21 Mechanical testing

22 Mechanical properties of metals and alloys

23 Sintered materials

31   Corrosion   31–1

32   Electroplating and metal finishing   32–1

33   Welding   33–1

34   Soldering and brazing   34–1

Preface

Over ten years have elapsed since the last edition of Smithells was published. Hence, a key objective of the editors for the present edition was to update the existing content. Thus, as can be seen from the table below, extensive changes have been made. In addition, the editors wished to expand the coverage of Smithells, both with respect to topics that have been overlooked in previous editions (such as metal working and machining) and to include aspects of metallurgy that have grown in importance, since the last edition was published (for example modelling).

Chapter	Title	Changes
1	Related designations	Rewritten completely, to reflect current designations.
2	Introductory tables and mathematical information	Major new section added on the statistics needed for process and quality control, etc.
3	General physical and chemical constants	No major changes.
4	X-ray analysis of metallic materials	Numerous edits to text, references updated and obsolete information removed.
5	Crystallography	Numerous edits to text.
6	Crystal chemistry	Updated comprehensively to bring all crystal structure and lattice parameter data into accord with commonly accepted values.
7	Metallurgically important minerals	Data table updated; introductory paragraphs rewritten.
8	Thermochemical data	No major changes.
9	Physical properties of molten salts	No changes.
10	Metallography	Rewritten completely to reflect modern specimen preparation techniques for light microscopy and contemporary practice in both electron microscopy and analytical techniques. New section added on applications in failure analysis. Numerous new references.
11	Equilibrium diagrams	Updated comprehensively to bring all phase diagrams into accord with commonly accepted data.
12	Gas–metal systems	Section on solutions of hydrogen updated completely and re-written.
13	Diffusion in metals	Numerous corrections, plus some new data.
14	General physical properties	All data on solid pure metals has been updated to match commonly accepted values. The section on liquid metals has been rewritten and now includes a more detailed narrative introduction.
15	Elastic properties, damping capacity and shape memory alloys	Minor corrections and updating of references.
16	Temperature measurement and thermoelectric properties	New section on thermoelectric materials, with narrative and data. Additional thermocouple data.

(continued)

Chapter	Title	Changes
17	Radiating properties of metals	Text rewritten completely.
18	Electron emission	Minor corrections.
19	Electrical properties	New references added on superconducting materials.
20	Magnetic materials and their properties	Text updated. Includes new references on contemporary magnetic materials.
21	Mechanical testing	Existing text edited extensively. Sections on tensile testing and fracture toughness testing re-written completely. New sections on fatigue testing, creep testing and non-destructive evaluation added.
22	Mechanical properties of metals and alloys	Minor editing of existing material; notes added concerning the applicability of the standards cited. New section added to provide data for cast Ni-base alloys.
23	Sintered materials	Edited extensively and updated.
24	Lubricants	Extensive revisions; new data tables.
25	Friction and wear	Extensive revisions; new data tables.
26	Casting alloys and foundry data	Extensive revisions, in particular extension and updating of the compositional and property data for foundry alloys.
27	Engineering ceramics and refractory materials	Extensive revisions, including new data on the properties of ceramics and standards for these materials.
28	Fuels	Extensive revisions, in particular to energy use data and standards.
29	Heat treatment	Rewritten entirely to reflect contemporary practice in steel and aluminium alloy heat-treatment. Provides a much greater level of detail than the previous edition.
30	Metal cutting and forming	New chapter providing a comprehensive overview of metal cutting and forming by both traditional and non-traditional techniques. Replaces a chapter that was focused narrowly on laser metal working.
31	Guide to corrosion control	Rewritten completely. Includes a new section on biocorrosion.
32	Electroplating and metal finishing	No changes.
33	Welding	Extensive revisions, in particular with respect to EN and ISO standards.
34	Soldering and brazing	Extensive revisions, principally to expand coverage with respect to processes and to include lead-free solders.
35	Vapour deposited coatings and thermal spraying	Coverage expanded to include a new section on thermal spraying. Some revision of content on vapour deposition.
36	Superplasticity	Rewritten completely to provide narrative and extensive tabular information on both microstructural and internal-stress superplastic systems.
37	Metal-matrix composites	Property data expanded and updated.
38	Non-conventional and emerging metallic materials	New chapter providing narrative and tabular information on structural intermetallic compounds, metal foams, metallic glasses and micro/nanoscale materials. Includes numerous references to both overviews and original research.
39	Modelling and simulation	New chapter providing an overview of the methods used to model metallic materials.
40	Supporting technologies for the processing of metals and alloys	New chapter containing information on furnace design, vacuum technology and metallurgical process control.
41	Bibliography of some sources of metallurgical information	New chapter comprised of a guide to major works of reference, texts, journals, conferences, databases and specialist search tools.

Acknowledgements

'Data! Data! Data!' he cried impatiently. 'I can't make bricks without clay.'

Sherlock Holmes,
in *The Adventure of the Copper Beeches*
by Sir Arthur Conan Doyle

Disclaimer

Although great care was exercised in the preparation of this volume, the contributors, editors and publisher provide no warranty of any kind (explicit or implied) as to the accuracy, reliability or applicability of the data and information contained herein. All data in this volume are provided for general guidance only and **cannot** be used as evidence of: merchantability; suitability for engineering design; fitness for a particular purpose; safety in storage, transportation or use; or other similar or related purposes.

Information provided in this volume is derived from the relevant professional literature, or other sources believed to be reputable by the contributors and editors, as specified in the detailed references provided. Where copyrighted material has been employed, this is used with permission of the copyright owner. Copyrighted material, used with permission, is indicated at the relevant location in the text. Mention of trademarked product or corporate names is purely for the purposes of identification and these remain the property of their owners and there is no intent to infringe upon ownership rights therein. Neither the presence, nor the absence of discussions of materials, processes, products or other items provides any indication as to the extent to which such items actually exist, are available commercially, or constitute original inventions.

All information within this volume is used entirely at the reader's own risk. Since the circumstances in which the contents of this volume might be employed will differ widely, the contributors, editors and publisher can not guarantee favourable results and expressly deny any and all liability connected with the use (and consequences of the use) of the information and data contained herein.

This volume is intended for readers with suitable professional qualifications, supplemented by sufficient experience in the field, to be capable of making their own professional judgement as to the reliability and appropriateness of the information and data contained within. Before using any of this information or data, a suitably qualified professional/chartered engineer must be consulted, possible risks analysed/managed and rigorous testing conducted under the actual conditions to be experienced.

Under no circumstances, whether covered in the disclaimer above or not, shall the liability of the contributors, editors or publisher of this work exceed the original purchase price of this volume and this shall constitute the sole remedy available to the purchaser (and subsequent readers) of this book. No liability is accepted for consequential or implied damages of any kind resulting from use of this volume.

1 Related designations

The following tables of related designations are intended as a guide to alloy correspondence on the basis of chemical composition. The equivalents should not be taken as exact, and in all cases of doubt the relevant national specification or standard should be consulted. The tables do not represent an exhaustive list of all alloys available; the references listed at the end of the chapter are more complete sources.

In the case of the United Kingdom, France, and Germany, the tables refer to designations and standards that have recently been superseded by European (EN) and international (ISO) standards. The older standards have been referenced because the alloy designations are still in common use, and because the new standards use in some cases several different designations for chemically identical alloys, depending on the product form. A list of all designations is beyond the scope of this book; the references should be consulted for further details.

Table 1.1 lists designations for steels, with subsections for steels of different types. Designations for wrought aluminium alloys are listed in Table 1.2; cast aluminium alloys are shown in Table 22.2. Table 1.3 gives related copper alloy designations, subdivided into coppers, brasses, bronzes, and nickel silvers. Magnesium alloys cast and wrought are in Table 1.4. Related designations for nickel and titanium alloys are listed in Sections 22.5 and 22.6, respectively.

Unified number designations—UNS designations are five-digit numbers prefixed by a letter that characterises the alloy system as shown below.

UNS Letter Designation[1]
A   Aluminium and aluminium alloys
B   Copper and copper alloys
D   Specified mechanical properties steels
E   Rare earth and rare earth like metals and alloys
F   Cast irons and cast steels
G   AISI and SAE carbon and alloy steels
H   AISI H-steels
J   Cast steels (except tool steels)
K   Miscellaneous steels and ferrous alloys
L   Low melting metals and alloys
M   Miscellaneous nonferrous metals and alloys
N   Nickel and nickel alloys
P   Precious metals and alloys
R   Reactive and refractory metals and alloys
S   Heat and corrosion resistant (stainless) steels
T   Tool steels
W   Welding filler metals

2 Introductory tables and mathematical information

2.1 Conversion factors

Conversion factors into and from SI units are given in Table 2.5. The table can also be used to convert from one traditional unit to another. Convenient multiples or sub-multiples of SI units can be derived by the application of the prefix multipliers given in Table 2.4. Table 2.6 gives commonly required conversions.

The majority of the conversion factors are based upon equivalents given in BS 350:Part 1:1983 'Conversion Factors and Tables'.

Throughout the conversions the acceleration due to gravity (g) has been taken as the standard acceleration $9.806\,65\,\mathrm{m\,s}^{-1}$. Units containing the word force like 'pounds force' are converted to SI units using this value of g.

The B.t.u. conversions are based on the definition accepted by the 5th International Conference on Properties of Steam, London, 1956, that 1 B.t.u. $\mathrm{lb}^{-1} = 2.326\,\mathrm{J\,g}^{-1}$ exactly. Conversions to joules are given for three calories; calories (IC) is the 'international table calorie' redefined by the 1956 conference referred to above as $4.186\,8$ J. Calories ($15°$C) refers to the calorie defined by raising the temperature of water at $15°$C by $1°$C and calories (US thermochemical) is the 'defined' calorie used in some USA work and is defined at 4.184 J exactly.

The conversions are grouped in alphabetical order of the physical property to which they relate but are not alphabetical within the groups.

2.1.1 SI units

In this edition quantities are expressed in SI (Système International) units. Where c.g.s. units have been used previously only SI units are given. However, familiar units in general technical use have been retained where they bear a simple power of ten relation to the strict SI unit. For instance density is given as $\mathrm{g\,cm}^{-3}$ and not as $\mathrm{kg\,m}^{-3}$. Where Imperial units have been used (e.g. in Mechanical Properties, etc.) data are given in both SI units and Imperial units.

The basic units of the SI system are given in Table 2.1, derived units with special names and symbols in Table 2.2 and derived units without special names in Table 2.3.

Multiples and sub-multiples of SI units are formed by prefixes to the name of the unit. The prefixes are shown in Table 2.4. The prefixed unit is written without a hyphen—for instance a thousand million newtons is written giganewton—symbol GN. The name of the unit is written with a small letter even when the symbol has a capital letter, e.g. ampere, symbol A. In the case of the kilogram, the multiple or sub-multiple is applied to the gram—for instance a thousand kilograms is written Mg.

In this edition stress is expressed in Pascals (Pa). A pascal (Pa) is identical to a newton per square metre ($\mathrm{N\,m}^{-2}$) and a megapascal (MPa) is identical to a newton per square millimetre ($\mathrm{N\,mm}^{-2}$).

PRINTED FORM OF UNITS AND NUMBERS

The symbol for a unit is in upright type and unaltered by the plural. It is not followed by a full stop unless it is at the end of a sentence. Only symbols of units derived from proper names are in the upper case.

When units are multiplied they will be printed with a space between them. Negative indices are used for units expressed as a quotient. Thus newtons per square metre will be $N\,m^{-2}$ and metres per second will be $m\,s^{-1}$.

The prefix to a unit symbol is written before the unit symbol without a space between and a power index applies to both the symbols. Thus square centimetres is cm^2 and not $(cm)^2$.

Numbers are printed with the decimal point as a full stop. For long numbers, a space and not a comma is given between every three digits. For example $\pi = 3.141\,592\,653$. When a number is entirely decimal it will begin with a zero, e.g. 0.5461. If two numbers are multiplied, a × sign is used as the operator.

HEADING OF COLUMNS IN TABLES AND LABELLING OF GROUPS

The rule adopted in this edition is that the quantity is obtained by multiplying the unit and its multiple given at the column head by the number in the table.

For example when tabulating a stress of 2×10^5 Pa the heading is stress, below which appears 10^5 Pa, with 2.0 appearing in the table. If no units are given in the column heading, the values given are numbers only. In graphs the power of ten and units by which the point on the graph must be multiplied are given on the axis label.

TEMPERATURES

The temperature scale IPTS–68 has been replaced by the International Temperature Scale of 1990 (ITS–90). For details of this see chapter 16, where Table 16.1 gives the differences between ITS–90 and EPT–76 and between ITS–76 and between ITS–90 and IPTS–68. Figure 16.1 gives differences $(t_{90} - t_{68})$ between ITS–90 and IPTS–68 in the range $-260°C$ to $1064°C$. Table 2.7 gives conversions between the old IPTS–68 and the old IPTS–48.

Table 2.1   BASIC SI UNITS

Quantity	Name of unit	Unit symbol
Length	metre	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Luminous intensity	candela	cd
Amount of substance	mole	mol
Plane angle	radian	rad
Solid angle	steradian	sr

From BS 1826:1952 Amendment No. 1, 2 February 1970. Example: 1 000°C according to IPTS–48 would be corrected to 1001.24°C to conform to IPTS–68.
For conversions from IPTS–68 to ITS–90 see Table 16.1.

Table 2.8 CORROSION CONVERSION FACTORS

The following conversion factors relating loss in weight and depth of penetration are useful in the assessment of corrosion.

$$\text{density of metal in grams/cubic centimetre} = d$$
$$\text{density of metal in kilograms/cubic metre} = 10^3 d$$

To convert B to A multiply by	*A*	*B*	*To convert A to B multiply by*
$10^{-3}\,d^{-1}$	millimetres	grams/square metre	$10^3 d$
$3.65 \times 10^{-1}\,d^{-1}$	millimetres/year	grams/square metre per day	$2.74\,d$
$8.76\,d^{-1}$	millimetres/year	grams/square metre per hour	$1.14 \times 10^{-1}\,d$
$3.937 \times 10^{-2}\,d^{-1}$	thousandths of an inch (mils)	grams/square metre	$2.54 \times 10\,d$
$1.44 \times 10\,d^{-1}$	mils/year	grams/square metre per day	$6.96 \times 10^{-2} d$
$3.45 \times 10^2\,d^{-1}$	mils/year	grams/square metre per hour	$2.90 \times 10^{-3} d$
$1.201 \times 10\,d^{-1}$	mils	ounces/square foot	$8.326 \times 10^{-2} d$

Table 2.9 TEST SIEVE MESH NUMBERS CONVERTED TO NOMINAL APERTURE SIZE FROM BS 410:1969

Wire cloth test sieves were designated by the mesh count or number. This method, widely used until 1962, was laid down in previous British Standards—BS 410. Sieves are now designated by aperture size: *see* BS 410:1969, for full details.

The table gives the previously used mesh numbers with the corresponding nominal aperture sizes, the preferred average wire diameters in the test sieves and the tolerances.

			Aperture tolerances		
Mesh No.	*Nominal aperture size* mm	*Preferred average wire diameter in test sieve* mm	*Max. tolerance for size of an individual aperture* mm +	*Tolerance for average aperture size* mm ±	*Intermediate tolerance* mm +
3	5.60	1.60	0.50	0.17	0.34

Mesh No.	*Nominal aperture size* mm	*Preferred average wire diameter in test sieve* μm	*Max. tolerance for size of an individual aperture* μm +	*Tolerance for average aperture size* μm ±	*Intermediate tolerance* μm +
150	106	71	43	7.4	25
170	90	63	43	6.6	25
200	75	50	41	6.1	24
240	63	45	41	5.3	23
300	53	36	38	4.8	21
350	45	32	38	4.8	21
400	38	30	36	4.0	20

Notes:
(1) No aperture size shall exceed the nominal by more than the maximum tolerance.
(2) The average aperture size shall not be greater or smaller than the nominal by more than the average tolerance size.
(3) Not more than 6% of the apertures shall be above the nominal size by more than the intermediate tolerance.

