J. Withers	Cambridge University Press, Cambridge, UK, 1995.	Yes	Comprehensive guide to metal matrix composites.
Metal Matrix Composites, Fundamentals of	S. Suresh, A. Mortensen and A. Needleman (Editors)	Butterworth-Heinemann, London, UK, 1993.	Yes	Comprehensive guide to metal matrix composites.
Physical Metallurgy and the Design of Steels	F. B. Pickering	Applied Science Publishers, London, UK, 1978.	No	Assuming a basic knowledge of physical metallurgy, this work explains how metallurgical principles are applied in commercial alloys.
Physical Metallurgy of Steels, The	W. C. Leslie	CBLS Publishers, 1991 (originally published by McGraw Hill, London, UK, 1983).	Yes	Discussion of ferrous physical metallurgy.
Steel Heat Treatment Handbook	G. E. Totten and M. A. H. Howes (Editors)	Marcel Dekker, Inc., New York, 1997.	Yes	Guide to heat-treatment of ferrous alloys.
Steels: Microstructure and Properties	R. W. K. Honeycombe and H. K. D. H. Bhadeshia	2nd Edition, Butterworth-Heinemann, Oxford, UK, 1996.	Yes	Discussion of ferrous physical metallurgy. Expanded in scope in the 2nd edition to include newer work, such as modelling.
Steels: Heat Treatment and Processing Principles	G. Krauss	ASM International, Materials Park, OH, 1990.	Yes	A guide to ferrous physical metallurgy with an emphasis on heat-treatment.
Narrative and data				
Aluminum Alloys and Tempers, Introduction to	J. G. Kaufmann	ASM International, Materials Park, OH, 2000.	Yes	Fairly broad coverage of aluminium alloys, with a focus on alloy and temper designations.
Aluminum: Physical Metallurgy and Processes, Handbook of	G. E. Totten and D. S. MacKenzie	Marcel Dekker, New York, NY, 2003.	In Press	Two volume guide to aluminium alloys.
Aluminum: Properties and Physical Metallurgy	J. E. Hatch	ASM International, Materials Park, OH, 1984.	Yes	Metallurgy of aluminium and its alloys.
Copper Development Association Publications	Various	Copper Development Association, New York, NY.	Yes	Wide range of publications on copper and copper-based alloys.

(*continued*)

Title	Author(s)/ Editor(s)	Bibliographic Details	In Print	Notes
Metal Foams: A Design Guide	M. F. Ashby, A. Evans, N. A. Fleck, L. J. Gibson, J. W. Hutchinson and H. N. G. Wadley	Butterworth-Heinemann, London UK, 2000.	Yes	Introduction to metallic foams.
Nickel Development Institute Library	Various	Nickel Development Institute, Toronto, Ontario, Canada, various dates.	Yes	Wide range of publications on nickel and nickel-based alloys.
Superalloys II High-Temperature Materials for Aerospace and Industrial Power	C. T. Sims, N. S. Stoloff and W. C. Hagel	John Wiley and Sons, New York, NY, 1987.	Yes	Comprehensive coverage of processing, structure and properties of nickel-base superalloys. Includes alloy data as an appendix.
Superalloys: A Technical Guide	M. J. Donachie and S. J. Donachie	2nd Edition, ASM International, Materials Park, OH, 2002.	Yes	Superalloy metallurgy and processing.
Titanium: a Technical Guide	M. J. Donachie, Jr.	2nd Edition, ASM International, Materials Park, OH, 2000.	Yes	Metallurgy and processing of titanium and its alloys.