For perforated plate sieve sizes with square or round holes—*see* BS 410:1969. Other national standards for test sieves may be found for France in NF X11–501, for Germany in DIN 4188 and for USA in ASTM E11–61.

2.1.2   Temperature scale conversions

The absolute unit of temperature, symbol K, is the kelvin which is 1/273.16 of the thermodynamic temperature of the triple point of water—*see* Section 16. Practical temperature scales are Celsius (previously Centigrade) symbol °C, and Fahrenheit, symbol °F. An absolute scale based on Fahrenheit is the Rankine, symbol °R.

Where K, C, F and R, represent the same temperature on the Kelvin, Celsius, Fahrenheit and Rankine scales, conversion formulae are:

$$K = C + 273.15 \qquad C = \frac{5}{9}(F - 32)$$

$$F = \frac{9}{5}C + 32 \qquad R = F + 459.67$$

Rapid approximate conversions between Celsius and Fahrenheit scales can be obtained from Figure 2.1.

2.2   Mathematical formulae and statistical principles

2.2.1   Algebra

IDENTITIES

$$a^2 - b^2 = (a - b)(a + b)$$
$$a^2 + b^2 = (a - ib)(a + ib) \quad \text{where i} = \sqrt{-1}$$
$$a^3 - b^3 = (a - b)(a^2 + ab + b^2)$$
$$a^3 + b^3 = (a + b)(a^2 - ab + b^2)$$
$$a^n - b^n = (a - b)(a^{n-1} - a^{n-2}b + \cdots + b^{n-1})$$
$$a^n + b^n = (a + b)(a^{n-1} - a^{n-2}b + \cdots + b^{n-1}) \quad \text{when } n \text{ is odd}$$
$$(a \pm b)^2 = a^2 \pm 2ab + b^2$$
$$(a \pm b)^3 = a^3 \pm 3a^2b + 3ab^2 \pm b^3$$

°C ⇌ °F   °C ⇌ °F   °C ⇌ °F   °C ⇌ °F   °C ⇌ °F   °C ⇌ °F

Figure 2.1   *Nomogram for approximate interconversion between Celsius and Fahrenheit temperature scales*

$$(a + b)^n = a^n + na^{n-1}b + \frac{n(n - 1)}{2!}a^{n-2}b^2$$

$$+ \cdots + \frac{n(n - 1)(n - 2)\cdots(n - r + 1)}{r!}a^{n-r}b^r + \cdots + b^n = \sum_{x=0}^{n}\binom{n}{x}a^{n-x}b^x$$

RATIO AND PROPORTION

If

$$\frac{a}{b} = \frac{c}{d}$$

then

$$\frac{a + b}{b} = \frac{c + d}{d}$$

and

$$\frac{a - b}{b} = \frac{c - d}{d}$$

In general,

$$\frac{a}{b} = \frac{c}{d} = \frac{e}{f} = \cdots = \left(\frac{pa^n + qc^n + re^n + \cdots}{pb^n + qd^n + rf^n + \cdots}\right)^{1/n}$$

where p, q, r and n are any quantities whatever.

LOGARITHMS

If

$$a^x = N, \quad \text{then } x = \log_a N$$

$$\log_a MN = \log_a M + \log_a N$$

$$\log_a \frac{M}{N} = \log_a M - \log_a N$$

$$\log_a(M^p) = p\log_a M$$

$$\log_a(M^{1/r}) = \frac{1}{r}\log_a M$$

$$\log_b N = \frac{1}{\log_a b} \times \log_a N$$

In particular,

$$\log_e N = 2.302\,58509 \times \log_{10} N \qquad e = 2.718\,28$$

$$\log_{10} N = 0.434\,294\,48 \times \log_e N$$

$$\log_e N \equiv \ln N \qquad \log_{10} N \equiv \lg N$$

THE QUADRATIC EQUATION

The general quadratic equation may be written

$$ax^2 + bx + c = 0$$

Solution $\quad x = \dfrac{-b \pm \sqrt{b^2 - 4ac}}{2a}$

If

$$\Delta = (b^2 - 4ac)$$

the roots are real and equal if $\Delta = 0$
the roots are imaginary and unequal if $\Delta < 0$
the roots are real and unequal if $\Delta > 0$

Also, if the roots are α and β,

$$\alpha + \beta = -\frac{b}{a}$$

$$\alpha\beta = \frac{c}{a}$$

THE CUBIC EQUATION

The general cubic equation may be written

$$y^3 + a_1 y^2 + a_2 y + a_3 = 0$$

If we put $y = x - \frac{1}{3}a_1$ the equation reduces to $x^3 + ax + b = 0$, where

$$a = a_2 - \frac{1}{3}a_1^2 \quad \text{and} \quad b = \frac{2}{27}a_1^3 - \frac{1}{3}a_1 a_2 + a_3$$

Solution $x = z + v$ or $-\dfrac{z+v}{2} \pm i\sqrt{3}\left(\dfrac{z-v}{2}\right)$,

where

$$z = \sqrt[3]{-\frac{1}{2}b + \sqrt{\frac{b^2}{4} + \frac{a^3}{27}}}$$

and

$$v = \sqrt[3]{-\frac{1}{2}b - \sqrt{\frac{b^2}{4} + \frac{a^3}{27}}}$$

Alternatively,[*]

$$x = 2\sqrt{\left(\frac{-a}{3}\right)}\cos\frac{\theta + 2k\pi}{3} \quad (k = 0, 1, 2)$$

where

$$\cos\theta = -\frac{b}{2}\left(\frac{-a^3}{27}\right)^{-1/2}$$

If

$$\Delta = \frac{b^2}{4} + \frac{a^3}{27}$$

there are two equal and one unequal root if $\Delta = 0$
three real roots if $\Delta < 0$
one real and two complex roots if $\Delta > 0$

---

[*] The second form of the solution is particularly useful when $\Delta < 0$ (i.e. in the case of three real roots).

2.2.2 Series and progressions

NUMERICAL SERIES

$$1 + 2 + 3 + \cdots + n = \frac{n}{2}(n+1)$$

$$1^2 + 2^2 + 3^2 + \cdots + n^2 = \frac{n}{6}(n+1)(2n+1)$$

$$1^3 + 2^3 + 3^3 + \cdots + n^3 = \frac{n^2}{4}(n+1)^2$$

ARITHMETIC PROGRESSION

$$a, a + d, a + 2d, \ldots, a + (n-1)d$$

$$S_n = \frac{n}{2}[2a + (n-1)d]$$

where S_n denotes the sum to n terms.

GEOMETRIC PROGRESSION

$$a, ar, ar^2, \ldots, ar^{n-1}$$

$$S_n = \frac{a(r^n - 1)}{(r-1)} = \frac{a(1 - r^n)}{(1 - r)}$$

where S_n denotes the sum to n terms.

If $\quad r^2 < 1 \quad$ and $\quad n \to \infty,$

$$S_\infty = \frac{a}{(1 - r)}$$

TAYLOR'S SERIES

$$f(x) = f(a) + (x - a)f'(a) + \frac{(x - a)^2}{2!}f''(a) + \frac{(x - a)^3}{3!}f'''(a) + \cdots$$

MACLAURIN'S SERIES

$$f(x) = f(0) + xf'(0) + \frac{x^2}{2!}f''(0) + \frac{x^3}{3!}f'''(0) + \cdots$$

In the following series, the region of convergence is indicated in parentheses. If no region is shown, the series is convergent for all values of x.

BINOMIAL SERIES

$$(1 \pm x)^n = 1 \pm nx + \frac{n(n-1)}{2!}x^2 \pm \frac{n(n-1)(n-2)}{3!}x^3 + \cdots \quad (x^2 < 1)$$

$$(1 \pm x)^{-n} = 1 \mp nx + \frac{n(n+1)}{2!}x^2 \mp \frac{n(n+1)(n+2)}{3!}x^3 + \cdots \quad (x^2 < 1)$$

LOGARITHMIC SERIES

$$\log_e(1 \pm x) = \pm x - \frac{x^2}{2} \pm \frac{x^3}{3} - \frac{x^4}{4} \pm \cdots \quad (x^2 < 1)$$

$$\log_e \frac{(1+x)}{(1-x)} = 2 \left(x + \frac{x^3}{3} + \frac{x^5}{5} + \cdots \right) \quad (x^2 < 1)$$

$$\log_e x = 2 \left[\frac{x-1}{x+1} + \frac{1}{3} \left(\frac{x-1}{x+1} \right)^3 + \frac{1}{5} \left(\frac{x-1}{x+1} \right)^5 + \cdots \right] \quad (x > 0)$$

$$\log_e(a + x) = \log_e a + 2 \left[\frac{x}{2a+x} + \frac{1}{3} \left(\frac{x}{2a+x} \right)^3 + \frac{1}{5} \left(\frac{x}{2a+x} \right)^5 + \cdots \right]$$

$$(a > 0, \; x + a > 0)$$

EXPONENTIAL SERIES

$$e = 1 + 1 + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \cdots$$

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \cdots$$

$$a^x = 1 + x \log_e a + \frac{(x \log_e a)^2}{2!} + \frac{(x \log_e a)^3}{3!} + \cdots$$

TRIGONOMETRIC SERIES

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \cdots$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \cdots$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{15} + \frac{17x^7}{315} + \frac{62x^9}{2835} + \cdots \quad \left(-\frac{\pi}{2} < x < \frac{\pi}{2} \right)$$

$$\sin^{-1} x = x + \frac{1}{2} \cdot \frac{x^3}{3} + \frac{1}{2} \cdot \frac{3}{4} \cdot \frac{x^5}{5} + \frac{1}{2} \cdot \frac{3}{4} \cdot \frac{5}{6} \cdot \frac{x^7}{7} + \cdots \quad (-1 \le x \le 1)$$

$$\cos^{-1} x = \frac{\pi}{2} - \sin^{-1} x$$

$$\tan^{-1} x = x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7} + \cdots \quad (-1 \le x \le 1)$$

If

$$x = 1, \frac{\pi}{4} = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \cdots$$

$$\cot^{-1} x = \frac{\pi}{2} - \tan^{-1} x$$

SERIES FOR HYPERBOLIC FUNCTIONS

$$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \cdots$$

$$\cosh x = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \cdots$$

$$\tanh x = x - \frac{x^3}{3} + \frac{2x^5}{5} - \frac{17x^7}{315} + \frac{62x^9}{2835} + \cdots \quad \left(-\frac{\pi}{2} < x < \frac{\pi}{2}\right)$$

$$\sinh^{-1} x = x - \frac{1}{2} \cdot \frac{x^3}{3} + \frac{1}{2} \cdot \frac{3}{4} \cdot \frac{x^5}{5} - \frac{1}{2} \cdot \frac{3}{4} \cdot \frac{5}{6} \cdot \frac{x^7}{7} + \cdots \quad (-1 < x < 1)$$

$$\tanh^{-1} x = x + \frac{x^3}{3} + \frac{x^5}{5} + \frac{x^7}{7} + \cdots \quad (-1 < x < 1)$$

$$\coth^{-1} x = \frac{1}{x} + \frac{1}{3x^3} + \frac{1}{5x^5} + \frac{1}{7x^7} + \cdots \quad (-1 < x < 1)$$

  $\qquad\qquad\quad = 4\pi r'^2 t + \dfrac{\pi}{3}t^3$

where t = thickness $= R - r$

and r' = mean radius $= \frac{1}{2}(R + r)$

*Right circular cylinder.** Height $= h$, radius $= r$

Area of curved surface $= 2\pi rh$

Total surface area $= 2\pi r(h + r)$

Volume $= \pi r^2 h$

Right circular cone.† Radius of base $= r$, height $= h$

Area of curved surface $= \pi r \sqrt{r^2 + h^2}$

Volume $= \dfrac{\pi}{3} r^2 h$

Area of curved surface of frustrum (radii R and r) $= \pi(R + r)\sqrt{h^2 + (R - r)^2}$

Volume of frustrum (radii R and r) $= \dfrac{\pi h}{3}(R^2 + Rr + r^2)$

2.2.5   Co-ordinate geometry (two dimensions, rectangular axes)

The length d of the straight line joining the points $A(x_1, y_1)$ and $B(x_2, y_2)$ is given by

$$d = \pm\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}$$

If $P(x, y)$ is a point on AB such that $\dfrac{AP}{PB} = \dfrac{m}{n}$,

$$x = \frac{mx_2 + nx_1}{m + n}; \quad y = \frac{my_2 + ny_1}{m + n}$$

STRAIGHT LINE

The general equation to a straight line is,

$$ax + by + c = 0$$

$$\text{Slope} = -\frac{a}{b}. \text{ Intercept on } y\text{-axis} = -\frac{c}{b}$$

Alternative forms are

1. $\dfrac{y_2 - y_1}{x_2 - x_1} = \dfrac{y - y_1}{x - x_1}$ for the line joining the points (x_1, y_1) and (x_2, y_2)

2. $y = mx + c$ for the line of slope, m, cutting y-axis at point $(0, c)$.

3. $y - y_1 = m(x - x_1)$ for the line through the point (x_1, y_1), slope m.

4. $\dfrac{x}{a} + \dfrac{y}{b} = 1$ for the line making intercepts of a and b on the axes of x and y, respectively.

5. $x\cos\alpha + y\sin\alpha = p$, where p is the length of the perpendicular from the origin to the line and α is the angle between the perpendicular and the positive direction of the x-axis.

The perpendicular distance d from the point (x_1, y_1) to the line $ax + by + c = 0$ is

$$d = \pm\frac{ax_1 + by_1 + c}{\sqrt{a^2 + b^2}}$$

---

* Volume of *any* cylinder $=$ area of base $\times$ vertical height.

† Volume of *any* cone or pyramid $= \frac{1}{3}$ [area of base $\times$ perpendicular distance from vertex to base].

The angle θ between two lines of slopes m_1 and m_2 is given by:

$$\tan\theta = \frac{m_1 - m_2}{1 + m_1 m_2}$$

If the two lines are parallel, $m_1 = m_2$
If the two lines are perpendicular, $m_1 m_2 = -1$

TRIANGLE

The area of a triangle, vertices (x_1, y_1), (x_2, y_2) and (x_3, y_3) is

$$\Delta = \frac{1}{2}(x_1 y_2 - x_2 y_1 + x_2 y_3 - x_3 y_2 + x_3 y_1 - x_1 y_3)$$

CIRCLE

The general equation to a circle is

$$x^2 + y^2 + 2gx + 2fy + c = 0$$
$$\text{centre}(-g, -f); \quad \text{radius} = \sqrt{g^2 + f^2 - c}$$

Equation to tangent at the point (x_1, y_1) on the circle is

$$xx_1 + yy_1 + g(x + x_1) + f(y + y_1) + c = 0$$

An alternative form of the equation to the circle is

$$(x - a)^2 + (y - b)^2 = R^2,$$
$$\text{centre}(a, b); \quad \text{radius} = R$$

ELLIPSE

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1. \text{ Centre at origin and semi-axes } a \text{ and } b$$

Equation to tangent at point (x_1, y_1) is $\dfrac{xx_1}{a^2} + \dfrac{yy_1}{b^2} = 1$

PARABOLA

$$y^2 = 4ax. \text{ Vertex at origin, } latus\ rectum = 2a$$

Equation to tangent at point (x_1, y_1) is $yy_1 = 2a(x + x_1)$

HYPERBOLA

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1. \text{ Centre at origin and semi-axes } a \text{ and } b$$

Equation to tangent at point (x_1, y_1) is $\dfrac{xx_1}{a^2} - \dfrac{yy_1}{b^2} = 1$

The asymptotes are $\dfrac{x}{a} \pm \dfrac{y}{b} = 0$

$\mathrm{d}\sin x = \cos x\ \mathrm{d}x$

$\mathrm{d}\cos x = -\sin x\ \mathrm{d}x$

$\mathrm{d}\tan x = \sec^2 x\ \mathrm{d}x$

$\mathrm{d}\cot x = -\operatorname{cosec}^2 x\ \mathrm{d}x$

$\mathrm{d}\sec x = \tan x \sec x\ \mathrm{d}x$

$\mathrm{d}\operatorname{cosec} x = -\cot x \operatorname{cosec} x\ \mathrm{d}x$

$\mathrm{d}\operatorname{vers} x = \sin x\ \mathrm{d}x$

$\mathrm{d}\sin^{-1} x = (1 - x^2)^{-1/2}\ \mathrm{d}x$

$\mathrm{d}\cos^{-1} x = -(1 - x^2)^{-1/2}\ \mathrm{d}x$

$\mathrm{d}\tan^{-1} x = (1 + x^2)^{-1}\ \mathrm{d}x$

$\mathrm{d}\cot^{-1} x = -(1 + x^2)^{-1}\ \mathrm{d}x$

$\mathrm{d}\sec^{-1} x = x^{-1}(x^2 - 1)^{-1/2}\ \mathrm{d}x$

$\mathrm{d}\operatorname{cosec}^{-1} x = -x^{-1}(x^2 - 1)^{-1/2}\ \mathrm{d}x$

$\mathrm{d}\operatorname{vers}^{-1}x = (2x - x^2)^{-1/2}\ \mathrm{d}x$

$\mathrm{d}\sinh x = \cosh x\ \mathrm{d}x$

$\mathrm{d}\cosh x = \sinh x\ \mathrm{d}x$

$\mathrm{d}\tanh x = \operatorname{sech}^2 x\ \mathrm{d}x$

$\mathrm{d}\coth x = -\operatorname{cosech}^2 x\ \mathrm{d}x$

$\mathrm{d}\operatorname{sech} x = -\operatorname{sech} x \tanh x\ \mathrm{d}x$

$\mathrm{d}\operatorname{cosech} x = -\operatorname{cosech} x \coth x\ \mathrm{d}x$

$\mathrm{d}\sinh^{-1} x = (x^2 + 1)^{-1/2}\ \mathrm{d}x$

$\mathrm{d}\cosh^{-1} x = (x^2 - 1)^{-1/2}\ \mathrm{d}x$

$\mathrm{d}\tanh^{-1} x = (1 - x^2)^{-1}\ \mathrm{d}x$

$\mathrm{d}\coth^{-1} x = -(x^2 - 1)^{-1}\ \mathrm{d}x$

$\mathrm{d}\operatorname{sech}^{-1}x = -x^{-1}(1 - x^2)^{-1/2}\ \mathrm{d}x$

$\mathrm{d}\operatorname{cosech}^{-1}x = -x^{-1}(x^2 + 1)^{-1/2}\ \mathrm{d}x$

INTEGRALS

Elementary forms

1. $\displaystyle\int a\ \mathrm{d}x = ax$

2. $\displaystyle\int a \cdot \mathrm{f}(x)\ \mathrm{d}x = a \int \mathrm{f}(x)\ \mathrm{d}x$

3. $\displaystyle\int \phi(y)\ \mathrm{d}x = \int \frac{\phi(y)}{y'}\ \mathrm{d}y, \quad \text{where } y' = \frac{\mathrm{d}y}{\mathrm{d}x}$

4. $\displaystyle\int (u + v)\ \mathrm{d}x = \int u\ \mathrm{d}x + \int v\ \mathrm{d}x, \quad \text{where } u \text{ and } v \text{ are any functions of } x$

5. $\displaystyle\int u\ \mathrm{d}v = uv - \int v\ \mathrm{d}u$

6. $\displaystyle\int u\frac{\mathrm{d}v}{\mathrm{d}x}\mathrm{d}x = uv - \int v\frac{\mathrm{d}v}{\mathrm{d}x}\mathrm{d}x$

7. $\displaystyle\int x^n\ \mathrm{d}x = \frac{x^{n+1}}{n+1}, \quad (n \neq -1)$

---

* From *Handbook of Chemistry and Physics*, Cleveland, Ohio, 1945.
[†] Differentials have been written as above for ease in use, e.g. $\mathrm{d}ax = a\mathrm{d}x$ instead of $(\mathrm{d}/\mathrm{d}x)ax = a$, which is the mathematically correct.

8. $\int \dfrac{f'(x)\,dx}{f(x)} = \log f(x), \quad [d\,f(x) = f'(x)\,dx]$

9. $\int \dfrac{dx}{x} = \log x, \quad \text{or} \quad \log(-x)$

10. $\int \dfrac{f'(x)\,dx}{2\sqrt{f(x)}} = \sqrt{f(x)} \quad [d\,f(x) = f'(x)\,dx]$

11. $\int e^x\,dx = e^x$

12. $\int e^{ax}\,dx = \dfrac{e^{ax}}{a}$

13. $\int b^{ax}\,dx = \dfrac{b^{ax}}{a\log b}$

14. $\int \log x\,dx = x\log x - x$

15. $\int a^x \log a\,dx = a^x$

16. $\int \dfrac{dx}{a^2 + x^2} = \dfrac{1}{a}\tan^{-1}\left(\dfrac{x}{a}\right), \quad \text{or} \quad -\dfrac{1}{a}\cot^{-1}\left(\dfrac{x}{a}\right)$

17. $\int \dfrac{dx}{a^2 - x^2} = \dfrac{1}{a}\tanh^{-1}\left(\dfrac{x}{a}\right), \quad \text{or} \quad \dfrac{1}{2a}\log\dfrac{a+x}{a-x}$

18. $\int \dfrac{dx}{x^2 - a^2} = -\dfrac{1}{a}\coth^{-1}\left(\dfrac{x}{a}\right), \quad \text{or} \quad \dfrac{1}{2a}\log\dfrac{x-a}{x+a}$

19. $\int \dfrac{dx}{\sqrt{a^2 - x^2}} = \sin^{-1}\left(\dfrac{x}{a}\right), \quad \text{or} \quad -\cos^{-1}\left(\dfrac{x}{a}\right)$

20. $\int \dfrac{dx}{\sqrt{x^2 \pm a^2}} = \log[x + \sqrt{x^2 \pm a^2}]$

21. $\int \dfrac{dx}{x\sqrt{x^2 - a^2}} = \dfrac{1}{a}\cos^{-1}\left(\dfrac{a}{x}\right)$

22. $\int \dfrac{dx}{x\sqrt{a^2 \pm x^2}} = -\dfrac{1}{a}\log\left[\dfrac{a + \sqrt{a^2 \pm x^2}}{x}\right]$

23. $\int \dfrac{dx}{x\sqrt{a + bx}} = \dfrac{2}{\sqrt{-a}}\tan^{-1}\sqrt{\dfrac{a+bx}{-a}}, \quad \text{or} \quad \dfrac{-2}{\sqrt{a}}\tanh^{-1}\sqrt{\dfrac{a+bx}{a}}$

More complex integrals are to be found in *Handbook of Chemistry and Physics*, Cleveland, Ohio, 1945.

DIFFERENTIAL EQUATIONS

Equations of the first order

1. $\dfrac{dy}{dx} = f(x)\phi(y)$ (Variable separable type)

   Solution $\int \dfrac{dy}{\phi(y)} = \int f(x)\,dx + A$

2a. $\dfrac{dy}{dx} = f\left(\dfrac{y}{x}\right)$ (Homogeneous equation)

Let $v = \dfrac{y}{x}$

Solution $\displaystyle\int \dfrac{dv}{f(v) - v} = \log x + A$

2b. $\dfrac{dy}{dx} = \dfrac{ax + by + c}{a'x + b'y + c'}$ (Reducible to homogeneous form if $a'b - ab' \neq 0$)

Let $x = X + h;\ y = Y + k$, where h and k are the values of x and y which satisfy equations

$$\left.\begin{array}{l} ax + by + c = 0 \\ a'x + b'y + c' = 0 \end{array}\right\}$$

Solution   obtained as in (2a) by putting $Y = vX$

3. $M\,dx + N\,dy = 0$ where M and N are functions of x and y and

$$\dfrac{\partial M}{\partial y} = \dfrac{\partial N}{\partial x} \quad \text{(Exact equation)}$$

Here, a function $u(x, y)$ exists such that

$$du = M\,dx + N\,dy$$

Solution $u = \displaystyle\int M\,dx\,(y\text{ constant}) + \int (\text{terms in } N \text{ independent of } x)\,dy = \text{constant}$

4. $\dfrac{dy}{dx} + Py = Q$ (Linear equation)

where P and Q are functions of x only (or constants).

Solution $y\,e^{\int P\,dx} = \displaystyle\int Q\,e^{\int P\,dx}\,dx + A$ (Integrating factor $= e^{\int P\,dx}$)

5. $\dfrac{dy}{dx} + Py = Qy^n$ (Bernouilli's equation)

where P and Q are functions of x only (or constants).
   Multiplying both sides of the equation by $(1 - n)y^{-n}$, and putting $z = y^{1-n}$ the equation becomes

$$\dfrac{dz}{dx} + (1 - n)Pz = (1 - n)Q$$

   This equation is linear.
Solution   obtained as in 4. [Integrating factor $= e^{\int (1-n)P\,dx}$]

6. $y = x\dfrac{dy}{dx} + f\left(\dfrac{dy}{dx}\right)$ (Clairaut's form)

Let $\dfrac{dy}{dx} = p$ and differentiate the equation with respect to x,

$$\dfrac{dp}{dx}[x + f'(p)] = 0$$

Solution $\dfrac{dp}{dx} = 0$ or $x + f'(p) = 0$

i.e. $p = \text{constant} = A$ or $y = Ax + B$

This solution is obtained by eliminating p from this equation and the original equation. The solution contains no arbitrary constant and is known as the *singular solution*.

Equations of the second order

7. $\dfrac{d^2y}{dx^2} = f(x)$

Solution $y = \displaystyle\int F(x)\,dx + Ax + B,$ where $F(x) = \displaystyle\int f(x)\,dx$

8. $\dfrac{d^2y}{dx^2} = f(y)$

   Let $\dfrac{dy}{dx} = p$; $\dfrac{1}{2}p^2 = \displaystyle\int f(y)\,dy + A$

   Integration of this equation of the first order may then lead to the required solution.

9.* $a\dfrac{d^2y}{dx^2} + b\dfrac{dy}{dx} + cy = 0$ (Linear equation, constant coefficients, RHS $= 0$)

   Auxilliary equation. $am^2 + bm + c = 0$
   Solution

   (a) If $b^2 > 4ac$ (roots m_1 and m_2), $Ae^{m_1 x} + Be^{m_2 x}$
   (b) If $b^2 = 4ac$ (two equal roots, m_1), $e^{m_1 x}(Ax + B)$
   (c) If $b^2 < 4ac$ (roots $m_1 \pm im_2$), $e^{m_1 x}(A \sin m_2 x + B \cos m_2 x)$
   $\qquad\qquad$ or $Ce^{m_1 x} \sin (m_2^x + \alpha)$
   $\qquad\qquad$ or $Ce^{m_1 x} \cos (m_2^x - \alpha)$

10.* $a\dfrac{d^2y}{dx^2} + b\dfrac{dy}{dx} + cy = P$ (Linear equation, constant coefficients, RHS a function of x only)

   Solution $y =$ complementary function + particular integral.
   The *complementary function* is the solution of the equation when $P = 0$ [*see* (9)].
   The *particular integral* is *any* solution of the equation which involves no arbitrary constants.
   The following examples of values of the particular integral may be useful:

   (a) $P =$ constant $= m$

   $\qquad$ *Particular solution* $y = \dfrac{m}{c}$

   (b) $P = p + qx + rx^2 + \cdots$ $(p, q, r \ldots$ are constants)
   $\qquad$ *Particular solution* $y = A + Bx + Cx^2 + \cdots$
   $\qquad\qquad$ If $C \neq 0, P$ and y are of the same degree.
   $\qquad\qquad$ If $C = 0, P$ and $\dfrac{dy}{dx}$ are of the same degree.

   (c) $P = k\,e^{mx}$
   $\qquad$ *Particular solution* $y = A\,e^{mx}$
   $\qquad\qquad$ If e^{mx} is a term of the complementary function, try $y = Ax\,e^{mx}$
   $\qquad\qquad$ If $x\,e^{mx}$ is a term of the complementary function, try $y = Ax^2\,e^{mx}$.

   (d) $P = l \sin nx + m \cos nx$ (l and m constants, or zero)
   $\qquad$ *Particular solution* $y = A \sin nx + B \cos nx$
   $\qquad\qquad$ If $C \sin nx + D \cos nx$ is a term of the complementary function try
   $\qquad\qquad$ $Ax \sin nx + Bx \cos$

Note: The constants *A, B, C, D,* etc. in the particular solutions are evaluated by substitution in the original equation.

2.2.7   Introduction to statistics

2.2.7.1   *Introduction and cross-references*

This section provides a brief introduction to statistics (Sections 2.2.7.2 and 2.2.7.3) and statistical process control theory (Section 2.2.7.4). Related material includes Sections 10.5 (Quantitative Image Analysis) and especially 40.4 (Metallurgical Process Control).

   The field of statistics is the science of collecting and summarising data and drawing inferences from the resulting data summary. The field is divided into two branches: descriptive statistics (section 2.2.7.2) and inductive (or inferencial) statistics (section 2.2.7.3).

2.2.7.2   *Descriptive statistics*

Descriptive statistics comprises of all methods that summarise collected data and is subdivided into 2 categories: (i) Numerical (or quantitative) measures of the mean (or the centre), and of variability. (ii) Pictorial and tabular measures: which consist of histograms and boxplots.

MEASURES OF CENTRE

Mean (or arithmetic average), median, geometric mean, harmonic mean, and the mode.