Process metallurgy

Data

Title	Author(s)/ Editor(s)	Bibliographic Details	In Print	Notes
Coatings and Coating Processes for Metals	J. H. Lindsay (Editor)	ASM International, Materials Park, OH, 1997.	Yes	Comprehensive list of coating processes and trade information.
Foseco Ferrous Foundryman's Handbook	J. Brown	11th Edition, Butterworth-Heinemann, London, UK, 2000.	Yes	Comprehensive data on ferrous metalcasting.
Foseco Non-Ferrous Foundryman's Handbook	J. Brown	11th Edition, Butterworth-Heinemann, London, UK, 1999.	Yes	Comprehensive data on non-ferrous metalcasting.
Heat-Treater's Guide: Practices and Procedures for Irons and Steels	H. Chandler (Editor)	2nd Edition, ASM International, Materials Park, OH, 1995.	Yes	Comprehensive heat-treatment data.
Heat-Treater's Guide: Practices and Procedures for Nonferrous Alloys	H. Chandler (Editor)	2nd Edition, ASM International, Materials Park, OH, 1996.	Yes	Comprehensive heat-treatment data.
Machinery's Handbook	E. Oberg, C. J. McCauley, R. Heald, M. I. Hussain, F. D. Jones and H. H. Ryffel (Editors)	26th Edition, Industrial Press, NY, 2000.	Yes	Comprehensive data on machining.

Narrative

Castings	J. Campbell	2nd Edition, Butterworth Heinemann, Oxford, UK, 2003.	Yes	Introduction to metalcasting.
Extraction Metallurgy	J. D. Gilchrist	3rd Edition, Pergamon Press, Oxford, UK, 1989.	No	Fundamentals of extractive metallurgy.
Foundry Technology	P. R. Beeley	2nd Edition, Butterworth-Heinemann, London, UK, 2001.	Yes	Comprehensive information on metalcasting.
Metal Forming: Fundamentals and Applications	T. Altan, S. Oh and H. Gegel	ASM International, Materials Park, OH, 1983.	Yes	Detailed introduction to metal forming.
Metallurgy of Welding	J. F. Lancaster	6th Edition, William Andrew Publishing, Norwich, NY, 1999.	Yes	Covers fusion welding, adhesive bonding, brazing, soldering, various solid-phase welding processes as well as fusion welding.
Physical Metallurgy of Welding, Introduction to the	K. Easterling	2nd Edition, Butterworth Heinemann, Oxford, UK, 1992.	No	Processing–structure–property relationships in welding.
Steelmaking, Fundamentals of	E. T. Turkdogan	The Institute of Materials, London, 1996.		Textbook on steelmaking.
Transport Phenomena in Material Processing	D. R. Poirer and G. H. Geiger	The Minerals, Metals & Materials Society, Warrendale, PA, 1994.	Yes	Covers fluid dynamics, mass and heat-transfer.

Narrative and data

Principles of Extractive Metallurgy	T. Rosenqvist	2nd Edition, McGraw-Hill, Tokyo, Japan, 1983.	No	Primarily a narrative work, but includes appendices with a significant body of thermodynamic data.
Hot Working Guide: A Compendium of Processing Maps	Y. V. R. K. Prassad, S. Sasidhara, H. L. Gegel and J. C. Malas (Editors)	ASM International, Materials Park, OH, 1997.	Yes	Data on the hot working of ferrous and non-ferrous materials with supporting discussion.
Welding Handbook	Various	8th Edition, American Welding Society, Miami Florida, various dates.	Yes	Multivolume handbook providing comprehensive coverage of a wide range of materials joining technologies, plus related cutting and coating processes.

Microstructural characterisation, mechanical and non-destructive testing of metals and alloys

Data

Handbook of Crystallography for Electron Microscopists and Others	A. G. Jackson	Springer-Verlag, New York, NY, 1991.	Yes	Compact reference manual for crystallography.