Example 1

The following data reports the oxidation-induction time (in minutes), X, for various commercial oils (data from Lubrication Engr., 1984: 75–83).
   87, 103, 130, 160, 180, 195, 132, 145, 211, 105, 145, 153, 152, 138, 87, 99, 93, 119, 129 minutes.
Since there are 19 sample values, then the sample size is n = 19.
   The value of the 1st observation is $x_1 = 87$, the 2nd observation is $x_2 = 103, \ldots$, and the nth sample value is $x_n = 129$.
   The sample (arithmetic) mean is defined as

$$\bar{x} = \frac{1}{n} \sum_{i=1}^{n} x_i$$

For the above data $\sum_{i=1}^{19} x_i = 2\,563$, and hence the value of the sample mean is $\bar{x} = 2\,563/19 = 134.894\,7$ minutes.
   In order to obtain the median, the data has to be put in order statistic format (i.e. rearranged from the smallest observation to the largest). The order statistics for the above data are $x_{(1)} = 87$, $x_{(2)} = 87$, $x_{(3)} = 93$, $x_{(4)} = 99$, $x_{(5)} = 103$, $x_{(6)} = 105$, $x_{(7)} = 119$, $x_{(8)} = 129$, $x_{(9)} = 130$, $x_{(10)} = 132$, $x_{(11)} = 138$, $x_{(12)} = 145$, $x_{(13)} = 145$, $x_{(14)} = 152$, $x_{(15)} = 153$, $x_{(16)} = 160$, $x_{(17)} = 180$, $x_{(18)} = 195$, $x_{(n)} = 211$. If the value of n is odd, like in this example, then the median or the 50th percentile is simply the value of the middle order statistic $x_{((n+1)/2)}$.
   For our example, the median is $\hat{x}_{0.50} = \tilde{x} = x_{(10)} = 132$. However, if the data contain an even number of observations such as n = 10, then the sample median is given by $\hat{x}_{0.50} = \tilde{x} = (x_{(n/2)} + x_{(1+(n/2))})/2$. As an example, the lifetimes of 10 incandescent lamps (in ascending order) are 2 120, 2 250, 2 690, 4 450, 4 800, 4 950, 5 700, 5 840, 5 888, 6 990 hours. The median for this data is the average of the 5th and the 6th order statistics, i.e. $\hat{x}_{0.50} = \tilde{x} = (4\,800 + 4\,950)/2 = 4\,875$ hours. Note that, unless the data contain outliers or is very skewed (i.e. asymmetrical), the values of the sample mean and median should generally be fairly close. The mean time to failure (MTTF) of the ten lamps is $\bar{x} = 4\,567.800$ hours.
   The Geometric mean is defined as $\bar{x}_g = (x_1, x_2, \ldots, x_n)^{1/n}$, i.e. $\bar{x}_g$ is the nth root of the product of all n sample items, $\prod_{i=1}^{n} x_i$, only if all x_i's > 0 for all i, and in general $\bar{x}_g \leq \bar{x}$. For the data of Example 1, $\bar{x}_g = (\prod_{i=1}^{19} x_i)^{1/19} = 130.564\,812 < 134.894\,7 = \bar{x}$. Geometric mean has applications in DOE (design of experiments) where at least 2 responses from each experimental unit are measured.
   The Harmonic mean is defined as $\bar{x}_h = \left[\sum_{i=1}^{n} (1/x_i)/n\right]^{-1} = (n/\Sigma(1/x_i))$, $x_i \neq 0$ for all i, i.e. $\bar{x}_h$ is the inverse of the average inverses of x_i's. For the data of Example 1:

$$\sum_{i=1}^{19} (1/x_i) = (1/87) + (1/103) + (1/130) + \cdots + (1/129) = 0.150\,325\,6 \longrightarrow$$

$$\bar{x}_h = \frac{19}{0.150\,325\,588\,522\,53} = 126.392\,3 < \bar{x}_g.$$

The Harmonic mean has applications in ANOVA (analysis of variance) when the design is unbalanced and gives the average sample size over all levels of a factor, and in general $\bar{x}_h \leq \bar{x}_g \leq \bar{x}$.
   The mode is the observation with the highest frequency. For the data of Example 1, MO1 = 87 and MO2 = 145 because both observations 87 and 145 have a frequency f = 2 (i.e. the data is bimodal). Most populations that should not be stratified for the purpose of sampling generally have a single mode. If a manufacturing product dimension has more than one mode, then there are quality problems with the process that manufactures the product. This is due to the fact that the ideal situation occurs when there is a single mode with a very high frequency at the ideal target of the product dimension.

MEASURES OF VARIABILITY

We present two measures of variability: the 1st measure, defined by R/d_2, is used in statistical process control when the size of the sample $n \leq 12$. The random variable R represents the sample range defined as $R = x_{(n)} - x_{(1)}$, where $x_{(n)}$ is the nth order statistic (i.e. the sample maximum) and $x_{(1)}$ is the sample minimum (i.e. the 1st order statistic). The parameter $d_2 = E(R/\sigma)$; the quantity R/σ, where σ is the process standard deviation, is called the relative range in the field of statistics and E represents the expected value operator. For a normal universe, the values of d_2 are given in Table 2.12 below.

For $n > 15$, the sampling distribution of sample range, R, becomes unstable and hence it is inadvisable to use R as a measure of variation regardless of the underlying parent population.

The 2nd measure of variability, and the most common, is the standard deviation (stdev) $= S$. In order to compute the stdev, S, we must always compute the variance first.

The sample variance, SV, is the average of deviations of x_i ($i = 1, 2, \ldots, n$) from their-own-mean squared, i.e. $SV = \sum_{i=1}^{n}(x_i - \bar{x})^2/n$, but SV generally underestimates the population variance σ^2 because $E(SV) = ((n-1)/n)\sigma^2$, where E stands for the expected-value operator. This implies that SV is a biased estimator of σ^2. In order to get rid of this bias, the quantity $S^2 = (1/(n-1))\sum_{i=1}^{n}(x_i - \bar{x})^2$ is used as a measure of variability. Another reason for dividing the corrected sum of squares $CSS = \sum_{i=1}^{n}(x_i - \bar{x})^2$ by $(n-1)$, instead of n, in order to obtain a measure of variation, is the fact that the $CSS = \sum_{i=1}^{n}(x_i - \bar{x})^2$ has only $(n-1)$ degrees of freedom because of the constraint $\sum_{i=1}^{n}(x_i - \bar{x}) \equiv 0$. For the above two stated reasons, S^2 is loosely referred to as the sample variance. The square root of S^2 provides the stdev, S, and dividing S by $\sqrt{n}$ gives the (estimated) standard error of the mean $\hat{\sigma}_{\bar{x}} = S/\sqrt{n}$. A simple binomial expansion of $(x_i - \bar{x})^2$ shows that the $CSS = \sum_{i=1}^{n}(x_i - \bar{x})^2 = \sum_{i=1}^{n}x_i^2 - \left(\sum_{i=1}^{n}x_i\right)^2/(n) = USS - CF$, where $USS = \sum_{i=1}^{n}x_i^2$ is called the uncorrected sum of squares and $CF = \left(\sum_{i=1}^{n}x_i\right)^2/n = n(\bar{x})^2$ is called the correction factor.

For the data of Example 1, the value of the correction factor $CF = 2\,563^2/19 = 345\,735.210\,526\,316$, the USS $= 87^2 + 103^2 + 130^2 + \cdots + 129^2 = 368\,501$, and thus the CSS $= 368\,501 - 345\,735.210\,53 = 227\,65.789\,473\,7$. Since there are 19 sample values, then there are 18 degrees of freedom and as a result $S^2 = 22\,765.789\,473\,7/18 = 1\,264.766\,1$ minutes.[2] Clearly, the units of variance is that of the data's squared and hence the true measure of variation is the positive square root of variance, namely $S = \sqrt{S^2} = (1\,264.766\,1)^{1/2} = 35.56\,355$ minutes. Although in Example 1 the sample size $n = 19$ is a bit too large to use $\hat{\sigma} = R/d_2$ as a measure of variation, we will compute this statistic for comparative purposes. The values of d_2 for $n = 16, 17, 18, 19$, and 20 are 3.532, 3.588, 3.640, 3.689, and 3.735, respectively. The sample range for the data of the example is $R = 211 - 87 = 124$, and hence $\hat{\sigma} = R/d_2 = 124/3.689 = 33.613\,445\,4$. For majority of samples encountered in practice, the value of $\hat{\sigma} \leq S$. Note that $\hat{\sigma}$ without a subscript represents the stdev of individual elements in the sample while $\hat{\sigma}_{\bar{x}} = S/\sqrt{n}$ gives the estimate of the standard error of $\bar{x}$ given by $se(\bar{x}) = \sigma/\sqrt{n}$.

As yet another example, for the $n = 10$ time to failures of incandescent lamps (2 120, 2 250, 2 690, 4 450, 4 800, 4 950, 5 700, 5 840, 6 990 hours), $S = 1\,687.018\,264$ while $\hat{\sigma}_x = R/d_2 = 1\,582.196\,231\,32$, and $\hat{\sigma}_{\bar{x}} = 1\,687.018\,264/\sqrt{10} = 533.482\,02$.

HISTOGRAM

Grouping a data set in the form of a histogram is appropriate only for large samples, say $n > 40$ units. In order to illustrate the construction of a histogram for a large data set, we will go through an example in a stepwise fashion.

Example 2

The data set given below consists of $n = 58$ observations on shear strength of spot welds made on a certain type of sheet (arbitrary units).

Table 2.12   VALUES OF d_2 FOR A NORMAL UNIVERSE

n	2	3	4	5	6	7	8	9	10	11	12	13	14	15
d_2	1.128	1.693	2.059	2.326	2.534	2.704	2.847	2.970	3.078	3.173	3.258	3.336	3.407	3.472

5 434, 5 112, 4 820, 5 378, 5 027, 4 848, 4 755, 5 207, 5 049, 4 740, 5 248, 5 227, 4 931, 5 364, 5 189, 4 948, 5 015, 5 043, 5 260, 5 008, 5 089, 4 925, 5 621, 4 974, 5 173, 5 245, 5 555, 4 493, 5 640, 4 986, 4 521, 4 659, 4 886, 5 055, 4 609, 5 518, 5 001, 4 918, 4 592, 4 568, 4 723, 5 388, 5 309, 5 069, 4 570, 4 806, 4 599, 5 828, 4 772, 5 333, 4 803, 5 138, 4 173, 5 653, 5 275, 5 498, 5 582, 5 188.

The 1st task in developing a histogram is to decide on the number of subgroups, denoted by C. The two guidelines for C are $C \cong \sqrt{n}$ and Sturges' practical guideline $C \cong 1 + 3.3 \log_{10}(n)$. It can be verified that for $n \geq 40$, $\sqrt{n} \geq 1 + 3.3 \log_{10}(n)$, and thus we generally select $1 + 3.3 \log_{10}(n) \leq C \leq \sqrt{n}$ with the option that both $1 + 3.3 \log_{10}(n)$ and $\sqrt{n}$ can be either rounded down or up to the next positive integer in order to obtain the value of C. For our shear strength data, $\sqrt{58} = 7.62$ and $1 + 3.3 \log_{10}(58) = 6.82$, and hence $6 \leq C \leq 8$. We settle on the value of $C = 6$ subgroups (or classes) for our histogram.

The 2nd task is to determine the length, Δ, of a subgroup, where it is mandatory to have equal class interval length. This is given by $\Delta = R/C$, where it is necessary to always round up to the same number of decimals as the data. For our shear strength data, $R = 5\,828 - 4\,173 = 1\,655$ and hence the length of each subgroup is equal to $\Delta = 1\,655/6 = 276$. Note that if the value of R/C is not rounded up in order to obtain Δ, then in most cases the C subgroups will not span over the entire data range.

The 3rd step in developing a histogram is to determine the class limits and boundaries for each subgroup, bearing in mind that class limits must have the same number of decimals as the original data while boundaries must have one more decimal than the original data. Table 2.13 gives the frequency distribution for the shear strength data, which clearly shows that the upper limit of the 1st subgroup is 4 448 and the lower class limit of the 2nd subgroup is 4 449. However, the upper boundary of the 1st class is $UB_1 = 4\,448.5$ which is equal to the lower boundary of the 2nd subgroup LB_2, i.e. $UB_1 = LB_2 = 4\,448.5$. In a similar manner, $UB_2 = LB_3 = 4\,724.5$, $UB_3 = LB_4 = 5\,000.5$, $UB_4 = LB_5 = 5\,276.5$, and $UB_5 = LB_6 = 5\,552.5$. Further, $\Delta_j = UB_j - LB_j = \Delta = 276$ for all j, and because there cannot be any overlapping of successive subgroups, then the $\sum_{j=1}^{C} f_j$ must always add to n (=58 in this case). The midpoint of the jth subgroup is given by $m_j = (UB_j + LB_j)/2$, or the average of upper and lower class limits of the same subgroup. Table 2.13 shows that $m_1 = (4\,448 + 4\,173)/2 = 4\,310.5$, $m_2 = (4\,724.5 + 4\,448.5)/2 = 4\,586.5, \ldots, m_6 = 5\,690.5$; note that Δ must equal to $m_j - m_{j-1}$ for $j = 2, 3, 4, \ldots, C$, i.e. $\Delta = m_j - m_{j-1}$. The histogram from Minitab software is provided in Figure 2.2.

Table 2.13   FREQUENCY DISTRIBUTION FOR DATA IN EXAMPLE 2

Subgroup Limits	4 173–4 448	4 449–4 724	4 725–5 000
f_j	1	9	14
Class Limits	5 001–5 276	5 277–5 552	5 553–5 828
f_j	20	8	6
Figure 2.2   *Histogram of Shear Strength (SHST) Data*

If an experimenter does not possess the raw data but only the histogram is available, then the computing formulas for the mean and standard deviation for grouped data may be used as given below:

$$\bar{x}_g = \frac{1}{n} \sum_{j=1}^{C} (m_j \times f_j),$$

where the subscript g stands for grouped, and

$$S_g^2 = \frac{1}{n-1} \sum_{j=1}^{C} (m_j - \bar{g})^2 \times f_j = \frac{1}{n-1} \left[\sum_{j=1}^{C} m_j^2 \times f_j - \frac{(\sum_{j=1}^{C} m_j \times f_j)^2}{n} \right].$$

The raw mean and standard deviation for the shear strength data are $\bar{x} = 5\,057.552$ and $S = 344.680\,9$, while those of the histogram in Figure 2.2 are $\bar{x}_g = 5\,067.1207$ and $S_g = 341.218\,3$.

THE BOXPLOT

A boxplot is a graphical measure of variability, and it can also assess if the data contain mild or extreme outliers. For the sake of illustration, we will obtain the boxplot for the data of Example 2 in a stepwise manner.

Step 1.   Draw a vertical line through the median $\tilde{x} = x_{0.50} = 5\,046$.
Step 2.   Draw vertical lines through the 25th percentile $x_{0.25} = Q1$ and the 75th percentile $x_{0.75} = Q3$; then connect at the bottom and the top to make a (rectangular) box. For the data of Example 2, the box is shown below.
Step 3.   Compute the values of interquartile range, $IQR = Q3 - Q1$, $1.5 \times IQR$, and $3 \times IQR$. For the Example 2, $IQR = 5\,275 - 4\,806 = 469$, $1.5 \times IQR = 703.50$ and $3 \times IQR = 1\,407.00$. Then all data points less than $Q1 - 3 \times IQR = 4\,806 - 1\,407 = 3\,399$ or larger than $Q3 + 3 \times IQR = 5\,275 + 1\,407 = 6\,682$ are extreme outliers. Example 2 data has no extreme outliers because no data point lies outside the interval [3 399, 6 682]. Next determine if there are any mild outliers by obtaining the interval $[x_{0.25} - 1.5 \times IQR, x_{0.75} + 1.5 \times IQR] = [4\,102.5, 5\,978.5]$. Since no data point falls outside the interval [4 102.5, 5 978.5], then Example 2 has no mild outliers.
Step 4.   Draw whiskers from $Q1 = x_{0.25}$ and $Q3 = x_{0.75}$ to the smallest and largest order statistics that are not outliers.

Note that only outliers for which assignable causes are found, and the corresponding corrective actions taken, should be removed from the data for further analysis, or else the outlier must remain as a part of the data.

LAWS OF PROBABILITIES

Definition.   The occurrence probability (pr) of an event A is defined as the function

$$P(A) = \frac{N(A)}{N(U)}$$
Figure 2.3   *Heat exchanger geometry for use with example 3*

iff (if and only if) all the N(U) elementary outcomes in the universe U are equally likely, and N(A) are those elementary outcomes that are favourable to the occurrence of the event A.

Example 3

An aluminium-alloy heat exchanger is furnace brazed so that the tubes, fins, and side rails, plus the headers used to attach the top and bottom tanks come out of the furnace as a single unit that makes up the body of the heat exchanger. After brazing, the top and bottom tanks are crimped into place. The orientation of the top and bottom tanks will determine the relative position of the ports through which coolant enters and leaves the heat exchanger. Thus, for the heat exchanger shown is in Figure 2.3, there are 4 possible outcomes because of the body symmetry. The two tanks can be assembled correctly as shown or vice versa on the other side of the body. The two unacceptable assemblies occur when port 1 (at the left of bottom tank) and port 2 (at the right of top tank) are on different sides. Letting F represent a port on the front and B a port on the back, the set of all possible outcomes for the assembly is $U = \{(F_1, F_2), (F_1, B_2), (B_1, B_2), (B_1, F_2)\}$. The conforming units are those with either (F_1, F_2) or (B_1, B_2) outcomes.

The function P(A) must satisfy the following axioms:

(1) $0 \leq P(A) \leq 1$ because $0 \leq N(A) \leq N(U)$.
(2) $P(U) \equiv 1$, and $P(\phi) \equiv 0$, i.e. the occurrence pr of the null set ϕ is identically zero.
(3) If A and B are mutually exclusive (MUEX), then $P(A \cap B) = P(\phi) = 0$, and $P(A \cup B) = P(A) + P(B)$; further, if $A_1, A_2, A_3, \ldots$ is a countably infinite jointly MUEX events, then

$$P\left(U_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} P(A_i)$$

The event $A \cap B$ occurs iff both A and B occur simultaneously, and $A \cup B$ occurs iff at least one of the two events occur. The event A' occurs iff A does not occur, i.e. the event A' is the complement of the event A. Since A and A' are MUEX events, then $A \cup A' = U$ and as a result $P(A \cup A') = 1 = P(A) + P(A') \rightarrow P(A') = 1 - P(A)$.

Let events A and B belong to the same sample space U. Then in general $P(A \cup B) = P(A) + P(B) - P(A \cap B)$ for all events A and B in the same universe U.

Example 4

A repairman claims that the pr that an air conditioning compressor is 'all right' is $P(A) = 0.85$, and $P(B) = 0.64$ that its fan motor is all right, and 0.45 that both the compressor and fan belt are all right. Can his claim be true?

$P(A \cup B) = P(A) + P(B) - P(A \cap B) = 0.85 + 0.64 - 0.45 = 1.04$. Clearly, his claim is false! If he revises his claim to $P(B) = 0.55$, then his claim would be correct because $P(A \cup B) = 0.95$ in which case the probability that neither A nor B occur is $P[(A \cup B)'] = P(A' \cap B') = 0.05$.

PERMUTATIONS

The total number of different ways that n distinct objects can be permuted is given by

$$_nP_n = n!$$

As an example, consider the 3 distinct objects A, B, C. The permutations of these objects are ABC, ACB, BAC, BCA, CAB, CBA, of which there are six. Therefore,

$$_3P_3 = 3! = 6$$

The total number of ways that $r(\leq n)$ objects can be selected from n objects and then permuted is given by

$$_nP_r = \frac{n!}{(n-r)!}$$

For example, consider 4 objects A, B, C and D. Then the elements of $_4P_2$ are: AB, BA, AC, CA, AD, DA, BC, CB, BD, DB, CD, DC, of which there are $12 = 4!/(4-2)!$, i.e. the permutations of 4 objects taken two at a time is equal to $_4P_2 = 12$.

COMBINATIONS

The total number of different ways that r distinct objects can be selected from n $(r \leq n)$ is given by

$$_nC_r = \binom{n}{r} = {_nP_r}/r! = \frac{n!}{(n-r)!r!}.$$

For example, consider the combinations of the 4 objects A, B, C and D, taken 2 at a time:

AB, AC, DA, BC, DB, CD,

of which there are $6 = {_4C_2} = 4!/(2! \times 2!)$ of them. Note that AB and BA are the same element of $_4C_2$, while they are two distinct elements of $_4P_2$.

Example 5

A production lot contains 80 units of which only 6 are nonconforming (NC) to customer specifications. A random sample of size $n = 10$ is drawn from the lot without replacement and the number of NC units in the sample is counted. What is the pr that the sample contains exactly 2 NC units? What is the pr that the sample contains at least one NC unit? Let the variable X represent the number of NC units in the random sample of size $n = 10$. Then,

$$P(X = 2) = \frac{({_6C_2})({_{74}C_8})}{{_{80}C_{10}}} = \frac{\binom{6}{2}\binom{74}{8}}{\binom{80}{10}} = 0.137\,305\,316\,27,$$

and

$$P(X \geq 1) = 1 - P(X = 0) = 1 - \frac{{_{74}C_{10}}}{{_{80}C_{10}}} = 0.563\,674\,217\,2.$$

Note that the procedure outlined in the above example is generally referred to as sampling inspection in the field of quality control (QC). Its objective often is to rectify an outgoing lot by first deciding whether to accept or reject a lot, and in case the lot is rejected, then it is subjected to 100% screening in order to remove all defective units before shipment to customer.

RANDOM VARIABLES AND THEIR FREQUENCY FUNCTIONS

A random variable (rv) is a real-valued function defined on the universe U. If the range space of a rv is discrete, then its frequency function is generally referred to as a pr mass function (pmf), and if its range space is continuous, then its frequency function is called a pr density function (pdf). For example, the rv of the Example 5 is discrete because its range space $R_x = \{0, 1, 2, 3, 4, 5, 6\}$ and its pmf is given by

$$p(x) = \frac{\binom{6}{x}\binom{74}{10-x}}{\binom{80}{10}}, \quad x = 0, 1, 2, 3, 4, 5, 6$$

In fact the above pmf is called the hypergeometric in the field of statistics. Clearly, if p(x) is a pmf, then it is absolutely necessary that $\sum_{R_x} p(x) \equiv 1$, and similarly, if the rv, X, is continuous with pdf f(x), then it is paramount that $\int_{R_x} f(x)dx \equiv 1$ (or 100%). The population mean, μ, and population variance, σ^2, of a rv are given by (the symbol E used below represents the expected-value operator).

$$\mu = E(X) = \begin{cases} \displaystyle\sum_{R_x} xp(x), & \text{if } X \text{ is discrete} \\ \displaystyle\int_{R_x} xf(x)\,dx, & \text{if } X \text{ is continuous} \end{cases}$$

and

$$\sigma^2 = V(X) = E[(X - \mu)^2] = \begin{cases} \displaystyle\sum_{R_x} (x - \mu)^2\, p(x), & \text{if } X \text{ is discrete} \\ \displaystyle\int_{R_x} (x - \mu)^2\, f(x)\,dx, & \text{if } X \text{ is continuous} \end{cases}$$

The most two important pmfs in the field of statistics are the binomial and Poisson.

THE BINOMIAL PMF

Consider $n > 1$ independent (or Bernoulli) trials in successions, where the experimental result can be classified as either 'success' or 'failure'. The binomial rv, X, is defined as X = 'The number of generic successes observed in n trials', where $R_x = \{0, 1, 2, 3, \ldots, n-1, n\}$, and p = pr of a success at each single trial. Then, the binomial pmf is given by

$$b(x; n, p) = {}_nC_x p^x (1 - p)^{n-x}$$

The PDF (pr distribution function) in this equation is called the binomial with parameters n and p and is denoted by Bin(n, p). Its cumulative distribution function (cdf) is given by $F(x) = P(X \leq x) = B(x; n, p) = \sum_{i=0}^{x} b(i; n, p) = \sum_{i=0}^{x} {}_nC_i \times p^i \times q^{n-i}$, where $q = 1 - p$ represents the failure pr at each trial. It can be verified that the binomial pmf, b(x; n, p), has a mean of $E(X) = np$ and a variance $\sigma^2 = npq$.

Example 6

A manufacturing process produces parts which are, on the average, 1% NC to customer specifications. A random sample of $n = 30$ items is drawn from a conveyor belt. Compute the pr that the sample contains exactly $x = 2$ NC units.

$$b(2; 30, 0.01) = {}_{30}C_2(0.01)^2(0.99)^{28} = 0.032\,83.$$

The pr that the sample contains at most two NC units is given by $P(X \leq 2) = B(2; 30, 0.01) = 0.996\,682\,3$, and the pr that the sample contains at least two NC units is given by

$P(X \geq 2) = 1 - P(X \leq 1) = 1 - B(1; 30, 0.01) = 0.036\,148$. The expected number of NC units in the sample is given by $\mu = n \times p = 0.30$ and the variance of X is given by $V(X) = \sigma^2 = npq = 0.297$.

Note that in the context of the Example 6 the statistic $\hat{p} = X/n$ is called the sample fraction NC and is used as a point estimate of process fraction NC, p. The binomial expansion of $(a + b)^n$ is given by

$$(a + b)^n = \sum_{i=0}^{n} {}_nC_{n-i} a^{n-i} b^i$$

which shows that $\sum_{x=0}^{n} b(x; n, p) = \sum_{x=0}^{n} {}_nC_x p^x (1 - p)^{n-x} = (p + q)^n = 1^n = 1$.

THE POISSON DISTRIBUTION

Consider many Bernoulli trials (i.e. $n \to \infty$) such that occurrence pr of success at each trial is small (say $p < 0.15$) and average number of successes per time unit, $\mu = n \times p = \lambda$, is a constant. Let the rv, X, denote the number of Poisson events (or generic successes) that occur during one time interval of unit length. Then the PDF (or pr distribution function) of X is given by

$$p(x; \lambda) = \frac{\lambda^x}{x!} e^{-\lambda}, \quad x = 0, 1, 2, 3, 4, \ldots \tag{2.1}$$

It can be shown that the Poisson pmf in (2.1) is simply the limiting distribution for a Bin(n, p) as $n \to \infty$ and simultaneously as $p \to 0$ but the product $n \times p$ stays fixed at a rate equal to λ, and is generally required that $n \times p \leq 20$. For $n \times p > 20$, the process becomes practically Gaussian (a pdf that will be defined later).

Example 7

The number of accidents per day in a certain city is Poisson distributed at an average rate of 5 accidents/day. The pr of no accidents occurring in the city during the next day is given by $p(0; 5) = (5^0/0!)\, e^{-5} = 0.006\,738$. The pr of at most 4 accidents occurring during the next day is $P(X \leq 4) = F_x(4; 5) = \sum_{x=0}^{4} (5^x/x!)\, e^{-5} = 0.440\,493\,3$.

The Poisson distribution can be used to compute probabilities over intervals of length t ($t \neq 1$ unit of time). Let Y = number of Poisson events occurring during an interval of length t ($t \neq 1$) where the average number of Poisson events per unit of time ($t = 1$) is $\lambda = \mu = np$. Then the average number of Poisson events per interval of length t is $E(Y) = \lambda t$. As a result the pmf for the rv Y is given by

$$p(y; \lambda t) = \frac{(\lambda t)^y}{y!} e^{-\lambda t}, \quad y = 0, 1, 2, 3, 4, \ldots$$

Consider the Poisson process of Example 7. We wish to compute the pr of exactly 6 accidents occurring during the next 2 days. Then, $\lambda = np = 5$ accidents/day, $t = 2$ days $\to \lambda \times t = 10$ accidents/two days $\to P(Y = 6) = (10^6/6!)\, e^{-10} = 0.144\,458\,2$, i.e. Y is $p(y; 10)$ read as Poisson distributed at an average rate of 10 accidents per two days. The pr that there will be exactly 11 accidents in the city during the next 3 days is $P(Y = 11) = (15^{11}/11!)\, e^{-15} = 0.066\,287\,4$. The pr that there will be at least 11 accidents in the next 3 days is given by $P(Y \geq 11) = 1 - P(Y \leq 10) = 1 - F_Y(10; 15) = 1 - \sum_{x=0}^{10} (15^x/x!) e^{-15} = 0.881\,536$.

It can be verified that the long-term (or weighted) average of X, as expected, is given by $\mu = E(X) = \lambda$ and $V(X) = \lambda = \mu$. As a result, all Poisson processes have a CV (coefficient of variation $= \sigma/\mu$) equal to $(100/\sqrt{\lambda})\%$.

CONTINUOUS FREQUENCY FUNCTIONS

If the range space of a rv is continuous, then the occurrence pr of a single point in the range space is zero, but the pr over a real interval [a, b] is given by $\int_a^b f(x)\, dx$, where f(x) is the probability density function (pdf) of the rv X. There are numerous pdfs in the field of statistics, each of which has specific applications.

The three most commonly encountered in practice are the uniform, normal (or Gaussian), and the exponential. The normal distribution is used to approximately model the distribution of almost any manufactured dimension, and the exponential has extensive applications in life testing and in Markov processes (specifically in queuing theory). The uniform distribution has extensive applications in statistical simulations because of the fact that all continuous cumulative distribution functions in the universe are uniformly distributed over the interval [0, 1].

THE UNIFORM pdf

A continuous rv, X, is said to be uniformly distributed over the real interval [a, b] iff its pdf is given by

$$f(x) = \begin{cases} \dfrac{1}{b-a}, & a \le x \le b \\ 0, & \text{elsewhere.} \end{cases}$$

This is expressed as $X \sim U(a, b)$. The population mean of a rv $X \sim U(a, b)$ is given by $\mu = E(X) = (a+b)/2$ and its population variance is given by $V(X) = \sigma^2 = (b-a)^2/12$.

THE NORMAL (OR GAUSSIAN) DISTRIBUTION $N(\mu, \sigma^2)$

A continuous rv, X, is said to be normally distributed with mean μ and variance σ^2 iff its pdf is given by

$$f(x; \mu, \sigma) = C\,e^{-((1/2)((x-\mu)/\sigma)^2)} = C\,\text{Exp}[-(x-\mu)^2/(2\sigma^2)], \quad -\infty < x < \infty$$

where C is a normalising constant and must be evaluated in such a manner that the total area under the pdf is exactly equal to 1 (or 100% pr), i.e. we must require that

$$\int_{-\infty}^{\infty} C\,e^{-((1/2)((x-\mu)/\sigma)^2)}dx = 1,$$

which leads to $C^2 = 1/(2\pi\sigma^2)$. Therefore, the only unique value of C that makes the value of the above improper integral equal to 100% is $C = 1/(\sigma\sqrt{2\pi})$. These developments show that a continuous rv, X, is $N(\mu, \sigma^2)$ [read as normally distributed or Gaussian with mean μ and variance σ^2] only if its pdf is given by

$$f(x; \mu, \sigma) = \frac{1}{\sigma\sqrt{2\pi}}e^{-((1/2)((x-\mu)/\sigma)^2)}, \quad -\infty < x < \infty.$$

The graph of the normal pdf in the equation above is symmetrical and is provided in Figure 2.4.

It can easily be verified that the modal point of a $N(\mu, \sigma^2)$ distribution, as shown in Figure 2.4, occurs at $x = \mu$. Secondly, its points of inflection occur at $x = \mu \pm \sigma$. Therefore, one invariant property of all normal distributions is the fact that the distance between the line $x = \mu$ and the point of inflection is exactly one standard deviation σ. Because of the enormous importance of this distribution, we list its first 4 moments, where the kth moment about a real constant C is given by $E[(X-C)^k]$.
Figure 2.4   *The modal point of a $N(\mu, \sigma^2)$ distribution*

It can be verified that the 1st four moments of any Gaussian distribution are $\mu_1' = \mu$, $V(X) = \mu_2 = \sigma^2$, $\alpha_3 \equiv \mu_3/\sigma^3 = 0$, and $\alpha_4 = \mu^4/\sigma^4 = 3.00$, where $\mu_4 = E[(X - \mu)^4]$ is called the 4th central moment of X, and μ_k' represents the kth origin moment.

It must be emphasised that the normal distribution has unlimited applications in all facets of human life (for example, in all sciences, in all fields of engineering, in agriculture, pharmacy and medicine, etc.). In fact the distribution of every dimension that is manufactured can be modelled closely by a normal curve! This implies that over 75% of all parent populations in the universe are assumed normally distributed with some mean μ and some variance σ^2. Application examples will now follow.

Example 8

The design tolerances (or consumers' specifications) on length of steel pipes is 30 ± 0.25 cm. The dimension or length of a pipe, X, is N(30, 0.006 4 cm^2). We wish to compute the pr that a randomly selected pipe has length below 30.10 cm?

$$P(X < 30.10 \text{ cm}) = \int_{-\infty}^{30.10} \frac{1}{\sigma\sqrt{2\pi}} e^{-((1/2)((x-\mu)/\sigma)^2)} dx,$$

where $\mu = 30.00$ cm and $\sigma = 0.08$ cm. To simplify the integrand, let $(x - \mu)/\sigma = z$; then, $dz/dx = 1/\sigma$ or $dz = dx/\sigma$.