Title	Author(s)/ Editor(s)	Bibliographic Details	In Print	Notes
International Tables for Crystallography	Various	International Union for Crystallography/ Kluwer Academic Publishers, Chester, UK, various dates.	Yes	Multivolume comprehensive reference work on crystallography.
Metallographic Etching	G. Petzow	2nd Edition, ASM International, Materials Park, OH, 1999.	Yes	Contains etchant recipes and etching procedures for most types of metals and alloys.
Narrative				
Chemical Microanalysis using Electron Beams	I. P. Jones	The Institute of Materials, London, UK, 1992.	Yes	Concise yet comprehensive guide to microanalysis.
Crystallography and Diffraction, The Basics of	C. Hammond	International Union of Crystallography/ Oxford University Press, Oxford, UK, 1997.	Yes	Coverage largely compliments, rather than duplicates, Cullity and Stock.
Electron Beam Analysis of Materials	M. H. Loretto	2nd Edition, Kluwer Academic Publishers, London, UK, 1993.	Yes	A concise work that concentrates on transmission electron microscopy, but also covers scanning electron microscopy and auger electron spectroscopy.
Electron Microdiffraction	J. C. H. Spence and J. M. Zuo	Kluwer Academic/Plenum Publishers, 1992.	Yes	Detailed guide to convergent beam diffraction. Compliments the more general transmission electron microscopy texts listed here.
Energy Dispersive X-ray Analysis, Fundamentals of	J. C. Russ	Butterworth-Heinemann, UK, 1984.	No	Covers energy dispersive x-ray spectroscopy in both TEM and SEM.
High-Resolution Transmission Electron Microscopy	P. Buseck, J. Cowley and L. Eyring (Editors)	Oxford University Press, Oxford UK, 1989.	Yes	Includes numerous case studies. Best suited for intermediate to advanced users.
Light Microscopy of Carbon Steels	L. E. Samuels	ASM International, Materials Park, OH, 1999.	Yes	Updated version of 'Optical Microscopy of Carbon Steels'.
Metallography: Principles and Practice	G. F. VanderVoort	ASM International, Materials Park, OH, 1984.	Yes	Covers most aspects of metallography.
Metallographic Polishing by Mechanical Methods	L. E. Samuels	4th Edition, ASM International, Materials Park, OH, 2003.	Yes	Metallurgical specimen preparation.
Royal Microscopical Society Handbooks	Various	Royal Microscopical Society, Oxford, UK, various dates.	Yes	Extensive collection of works on various aspects of microscopy.

Scanning and Transmission Electron Microscopy—An Introduction	S. L. Flegler, J. W. Heckman Jr. and K. L. Klomparens	Oxford University Press, 1993.	Yes	Introductory level textbook covering the basics of transmission and scanning electron microscopy in a concise fashion.
Scanning Electron Microscopy and X-Ray Microanalysis	J. Goldstein, D. E. Newbury, D. C. Joy, C. E. Lyman, P. Echlin, E. Lifshin, L. C. Sawyer and J. R. Michael	3rd Edition, Kluwer Academic/Plenum Publishers, 2003.	Yes	Comprehensive guide to scanning electron microscopy and associated analytical techniques.
Surface and Interface Analysis, Handbook of	J. C. Riviere and S. Myhra (Editors)	Marcel Dekker, New York, NY, 1998.	Yes	Covers both surface analysis and surface modification techniques.
Transmission Electron Microscopy of Materials	G. Thomas and M. J. Goringe	2nd Edition, TechBooks, Fairfax, VA, 1981 (originally published by John Wiley and Sons, 1979).	Yes	Concise, yet comprehensive coverage of transmission electron microscopy.
Transmission Electron Microscopy: A Textbook for Materials Science	D. B. Williams and C. B. Carter	Kluwer Academic/Plenum Publishers, New York, 1996.	Yes	Comprehensive information on transmission electron microscopy techniques and the interpretation of images, diffraction patterns and analytical data.

Narrative and data

Encyclopedia of Materials Characterisation Surfaces, Interfaces, Thin Films	C. Evans, R. Brundle and S. Wilson	1st Edition, Butterworth-Heinemann, UK, 1992.	Yes	Comprehensive survey of analytical techniques.
Hardness Testing	H. Chandler	2nd Edition, ASM International, Materials Park, OH, 1999.	Yes	Comprehensive overview of hardness testing.
NDE Handbook: Non-destructive Examination Methods for Condition Monitoring	K. Bøving (Editor)	Woodhead Publishing Ltd., Cambridge, UK, 1989.	Yes	Comprehensive overview of non-destructive testing.
Nondestructive Testing	L. Cartz	ASM International, Materials Park, OH, 1995.	Yes	Introduction to non-destructive testing, covering major techniques.
Practical Electron Microscopy in Materials Science	J. W. Edington	CBLS, 1976 (originally published as the Philips Technical Library Monographs).	Yes	Single volume compilation of the first four volumes of this five volume series. Some data provided in appendices.
Tensile Testing	P. Han (Editor)	ASM International, Materials Park, OH, 1992.	Yes	Comprehensive overview of tensile testing.
X-Ray Diffraction, Elements of	B. D. Cullity and S. R. Stock	3rd Edition, Prentice Hall College Div., Upper Saddle River, NJ, 2001.	Yes	Recently updated with expanded coverage of related topics, such as electron diffraction. Limited data provided in appendices.

Title	Author(s)/ Editor(s)	Bibliographic Details	In Print	Notes
X-Ray Diffraction. A Practical Approach	C. Suryanarayana and M. Grant Norton	Kluwer Academic/Plenum Publishers, 1998.	Yes	Introductory text, using a workbook approach. Limited data provided in appendices.

Metallurgical and related search tools

Data

Title	Author(s)/ Editor(s)	Bibliographic Details	In Print	Notes
Cambridge Scientific Abstracts Databases	Various	Cambridge Scientific Abstracts, Bethesda, Maryland, continuously updated.	Yes	Provides a gateway into a number of bibliographic databases relevant to materials.
SciFinder Scholar (incorporates the Chemical Abstracts)	Various	Chemical Abstracts Service, American Chemical Society Washington DC, continuously updated.	Yes	On-line search tool for literature on all aspects of chemistry. Includes extensive information on metallic materials.
Compendex	Various	Engineering Information Inc., Hoboken, NJ, continuously updated.	Yes	On-line search tool for literature on all aspects of engineering. Extensive coverage of metallurgy and materials.
Dictionary of Physical Metallurgy in Five Languages: English, German, French, Russian and Spanish.	R. Freiwillig	Elsevier Science Ltd, 1987.	Yes	Equivalent terms.
Metadex	Various	Chemical Abstracts Service, American Chemical Society Washington DC, continuously updated.	Yes	On-line search tool for literature on all aspects of metallurgy.
Metallurgy/Materials Education Yearbook	K. Mukherjee (Editor)	40th Edition, ASM International Foundation, Materials Park, OH, 2001.	Yes	Comprehensive list of metallurgy and materials-related programmes at US and Canadian Universities. Lists research interests and contact details for individual faculty. Provides some details of materials-related programmes at universities outside North America.
Web of Science (incorporates the Science Citation Index)	Various	Institute for Scientific Information, Philadelphia, PA, continuously updated.	Yes	Comprehensive bibliographic search tools for all aspects of science.
Science Direct	Various	Elsevier Science, Amsterdam, The Netherlands, continuously updated.	Yes	On-line search tool for literature on all aspects of science. Allows searches to easily be restricted to materials science.
UMI dissertation databases	Various	UMI (formerly University Microfilms), Ann Arbor, MI, continuously updated.	Yes	Permits bibliographic searches for dissertations.

Peer-reviewed metallurgical and related journals

There are numerous journals covering metallurgy and materials science. For a fairly comprehensive list see the Science Citation Index (SCI), Journal Citation Reports (JCR) which lists journals by subject and provides ranking metrics.