Substituting the transformation $z = (x - \mu)/\sigma$ into the above integral results in:

$$P(X < 30.10) = \int_{-\infty}^{1.25} \frac{1}{\sqrt{2\pi}} e^{-z^2/2} dz = \int_{-\infty}^{1.25} \phi(z) dz = \Phi(1.25).$$

The pdf $\phi(z) = (1/\sqrt{2\pi})e^{-z^2/2}$ is called the standard normal density function because its mean is zero and its variance is equal to 1. Unfortunately, $\phi(z)$ has no closed-form simple antiderivative, and therefore its cdf has been tabulated for different values of z (using numerical integration) in tables in almost all statistical texts. For example, see pages 722–723 of J. L. Devore 'Probability and Statistics for Scientists and Engineers', Duxbury Press, Belmont, CA, 2000. The cdf of the standard normal density N(0, 1) is universally denoted by $\Phi(z)$. For example, from Table A.3, p. 723 of Devore, $\Phi(1.5) = 0.933\,19$, $\Phi(-1.5) = 0.066\,81$, $\Phi(1.96) = 0.975$, $\Phi(-1.96) = 0.025$, $\Phi(3) = 0.998\,65$, $\Phi(-3) = 0.001\,35$ [Note that $\Phi(-z) = 1 - \Phi(z)$]. Thus, $P(X < 30.10) = F_X(30.10) = P(Z \le 1.25) = \Phi(1.25) = 0.894\,35$. The graph of $\phi(z)$ is shown in Figure 2.5. Microsoft Excel will provide both normal prs and the normal inverse. The reader can open Excel, click on Insert, Function, Statistical, scroll down to NORMSDIST, insert the desired value of z, then Excel will provide the corresponding value of cdf of z, that is denoted by $\Phi(z)$. Figure 2.5 graphs the standard normal density $\Phi(z)$ versus z.
Figure 2.5   *Standard normal density $\Phi(z)$ versus z*

Suppose a pipe is selected at random. We wish to compute the pr that its length falls within 2σ of the mean $\mu = 30$ cm.

$$P(|X - \mu| \le 2\sigma) = P(29.84 \le X \le 30.16)$$

$$= P\left(\frac{29.84 - 30}{0.08} \le \frac{X - \mu}{\sigma} \le \frac{30.16 - 30}{0.08}\right)$$

$$= P(-2 \le Z \le 2) = \Phi(2) - \Phi(-2) = 0.977\,25 - 0.022\,75 = 0.954\,50.$$

Further, the pr that the length of a pipe is within 3 sigma of μ is given by $P(|X - \mu| \le 3\sigma) = P(-3 \le Z \le 3) = \Phi(3) - \Phi(-3) = 0.998\,65 - 0.001\,35 = 0.997\,30$. Finally, the $P(\mu - 4\sigma \le X \le \mu + 4\sigma) = \Phi(4) - \Phi(-4) = 0.999\,968\,33 - 0.000\,031\,671 = 0.999\,936\,66$.

Next, the fraction of the pipes that are not conforming to the lower specification limit $LSL = 29.75$ cm and upper specification limit $USL = 30.25$ cm is called the fraction NC (FNC) of the process, denoted by p, and is computed below.

$$p = FNC = P(X < 29.75) + P(X > 30.25) = P(Z \le -3.125) + P(Z \ge 3.125)$$
$$= \Phi(-3.125) + [1 - \Phi(3.125)] = 2 \times \Phi(-3.125) = 2 \times 0.000\,889\,025 = 0.001\,778\,051.$$

Suppose that the process in the Example 8 is not centred at $\mu = 30.00$ cm. Then, the process fraction NC under the condition that $\mu \ne 30.00$ cm will always exceed $p = 0.001\,778$ (at the same value of σ). For example, if $\mu = 30.05$ cm, then $Z_L = -3.75$, $p_L = 0.000\,088\,42$, $Z_U = 2.50$, $p_U = 0.006\,21$, and $p = 0.006\,298\,1$ at $\sigma = 0.08$ cm.

THE PERCENTILES OF A NORMAL DISTRIBUTION

For the standard normal density, N(0, 1), the 95th percentile is denoted by $z_{0.05}$, and is defined such that the $P(Z \le z_{0.05}) = 0.95$. Similarly, the 90th percentile of Z is defined as $P(Z \le z_{0.10}) = 0.90$. This definition implies that for the standard normal density function (STNDF), $\Phi(z_{0.05}) = 0.95$ and $\Phi(z_{0.10}) = 0.90$. Table A.3 on page 723 of Devore shows that $z_{0.05} = 1.645$ while $z_{0.10} = 1.282$. By symmetry of the STNDF, it follows that the 5th percentile of Z is equal to $z_{0.95} = -1.645$ and the 10th percentile $z_{0.90} = -1.282$, i.e. the $P(Z \le -1.645) = \Phi(-1.645) = 0.05$ and the $P(Z \le -1.282) = \Phi(-1.282) = 0.10$. It should be noted that $z_{0.05} = 1.645$ is also called the 5 percentage point of the STNDF and $z_{0.10} = 1.282$ is called the 10 percentage point of a STNDF. It turns out that in the field of statistics, a percentage point, such as z_α, is the distance from the origin beyond which the right tail pr is exactly equal to α. Further, for the STNDF, it should be clear that $z_\alpha = -z_{1-\alpha}$ for all $0 < \alpha < 1$. Figure 2.5 shows that $z_{0.105\,65} = 1.250$ and hence $z_{0.894\,35} = -1.250$.

If the rv, X, is normally distributed but either $\mu \ne 0$, or $\sigma \ne 1$ (or both), the 95th percentile of X is defined as $x_{0.95}$ such that the $P(X \le x_{0.95}) = 0.95$, and similarly the 90th percentile of X is defined such that $P(X \le x_{0.90}) = 0.90$. Furthermore, in general $x_{0.95} \ne -x_{0.05}$ or $x_p \ne x_{1-p}$.

THE REPRODUCTIVE PROPERTY OF THE NORMAL DISTRIBUTION

Suppose $X_1, X_2, \ldots, X_n$ are n normally distributed rvs with means μ_i and variances σ_i^2 and correlation coefficients $\rho_{ij} = \sigma_{ij}/\sigma_i\sigma_j$, where $\sigma_{ij} = E[(X_i - \mu_i) \times (X_j - \mu_j)]$ is called the covariance between the two random variables X_i and X_j ($i \ne j$). Further, $c_1, c_2, \ldots, c_n$ are known or given constants. Then it has been proven in the theory of statistics that the linear combination (LC).

$$Y = c_1X_1 + c_2X_2 + \cdots + c_nX_n = \sum_{i=1}^{n} c_iX_i$$

is also normally distributed with mean

$$E(Y) = \sum_{i=1}^{n} c_i\mu_i$$

and variance

$$V(Y) = \sum_{i=1}^{n} c_i^2 \sigma_i^2 + 2 \sum_{i=1}^{n-1} \sum_{j>i}^{n} c_i c_j \sigma_{ij}, \quad \text{i.e., } Y \sim N \left(\sum_{i=1}^{n} c_i \mu_i, \sum_{i=1}^{n} c_i^2 \sigma_i^2 + 2 \sum_{i=1}^{n-1} \sum_{j>i}^{n} c_i c_j \sigma_{ij} \right).$$

If the dimensions X_i and X_j are mutually independent for all $i \neq j$, then $\sigma_{ij} = 0$, and the $V(Y)$ reduces to $\sigma_y^2 = \sum_{i=1}^{n} c_i^2 \sigma_i^2$. Note that zero covariance does not always imply independence.

Example 8 (*continued*)

Three steel pipes are selected at random from the N(30, 0.006 4) process and placed end-to-end. Compute the pr that the total length of the assembly exceeds 90.24 cm. [$n = 3$, each $c_i = 1$, and each $X_i \sim N(30.00, 0.006\,4)$]. $\rightarrow Y = X_1 + X_2 + X_3 \rightarrow E(Y) = 30 + 30 + 30 = 90.00$, $V(Y) = 0.006\,4 + 0.006\,4 + 0.006\,4 = 0.004\,8 \rightarrow Y \sim N(90, 0.019\,2)$, and hence

$$P(Y > 90.24 \text{ cm}) = P \left(\frac{y - \mu_y}{\sigma_y} > \frac{90.24 - 90.00}{0.138\,564} \right) = P(Z > 1.732\,051)$$

$$= 1 - \Phi(1.732\,051) = 1 - 0.958\,368 = 0.041\,632\,3.$$

THE CENTRAL LIMIT THEOREM (CLT)

If $X_1, X_2, \ldots, X_n$ are independent, but not necessarily normal, rvs with $E(X_i) = \mu_i$ and $V(X_i) = \sigma_i^2$, then the distribution of $Y = X_1 + X_2 + \cdots + X_n$, as $n \rightarrow \infty$, approaches normality with $E(Y) = \sum_{i=1}^{n} \mu_i$ and $V(Y) = \sum_{i=1}^{n} \sigma_i^2$. Note that the more skewed the frequency functions of the individual X_i's in the sum $\sum_{i=1}^{n} X_i$ are, the more slowly (in terms of n) the distribution of Y approaches normality. For example, if the X_i's are uniformly distributed, then for $n > 8$, the distribution of the sum, $Y = \sum_{i=1}^{n} X_i$, is approximately normal, while if X_i's are exponentially distributed, then a value of $n > 200$ is needed. The uniform skewness is $\alpha_3 = E\left[(x - \mu/\sigma)^3\right] = 0$, while that of exponential distribution is $\alpha_3 = 2.00$.

In case X_i's have the same mean and variance, then the distribution of Y approaches normality with $E(Y) = n\,\mu$ and $V(Y) = n\,\sigma^2$. A general conservative rule of thumb is that a value of $n > 25\alpha_3^2$ and simultaneously $n > 5\alpha_4$ (and in most applications at least $n > 30$) is needed in order for the distribution of the sum $Y = \sum_{i=1}^{n} X_i$ to become approximately Gaussian. Again, the quantity $\alpha_3 = E[(X - \mu)^3/\sigma^3]$ is called the coefficient of skewness, or simply the skewness of X. The closer $\alpha_3(X)$ is to zero, the smaller n is needed for an adequate normal approximation to the distribution of the sum $\sum_{i=1}^{n} X_i$.

Example 9

A large freight elevator can transport a maximum of 10 000 kg of load. A load of cargo containing 50 boxes of a certain product is transported on the elevator every hour. The weights of the boxes are independent (not normal but identically distributed) each with $E(X_i) = 190$ kg and $V(X_i) = 900$ kg^2. Estimate (using the CLT) the pr that the maximum limit is exceeded on a given hour and disrupts the transporting process?

Solution: $Y = $ a Cargo Load $= \sum_{i=1}^{50} X_i \rightarrow E(Y) = 50 \times 190 = 9\,500$ and $V(Y) = 50 \times 900 = 45\,000.00$. $P(Y > 10\,000 \text{ kgs}) = P(Z > (10\,000 - 9\,500/212.132)) = P(Z > 2.357\,02) = 1 - \Phi(2.357\,023) = 1 - 0.990\,789 = 0.009\,211\,1$.

THE NORMAL APPROXIMATION TO THE BINOMIAL

Since a binomial rv, X_{Bin}, is the sum of n independent Bernoulli rvs, i.e. then the binomial rv $X_{Bin} = \sum_{i=1}^{n} X_i$, where each X_i is Bernoulli (i.e. X_i has a binomial distribution with the parameter $n \equiv 1$) with $E(X_i) = p$ and $V(X_i) = pq$. As a result of the CLT, as $n \rightarrow \infty$, the binomial pmf can be approximated by a normal pdf with $E(X) = np$ and $V(X) = npq$. However, because a binomial rv has a discrete range space, a correction for continuity has to be applied as will be illustrated in the following example. The approximation is adequate when n is large enough such that the product $np > 15$ and $0.10 < p < 0.90$. If $np < 15$, we would recommend the Poisson approximation to the Binomial. The general rule of thumb was that n must be large enough such that $n > 25\alpha_3^2$ and simultaneously $n > 5\alpha_4$, where for a single Bernoulli trial $\alpha_3^2 = (q - p)^2/(p \times q)$, and $\alpha_4 = (1 - 3p + 3p^2)/(p \times q) = (1 - 3\,pq)/$

(p × q). It can be shown that for a Bin(n, p) distribution the value of skewness is $\alpha_3 = (q - p)/\sqrt{npq}$ and the binomial $\alpha_4 = E[((X - \mu)/\sigma)^4] = E(Z^4)$ is given by $\alpha_4 = (1 + 3(n - 2)pq/npq)$.

Example 10

Consider a binomial distribution with n = 50 trials and p = 0.30 (so that $\mu = np = 15$). Note that we would like to have np > 15, but $25\alpha_3^2 = 19.05$ implies that the requirement on skewness $n = 50 > 25\alpha_3^2$ is easily satisfied and similarly, $5\alpha_4 = 14.876\,2$ shows that the α_4 requirement is also satisfied because n > 14.876 2. Then the range space of the discrete rv, X_D, is $R_x = \{0, 1, 2, 3, \ldots, 50\}$. The exact pr of attaining exactly 12 successes in 50 trials is given by $b(12; 50, 0.30) = P(X_D = 12) = {}_{50}C_{12}(0.30)^{12}(0.70)^{38} = 0.083\,83$.

To apply the normal distribution (with $\mu = 15$ and $\sigma^2 = npq = 10.50$) in order to approximate the $P(X_D = 12)$, we 1st have to select an interval on a continuous scale, X_C, to represent $X_D = 12$. Clearly this continuous interval on X_C has to be (11.5, 12.5), i.e. we will have a correction of 0.50 for continuity. In short, $X_D = 12 \cong (11.5, 12.5)_C$. Thus,

$$P(X_D = 12) \cong P(11.5 \leq X_C \leq 12.5) = P\left(\frac{11.5 - 15}{3.240\,4} \leq Z \leq \frac{12.5 - 15}{3.240\,4}\right)$$

$$= P(-1.080\,1 \leq Z \leq -0.771\,52) = \Phi(-0.771\,52) - \Phi(-1.080\,1)$$

$$= 0.220\,200 - 0.140\,044 = 0.080\,157.$$

Since the exact pr was 0.083 83, the percent relative error in the above approximation is

$$\% \text{ Relative Error} = \left(\frac{0.083\,83 - 0.080\,157}{0.083\,83}\right) \times 100 = 4.382\%.$$

Next we compute the exact pr that X exceeds 12, i.e. $P(X_D > 12) = 1 - B(12; 50, 0.30) = 1 - 0.222\,865\,8 = 0.777\,134$. The normal approximation to this binomial pr is

$$P(X_C \geq 12.5) = P(Z \geq -0.77\,152) = 0.779\,80 \cong P(X_D > 12).$$

The % error in this approximation is 0.343%.

As stated earlier, the normal approximation to the binomial should improve as n increases and as p → 0.50. To illustrate this fact, consider a binomial distribution with parameters n = 65 and p = 0.40. Then, $\mu = np = 26$, $\sigma = (npq)^{1/2} = 3.949\,7$, and $P(X_D = 22) = {}_{65}C_{22}(0.40)^{22}(0.60)^{43} = 0.061\,7$. The normal approximation to this b(22; 65, 0.40) is $P(21.5 \leq X_C \leq 22.5) = P(-1.139\,33 \leq Z \leq -0.886\,15) = 0.187\,77 - 0.127\,28 = 0.060\,5$ with relative % error of 1.935%.

Further, $P(X_D < 23) = B(22; 65, 0.40) = \sum_{x=0}^{22} {}_{65}C_x(0.40)^x(0.60)^{65-x} = 0.188\,327$. The normal approximation to this binomial cdf corrected for continuity (cfc) is $P(X_C \leq 22.5) = P(Z \leq -0.886\,15) = \Phi(-0.886\,15) = 0.187\,769\,2$ with an error of 0.296 2%.

THE EXPONENTIAL pdf

A continuous rv, X, with pdf $f(x; \lambda) = \lambda e^{-\lambda x}$ is said to be exponentially distributed at the average rate of $\lambda > 0$. The cdf of the exponential density is given by

$$F(x) = \int_0^x \lambda e^{-\lambda t} dt = 1 - e^{-\lambda x}.$$

The exponential pdf has widespread and enormous applications in reliability engineering (or life testing) and in stochastic processes (specifically queuing theory). The majority of its applications occur because of its relation to the Poisson distribution as shown below.

Consider a Poisson event that occurs at a rate of λ per unit of time. The average number of occurrences during an interval of length t is λt. Let X(t) represent the number of Poisson events occurring during an interval of length t, i.e. $R_{X(t)} = \{0, 1, 2, 3, \ldots\}$. Then from the Poisson pmf

$$P[X(t) = 0] = \frac{(\lambda t)^0}{0!} e^{-\lambda t} = e^{-\lambda t}.$$

Next, define a continuous rv, T, as follows: T = the time between the occurrences of 2 successive Poisson events (or T = intercurrence or intervening time of 2 successive Poisson events). Clearly, the following two events are equivalent.

$$[X(t) = 0] = [T > t].$$

Thus,

$$P(T > t) = P[X(t) = 0] = e^{-\lambda t} = 1 - P(T \le t) = 1 - F(t) \quad \longrightarrow \quad F(t) = 1 - e^{-\lambda t}$$
$$\longrightarrow \quad f(t) = dF(t)/dt = \lambda e^{-\lambda t}$$

The above developments show that if the number of occurrences of an event is Poisson distributed, then the occurrence time, T, to the next Poisson event measured from the last occurrence is exponentially distributed.

Example 11

The number of downtimes of a computer network is Poisson distributed with an average of 0.20 downtime/week. Compute the pr of exactly 2 failures next week.

$$p(2; 0.20) = \frac{(0.20)^2}{2!} \times e^{-0.20} = 0.016\,4.$$

Next, the pr that the time between 2 future successive downtimes exceeds one week is given by $P(T > 1) = P[X(1) = 0] = e^{-0.20} = 0.818\,73$. The pr that exactly 2 failures occur in the next 3 weeks is computed as follows.

$$Y = \text{number of failures}/(3 \text{ weeks}) \quad \longrightarrow \quad \mu = \lambda t = (0.20) \times 3 = 0.60$$

$$P(Y = 2) = \frac{(0.60)^2}{2!} e^{-0.60} = 0.098\,79.$$

The pr that the time between 2 successive downtimes (or failures) exceeds 3 weeks is $P(T > 3) = P[X(3) = Y = 0] = e^{-0.60} = 0.548\,812$. The pr that the time between next 2 failures will be shorter than 2 weeks is given by $P(T < 2) = P[X(2) \ge 1] = 1 - P[X(2) = 0] = 1 - e^{-0.40} = 0.329\,7$. This pr can also be computed by the direct integration of the exponential pdf as $P(T < 2) = \int_0^2 0.20\,e^{-0.20t}dt = 1 - e^{-0.20 \times 2} = 0.329\,7$.

Finally, the pr that the time (since the last system failure) to the next downtime will be less than 4 weeks is $P(T < 4) = 1 - e^{-0.80} = 0.550\,7$.

In this last example, the $P(T < 4)$ also is referred to as the unreliability at time $t = 4$ weeks, and therefore, the reliability at time $t = 4$ weeks is defined as $R(4) = P(T > 4) = 1 - P(T \le 4) = 0.449\,3$. Note that by reliability at 4 units of time we mean the pr that a system survives beyond $t = 4$, i.e. in general $R(t) = Pr(\text{survival} > t) = P(T > t) = \int_t^\infty f(x)\,dx$, where $f(t)$ represents the mortality (or failure) density function of the rv T.

2.2.7.3   *Statistical inference*

By statistical inference (SI) we mean estimation and/or test of hypothesis. There are two types of estimates: point and (confidence) interval estimate. A point estimate, or estimator,[*] is a random variable (or statistic) before the sample is drawn, but it becomes a numerical value after the sample is drawn estimating a population parameter (such as μ and σ). For example, any one of the statistics, the sample mean $\bar{x}$, the median $\tilde{x}$, the sample mode MO, etc., can be considered as point estimators of the population mean μ. If the parameter under consideration is the population variance σ^2, then we may use any one of the statistics

$$S^2 = \frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})^2, \quad \hat{\sigma}^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^2,$$

---

[*] The term estimator, $\hat{\theta}$, is applied to the random variable, and the word estimate is reserved for the numerical value of $\hat{\theta}$ taken on by the random variable after the sample is drawn and the experimental data have been inserted.

or $(R/d_2)^2$ as estimators of σ^2, where R is the sample range, $d_2 = E(R/\sigma)$, and the rv $w = R/\sigma$ is called the relative range in the field of QC. Note that any symbol with a hat atop it implies an estimator. The question is then how one chooses among several available estimators of a given process parameter? The obvious answer is to select the estimator that is the most accurate, i.e. whose value comes closest to the true value of the parameter being estimated in the long run.

Since a point estimator, $\hat{\theta}$, is a random variable (i.e. it changes from sample to sample), it has a pr density function, and for $\hat{\theta}$ to be an 'accurate' estimator, the pdf of $\hat{\theta}$ should be closely concentrated about the population parameter θ. The criterion used to decide which one of the two estimators ($\hat{\theta}_1$ or $\hat{\theta}_2$) of the parameter θ is better now follows.

The statistic $\hat{\theta}_1$ is said to be a more accurate estimator of θ than $\hat{\theta}_2$ iff $E[(\hat{\theta}_1 - \theta)^2] < E[(\hat{\theta}_2 - \theta)^2]$. Since $E[(\hat{\theta} - \theta)^2]$ is defined to be the mean square error of $\hat{\theta}$, i.e. $MSE(\hat{\theta}) = E[(\hat{\theta} - \theta)^2]$, then $\hat{\theta}_1$ is a more accurate estimator than $\hat{\theta}_2$ iff MSE $(\hat{\theta}_1) <$ MSE $(\hat{\theta}_2)$.

PROPERTIES OF POINT ESTIMATORS

An estimator is said to be consistent iff the limit $(n \to \infty)$ of $\hat{\theta} = \theta$. If the population is finite of size N, then $\hat{\theta}$ is consistent iff limit of $\hat{\theta} = \theta$ as $n \to N$. For example, $\bar{x}$ is a consistent estimator of μ for both finite and infinite populations because limit of $\bar{x} = \mu$ as $n \to N$. However, S^2 is not a consistent estimator of σ^2 for finite populations but S^2 becomes consistent as $N \to \infty$.

One of the most important property of a point estimator is the amount of bias in the estimator. The amount of bias in a point estimator is defined as

$$B(\hat{\theta}) = E(\hat{\theta}) - \theta = E(\hat{\theta} - \theta)$$

and, therefore, $\hat{\theta}$ is an unbiased estimator iff $E(\hat{\theta}) = \theta$ (i.e. $B = 0$). Users make the common mistake that an unbiased estimator is one whose value is equal to the parameter it is estimating. This is completely false!

We now give the relationship between the accuracy of an estimator $\hat{\theta}$, measured by its MSE, and the amount of bias in $\hat{\theta}$. It can be shown that

$$MSE(\hat{\theta}) = V(\hat{\theta}) + B^2 = [E(\hat{\theta}^2) - E^2(\hat{\theta})] + B^2$$

This equation clearly shows that MSE $(\hat{\theta}) = V(\hat{\theta})$ iff $\hat{\theta}$ is an unbiased estimator of θ.

Example 12

Consider an infinite population (not necessarily a normal population) with parameters μ and σ^2, and a simple random sample of size of $n > 1$ is drawn. Then $E(\bar{x}) = \mu$, i.e. $\bar{x}$ is an unbiased estimator of the population mean μ. The identity

$$\sum_{i=1}^{n}(x_i - \bar{x})^2 \equiv \sum_{i=1}^{n}[(x_i - \mu) - (\bar{x} - \mu)]^2 \equiv \cdots \equiv \sum(x_i - \mu)^2 - n(\bar{x} - \mu)^2,$$

can be used to further prove that $E(S^2) = \sigma^2$ only for infinite populations. That is, S^2 is an unbiased estimator of process variance σ^2 for any infinite population.

The relative efficiency (REL-EFF) of $\hat{\theta}_1$ to $\hat{\theta}_2$ is defined as $MSE(\hat{\theta}_2)/MSE(\hat{\theta}_1)$. As an example, consider a random sample of size $n = 6$ from a population with unknown mean μ. Let $\hat{\theta}_1 = (x_1 + x_2 + x_3 + x_4 + x_5 + x_6)/6 = \bar{x}$, and $\hat{\theta}_2 = (2x_1 + x_4 - x_6)/2$. Then, E $(\hat{\theta}_1) =$ E $(\hat{\theta}_2) = \mu$, i.e. both $\hat{\theta}_1$ and $\hat{\theta}_2$ are unbiased estimates of μ but the MSE $(\hat{\theta}_1) = \sigma^2/6$, $MSE(\hat{\theta}_2) = 1.5\sigma^2$ so that the REL-EFF of $\hat{\theta}_1$ to $\hat{\theta}_2 = (1.5\sigma^2)/(\sigma^2/6) = 900\%$.

SAMPLING DISTRIBUTIONS OF STATISTICS WITH UNDERLYING NORMAL PARENT POPULATIONS

In carrying out statistical inference, we will assume that the underlying distribution (or the parent population) is Gaussian (or approximately so) in which case the sampling distribution of sample

elements $x_1, x_2, \ldots, x_n$ is normal and mutually independent of each other. A summary of the most commonly occurring normally-related statistics that are used to conduct SI on different population parameters will now follow.

(i) Suppose $X \sim N(\mu, \sigma^2)$ and a random sample of size n has been drawn with sample values $x_1, x_2, \ldots, x_n$. Since the statistic $\bar{x} = \left(\sum_{i=1}^{n} x_i\right)/n$ is a linear combination of normally and independently distributed (NID) rvs, then $\bar{x}$ is also $N(\mu, \sigma^2/n)$. This implies that the sampling distribution (SMD) of $Z = (\bar{x} - \mu)/(\sigma/\sqrt{n}) = ((\bar{x} - \mu)\sqrt{n})/\sigma$ is that of the standardised normal distribution $N(0, 1)$ so that Z can be used for SI on μ if the value of σ is known.

(ii) If σ is unknown and has to be estimated from the sample statistic S, then the SMD of $((\bar{x} - \mu)\sqrt{n})/S = (\bar{x} - \mu)/\hat{\sigma}_{\bar{x}}$ is that of a Student's t with $(n - 1)$ degrees of freedom.

(iii) To compare the means of two normal populations, we make use of the fact that the SMD of $\bar{x}_1 - \bar{x}_2$ is $N(\mu_1 - \mu_2, (\sigma_1^2/n_1) + (\sigma_2^2/n_2))$. In case the two population variances are unknown but equal, i.e. $\sigma_1^2 = \sigma_2^2 = \sigma^2$, then rv $[(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)]/[S_p\sqrt{(1/n_1) + (1/n_2)}]$ has a t sampling distribution with $\nu = n_1 + n_2 - 2$ df, where

$$S_p^2 = \frac{(n_1 - 1)S_1^2 + (n_2 - 1)S_2^2}{n_1 + n_2 - 2} = \frac{CSS_1 + CSS_2}{n_1 + n_2 - 2}.$$

(iv) It can be shown that if $Z \sim N(0, 1)$, then the rv Z^2 has a chi-square (χ^2) distribution with 1 degree of freedom (df). Using this fact, then it can be shown that the SMD of $S^2(n-1)/\sigma^2 = \sum_{i=1}^{n}(x_i - \bar{x})^2/\sigma^2$ follows a χ^2 with $(n-1)$ df (not n degrees of freedom).

(v) If S_x^2 represents the sample variance of machine X from a random sample of size n_x and S_y^2 represents that of machine Y, then from statistical theory the sampling distribution of $S_x^2/\sigma_x^2)/(S_y^2/\sigma_y^2$ follows (Sir R.A.) Fisher's F with numerator degrees of freedom $\nu_1 = n_x - 1$, and denominator degrees of freedom $\nu_2 = n_y - 1$, where n_y is the number of items sampled at random from machine Y.

CONFIDENCE INTERVALS FOR ONE PARAMETER OF A NORMAL UNIVERSE

Let $(1 - \alpha)$ be the confidence interval (CI) coefficient (or confidence level) for the population mean μ. In the case of known σ for the normal underlying distribution, the two-sided confidence interval for μ is given by

$$\bar{x} - Z_{\alpha/2}\sigma/\sqrt{n} \leq \mu \leq \bar{x} + Z_{\alpha/2}\sigma/\sqrt{n}, \tag{2.2a}$$

where $Z_{\alpha/2}$ is the $(\alpha/2) \times 100$ percentage point of a standardised normal distribution. For example, $Z_{0.025} = 1.96$ is the same as the 97.5 percentile (or the 2&1/2 percentage point) of a $N(0, 1)$ distribution. If the quality characteristic of interest, X, is of smaller-the-better (STB) type (such as loudness of a compressor, or radial force harmonic of a tire), then from an engineering standpoint it is best to obtain an upper one-sided confidence interval for μ given by

$$0 < \mu \leq \bar{x} + Z_\alpha\sigma/\sqrt{n}. \tag{2.2b}$$

Conversely, if the quality characteristic, X, is of larger-the-better (LTB) type (such as tensile strength, efficiency, etc) then it is best to provide a lower one-sided confidence interval for μ, which is given by

$$\bar{x} - Z_\alpha\sigma/\sqrt{n} \leq \mu < \infty. \tag{2.2c}$$

If the population standard deviation, σ, of the normal universe is unknown and has to be estimated by sample statistic $S = \sqrt{(1/(n - 1))\sum_{i=1}^{n}(x_i - \bar{x})^2}$, then in equations (2.2) for the CI on μ, replace σ by its estimator S and replace Z_α with $t_{\alpha;n-1}$ where $t_{\alpha;n-1}$ is the $\alpha \times 100$ percentage point of a Student's t distribution with $(n - 1)$ degrees of freedom.

Example 13

A normal process manufactures wires with a strength lower specification limit $LSL = 8.28$ units and variance $\sigma^2 = 0.029\,93$ units^2 ('units' is used to indicate some measure of strength). A random sample of size $n = 25$ items gave $\sum_{i=1}^{25} X_i = 217.250$ units. Our objective is to obtain the point and 95% interval estimators $(1 - \alpha = 0.95)$ for the process mean μ.

The point estimator of the process mean strength, μ, is

$$\hat{\mu} = \overline{x} = \frac{1}{25} \sum_{i=1}^{25} x_i = 8.690 \text{ units}.$$

Since μ is an LTB type parameter, then we develop a 95% lower CI for μ (note that there are no concerns about strength being too high from the consumers' standpoint). The lower 95% confidence limit for μ, from (2.2c), is given by $\mu_L = \overline{X} - Z_{0.05} \times \sigma/\sqrt{n} = 8.690 - 1.645 \times 0.173/\sqrt{25} = 8.690 - 0.0569 = 8.633\,1$ units. Thus, we are 95% confident that μ lies in the interval $8.633\,1 \le \mu < \infty$. The number interval $[8.633\,1 \text{ units}, \infty]$ no longer has a pr of 0.95 to contain the true value of μ because that pr is either 0 or 1. However, the random interval $\overline{x} - 1.645\sigma/\sqrt{n} \le \mu < \infty$ has a pr of 95% to contain μ before the sample is drawn because $\overline{x}$ is a rv before the random drawing of the n sample values. This implies that if we wish to test the null hypothesis $H_0 : \mu = 8.621$ versus the one-sided alternative $H_1 : \mu > 8.621$ at the level of significance of $\alpha = 0.05$, then our 95% CI: $8.6331 \le \mu < \infty$ dictates that we must reject H_0 in favour of H_1 at the 5% level of significance because the hypothesised value of process mean $\mu_0 \equiv 8.621$ is outside the 95% CI, or $\mu_0 \equiv 8.621 < \mu_L = 8.633\,1$ units. On the other hand, our 95% CI does not allow us to conclude that $\mu > 8.650$ units at the 5% level because 8.650 is inside the 95% CI $8.633\,1 \le \mu < \infty$.