Acta Materialia	Covers both experimental and modelling work on materials, extensive metallurgical content.
Corrosion	Covers corrosion of materials.
Corrosion Science	Covers corrosion of materials.
International Materials Reviews	Consists of lengthy review papers, each with numerous references.
Journal of Alloys and Compounds	Covers materials with low-volume usage. Formerly called the 'Journal of Less-Common Metals'.
Journal of Materials Research	Covers both experimental and modelling work on materials, especially non-metallic materials.
Journal of Materials Science	Covers general materials science, with subsidiary journals covering specific topics.
Journal of Materials Science Letters	Short papers.
Journal of Nuclear Materials	Covers a wide variety of metallurgical topics for materials used in the nuclear industry.
Materials Characterisation	Covers both microstructural characterisation techniques and application of microscopy to materials.
Materials Science and Engineering	Covers general materials science. Includes four series: A consists of research papers on structural materials, B consists of research papers on solid-state materials, C consists of research papers on biomaterials and R consists of long review papers.
Materials Science and Technology	Covers general materials science.
Metallurgical and Materials Transactions	Covers both experimental and modelling work, almost all on metallic materials. Has two series: A covers physical metallurgy and materials science, B covers chemical metallurgy, with some overlap between the two.
Oxidation of Metals	Covers high-temperature reaction of materials.
Philosophical Magazine	Focuses on the pure science of materials.
Science and Technology of Welding and Joining	Covers joining of materials.
Scripta Materialia	Short papers.
Ultramicroscopy	Covers issues related to advanced microscopy techniques.
Welding Research Supplement (Welding Journal)	Covers research on joining of materials, often with a focus on more applied aspects.
Zeitschrift für Metallkunde	Covers general metallurgy.

Professional magazines (see the professional societies list below for acronyms)

Advanced Materials and Processes	Published by ASM International.
JOM	Published by TMS.
MRS Bulletin	Published by MRS.
Materials World	Published by IoM.
Welding Journal	Published by AWS.

Metallurgical and related conference series

There are numerous metallurgy-related conferences held worldwide (many with English as the conference language or with simultaneous translation) and so the following is only a limited selection. Most conferences are sponsored by one or more professional societies (see the professional societies list below for abbreviations).

AFS Transactions	Covers metalcasting.
ASM Materials Solutions Conference	Annual conference with sessions on a wide variety of materials topics.
ASM Subject-Specific Conferences	Numerous conference series.
AWS Convention	Annual conference and trade show on all aspects of joining.
AWS Subject-Specific Conferences	Numerous conference series on joining and related topics.
DGM Conferences	Various materials conferences, a number of which have English as the conference language.
DVS Conferences	Various joining-related conferences.
Euromat Conference	Conference held annually in a different FEMS member country.
Gordon Research Conferences	Conferences devoted to a series of specific materials topics.
IoM Conferences	General materials conferences and meetings on specific materials topics.
MRS Symposia	Semi-annual conferences comprised of a large number of symposia on different aspects of materials.
MSA Conference	Annual conference on all aspects of microscopy in the materials and biological sciences.
TMS Materials Week	Annual conference with sessions on a wide variety of materials topics.
TMS Subject-Specific Conferences	Numerous conference series.

Metallurgical and related professional societies

Many countries have one or more metallurgical/materials-related professional societies. The list below provides some examples.

American Foundry Society (AFS)	Society for metalcasting.
American Welding Society (AWS)	Professional society for all forms of materials joining, plus related cutting and surface treatment processes. Develops standards and a variety of accreditation programmes for welding personnel.
ASM International	Comprehensive US-based materials society devoted primarily to publishing and the organisation of conferences.
ASM Affiliate Societies	Semi-autonomous societies devoted to specific aspects of metallurgy and materials (e.g. International Metallographic Society).
Deutsche Gesellschaft für Materialkunde (DGM)	German materials society.
Deutscher Verband für Schweißen (DVS)	German welding society.
Federation of European Materials Societies (FEMS)	Consortium of professional materials societies throughout Europe.
Institute of Materials (IoM)	UK professional society for materials engineers. Administers the award of chartered-engineer status to materials engineers.
Materials Research Society (MRS)	Comprehensive US-based materials society devoted primarily to publishing and the organisation of conferences.
Microscopy Society of America (MSA)	US society devoted primarily to publishing and the organisation of conferences on both materials and biological microscopy.
Society of Materials Science, Japan (JSMS)	Japanese Materials Society.
The Minerals Metals and Materials Society (TMS)	US professional society for materials engineers. Addresses accreditation issues for materials-related bachelor's degree programmes at US universities with ABET (the Accreditation Board for Engineering and Technology).