With the above example we have demonstrated that all confidence intervals in the universe are tests of hypotheses in disguise because a lower $(1 - \alpha)100\%$ one-sided CI for μ provides all possible right-tailed tests at the level of significance α for the parameter μ. In the above example if the process variance σ^2 were unknown and had to be estimated from the sample, then the sample values must be used to compute the USS $= \sum_{i=1}^{n} x_i^2$, say that for the above example the uncorrected sum of squares were computed to be $\sum_{i=1}^{n} x_i^2 = 1\,888.790 \text{ units}^2$. Then, the CSS $= 1\,888.790 - 217.25^2/25 = 0.887\,50$, $S^2 = 0.887\,5/24 = 0.037\,0$, and $S = 0.192\,3$ units would the point estimate of the unknown parameter σ. The corresponding 95% lower confidence limit for μ is given by $\mu_L = \overline{x} - t_{0.05;24} \times S/\sqrt{n} = 8.690 - 1.711 \times 0.192\,3/\sqrt{25} = 8.624$ units, which results in the confidence interval $8.624 \le \mu < \infty$.

CONFIDENCE INTERVALS FOR PARAMETERS OF TWO NORMAL UNIVERSES

The Student's t distribution must be used (except when the two process variances are known) in order to compare two population means while the Fisher F distribution is used to compare two process variances. We provide an example of how to compare two normal population means.

Example 14

For the sake of illustration consider the Experiment reported in the Journal of Waste and Hazardous Materials (Vol. 6, 1989), where $X_1 =$ weight percent calcium in standard cement, while $X_2 =$ weight percent calcium in cement doped with lead. Reduced levels of calcium would cause the hydration mechanism to become blocked and allow water to attack various locations of the cement structure. Ten samples of standard cement gave $\overline{x}_1 = 90.0\%$ with $S_1 = 5.0$ while $n_2 = 15$ samples of lead-doped cement resulted in $\overline{x}_2 = 87.0$ with $S_2 = 4.0$. Assuming that $X_1 \sim N(\mu_1, \sigma^2)$ and $X_2 \sim N(\mu_2, \sigma^2)$, then the rv $[(\overline{x}_1 - \overline{x}_2) - (\mu_1 - \mu_2)]/[S_p \sqrt{(1/n_1) + (1/n_2)}]$ has a t sampling distribution with $\nu = n_1 + n_2 - 2$df. The expression for the two-sided 95% CI for $\mu_1 - \mu_2$ is given by $\overline{x}_1 - \overline{x}_2 - t_{0.025;23} \times S_p\sqrt{(1/n_1) + (1/n_2)} \le \mu_1 - \mu_2 \le \overline{x}_1 - \overline{x}_2 + t_{0.025;23} \times S_p\sqrt{(1/n_1) + (1/n_2)}$, where $t_{0.025;23} = 2.069$ and $S_p^2 = [9(25) + 14(16)]/(23) = 19.521\,74$. Substitution of sample results into the above expression yields $(\mu_1 - \mu_2)_L = 3 - 2.069 \times 1.8038 = -0.732$ and $(\mu_1 - \mu_2)_U = 3 + 3.732 = 6.732$. Since this 95% CI, $-0.732 \le \mu_1 - \mu_2 \le 6.732$, includes zero, then there does not exist a significant difference between the two population parameters μ_1 and μ_2 at the 5% level, i.e. the null hypothesis $H_0 : \mu_1 - \mu_2 = 0$ cannot be rejected at the 5% level of significance. This implies that doping cement with lead does not significantly (at the 5% level) alter water hydration mechanism. Note that the null hypothesis $H_0 : \mu_1 - \mu_2 = 7$ must be rejected at the 5% level of significance because 7 is outside the 95% CI.

When the variances of the two independent normal populations, σ_1^2 and σ_2^2, are unequal and unknown, then the CI for $\mu_1 - \mu_2$ must be obtained from the fact that the SMD of the rv

$$\frac{(\overline{x}_1 - \overline{x}_2) - (\mu_1 - \mu_2)}{\sqrt{\dfrac{S_1^2}{n_1} + \dfrac{S_2^2}{n_2}}}$$

follows a Student's t distribution with df ν given by the following equation.

$$\nu = \frac{(S_1^2/n_1 + S_2^2/n_2)^2}{\dfrac{(S_1^2/n_1)^2}{n_1 - 1} + \dfrac{(S_2^2/n_2)^2}{n_2 - 1}} \tag{2.3}$$

where $\text{Max}(n_1 - 1, n_2 - 1) < \nu < n_1 + n_2 - 2$. As a general rule of thumb, we would recommend against using the pooled t procedure outlined in Example 14 if $S_1^2 > 2S_2^2$, or vice a versa. From the above discussions we conclude that in case $S_1^2 > 2S_2^2$, then the t statistic for testing the null hypothesis $H_0 : \mu_1 - \mu_2 = \delta$ is given by

$$t_0 = \frac{(\bar{x}_1 - \bar{x}_2) - \delta}{\sqrt{\dfrac{S_1^2}{n_1} + \dfrac{S_2^2}{n_2}}}.$$

If the test is 2-sided, then the acceptance interval for testing $H_0 : \mu_1 - \mu_2 = \delta$ at a level of significance 0.05 is given by $(-t_{0.025;\nu}, t_{0.025;\nu})$, where ν is given in equation (2.3).

2.2.7.4   *Statistical process control (SPC)*

The objective of SPC is to test the null hypothesis that the value of a process parameter is either at a desired specified value, or at a value that has been established from a long-term data. This objective is generally carried out through constructing a Shewhart control chart from $m > 1$ subgroups of data. Further, it is assumed that the underlying distribution is approximately Gaussian, and for moderately large sample sizes, it is also assumed that the SMD of the statistic used to construct the Shewhart chart is also Gaussian. When a sample point goes out of control limits, the process must be stopped in order to look for assignable causes, and if one is found, then corrective action must be taken and the corresponding point should be removed from the chart. In case no assignable (or special) causes are found, then the control chart has led to a false alarm (or a type I error). Since false alarms are very expensive and disruptive to a manufacturing process, all Shewhart charts are designed in such a manner that the pr of committing a type I error, α, is very small. The standard level of significance, α, of all charts are set at $\alpha = 0.002\,7$.

When departures from the underlying assumptions are not grossly violated, then a Shewhart control chart will generally lead an experimenter to 27 false alarms in 10 000 random samples. Moreover, setting the value of α at 0.002 7, will correspond to three-sigma control limits for a control chart as long as the normality assumption is tenable. We will discuss only two types of charts: (1) Charts for continuous variables, and (2) Charts for attributes, where the measurement system merely classifies a unit either as conforming to customer specifications or nonconforming to specifications (i.e. success/failure, 0/1, defective/effective, etc.).

SHEWHART CONTROL CHARTS FOR VARIABLES

As an example, suppose we wish to control the dimension of piston ring inside diameters, X, with design specifications X: 74.00 ± 0.05 mm. The rings are manufactured through a forging process. Since the random variable X is continuous, then we need two charts; one to control variability (or σ), and a second chart for controlling the process mean μ. If subgroup sample sizes, n_i, are identical and lie within $2 \le n \le 15$, then an R-chart (i.e. range-chart) should be used to monitor variability, but for $n > 15$, an S-chart should be used for control of variation. This is due to the fact that the SMD of sample range, R, becomes unstable for moderate to large sample sizes. Samples of sizes n_i $(i = 1, 2, \ldots, m)$ are taken from the process, generally at equal intervals of time, (where hourly or daily samples, or samples taken at different shifts, are the most common), and the number of subgroups m should generally lie within $20 \le m \le 50$. Samples should be taken in such a manner as to minimise the variability within samples and maximise the variability among samples, a concept that is consistent with design of experiments (DOE). Such samples are generally referred to as rational subgroups.

R- AND $\overline{\text{X}}$-CHARTS (FOR $2 \le n \le 15$)

In practice the R-chart should be constructed first in order to bring variability in a state of statistical control, followed by developing the $\overline{\text{x}}$-chart for the purpose of monitoring the process mean. In order to use the R-chart for monitoring process variation, the subgroup sample sizes n_i ($i = 1, 2, \ldots,$ m) must be the same, i.e. $n_i = n$ for all i, or else an R-chart cannot be constructed. All univariate control charts consist of a central line, CNTL, a lower control limit LCL, and an upper control limit UCL. Further, nearly in all cases, $\text{LCL} = \text{CNTL} - 3 \times$ se (sample statistic) and $\text{UCL} = \text{CNTL} + 3 \times$ se (sample statistic), where in the case of the R-chart the sample statistic will be the sample range R, while for the $\overline{\text{x}}$-chart the sample statistic will be the sample mean $\overline{\text{x}}$. The pertinent formulas are provided below.

$$\text{CNTL}_R = \overline{R} = \frac{1}{m} \sum_{i=1}^{m} R_i$$

Note that we are taking the liberty to use the terminology standard error, se, as the estimate of the Stdev of the sample statistic.

The $\text{se}(R) = \hat{\sigma}_R = d_3 \overline{R}/d_2$, the values of d_2 are given in Table 2.12 for $n = 2, 3, \ldots, 15$, $d_3^2 = V(R/\sigma)$, and the values of d_3 for a normal universe are given in Table 2.14. Since the most common of all sample sizes for constructing an R- and $\overline{\text{x}}$-Chart is $n = 5$, we compute $\hat{\sigma}_R$ only for $n = 5$. From Tables 2.12 & 2.14, $\text{se}(R) = 0.864 \times \overline{R}/2.326 = 0.371\,45 \times \overline{R}$. Then for $n = 5$, the $\text{LCL}_R = \overline{R} - 3 \times 0.371\,45 \times \overline{R} = \overline{R}(1 - 1.114\,4) \rightarrow \text{LCL}_R = 0$, and $\text{UCL}_R = 2.114\,36 \times \overline{R}$. In fact, it can be shown that the $\text{LCL}_R = 0$ for all sample sizes in the range $2 \le n \le 6$, but $\text{LCL}_R > 0$ for all $n > 6$.

The central line for an $\overline{\text{x}}$-Chart is given by $\text{CNTL}_{\overline{x}} = 1/m \sum_{i=1}^{m} \overline{x}_i = \overline{\overline{X}}$ and the $\text{se}(\overline{x}) = \sigma/\sqrt{n}$. Since a point estimate of σ is given by $\hat{\sigma}_x = \overline{R}/d_2$, then $\hat{\sigma}_{\overline{x}} = \overline{R}/d_2\sqrt{n}$, as a result the $\text{LCL}_{\overline{x}} = \overline{\overline{X}} - 3 \times \text{se}(\overline{x}) = \overline{\overline{X}} - 3\overline{R}/d_2\sqrt{n}$, and $\text{UCL}_{\overline{x}} = \overline{\overline{X}} + 3\overline{R}/d_2\sqrt{n}$. For samples of size $n = 5$, these last two control limits reduce to

$$\text{LCL}_{\overline{x}} = \overline{\overline{X}} - 0.5768\overline{R}, \quad \text{and} \quad \text{UCL}_{\overline{x}} = \overline{\overline{X}} + 0.5768\overline{R}.$$

S- AND $\overline{\text{x}}$-CHARTS

If subgroup sample sizes differ and/or $n > 12$, then process variation must be monitored by an S-chart. The most common occurrence of an S-chart is when the sampling design is not balanced, i.e. n_i's ($i = 1, 2, \ldots,$ m) are not the same, then the experimenter has no option but to use an S-chart for the control of variation. The central line is given by

$$\text{CNTL}_S = S_p = \left[\frac{\sum_{i=1}^{m} (n_i - 1)S_i^2}{\sum_{i=1}^{i=m} (n_i - 1)} \right]^{1/2} = \left[\sum_{i=1}^{m} (n_i - 1)S_i^2/(N - m) \right]^{1/2}$$

where $N = \sum_{i=1}^{i=m} n_i$, and the quantity $(n_i - 1)S_i^2 = \sum_{j=1}^{j=n_i} (x_{ij} - \overline{x}_i)^2$ is called the corrected sum of squares within the ith subgroup. It can be shown (using the properties of χ^2) that for a normal universe the $E(S) = c_4\sigma$, where the constant $c_4 = \sqrt{2/(n - 1)} \times \Gamma(n/2)/\Gamma[(n - 1)/2]$ lies in the interval $(0.797\,884\,5, 1)$ for all $n \ge 2$ and its limit as $n \rightarrow \infty$ is equal to 1. Further, the authors have shown that for $n \ge 20$ the value of c_4 can be approximated to 5 decimals by $c_4 \cong 4n^2 - 8n + 3.875/(4n - 3)(n - 1)$. These discussions imply that, in the long-run, the statistic S underestimates the population standard deviation σ, and hence an unbiased estimator of σ for a normal universe is given by $\hat{\sigma}_x = S/c_4$ (this is due to the fact that $E(S) = c_4\sigma$).

Table 2.14   THE VALUES OF d_3 FOR A NORMAL UNIVERSE

n	2	3	4	5	6	7	8	9	10	11	12	13	14	15
d_3	0.853	0.888	0.880	0.864	0.848	0.833	0.820	0.808	0.797	0.787	0.778	0.770	0.763	0.756

To compute the se(S), we make use of the fact that $V(S) = E(S^2) - [E(S)]^2 = \sigma^2 - (c_4\sigma)^2 = (1 - c_4^2)\sigma^2$. This development implies that $se(S) = (1 - c_4^2)^{1/2}\hat{\sigma}_x = (1 - c_4^2)^{1/2}(S/c_4) = S\sqrt{(c_4)^{-2} - 1}$. Thus the control limits are given by

$$LCL_i(S) = S_p - 3\,S_p\sqrt{(c_4)^{-2} - 1} = [1 - 3\sqrt{(c_4)^{-2} - 1}]S_p$$
$$UCL_i(S) = S_p + 3\,S_p\sqrt{(c_4)^{-2} - 1} = [1 + 3\sqrt{(c_4)^{-2} - 1}]S_p.$$

Note that the $LCL_S = 0$ when $2 \le n_i \le 5$, but $LCL_S > 0$ when $n > 5$. If the sampling design is balanced, i.e. $n_i = n > 12$ for all i, then replace S_p in the previous two equations with $\overline{S} = (1/m)\sum_{i=1}^{m} S_i$.

Once variability is in a state of statistical control (i.e. all sample S_i's lie within their own control limits), then an $\overline{x}$-chart is developed to monitor the process mean. The central line for an $\overline{x}$-chart is given by

$$CNTL_{\overline{x}} = \overline{\overline{x}} = \sum_{i=1}^{m} n_i\overline{x}_i/N$$

where $N = \sum_{i=1}^{i=m} n_i$. Since the $V(\overline{x}_i) = \sigma^2/n_i$, then $se(\overline{x}_i) = \hat{\sigma}_x/\sqrt{n_i} = (S_p/c_4\sqrt{n_i})$, and as a result

$$LCL_i(\overline{x}) = \overline{\overline{x}} - 3\frac{S_p}{c_4\sqrt{n_i}}, \quad \text{and} \quad UCL_i(\overline{x}) = \overline{\overline{x}} + 3\frac{S_p}{c_4\sqrt{n_i}}. \tag{2.4}$$

Note that if the sampling design is unbalanced, then all points on the S- and $\overline{x}$-charts have the same CTLNs but every point on both charts has its own control limits due to differing sample sizes. When the sampling scheme is balanced (i.e. $n_i = n$ for all i), then in equation (2.4) replace S_p with $\overline{S} = (1/m)\sum_{i=1}^{m} S_i$.

SHEWHART CONTROL CHART FOR FRACTION NONCONFORMING (THE P-CHART)

As an example, consider an injection moulding process that produces instrument panels for an automobile. The occurrence of splay, voids, or short shots will make the panel defective. Thus we have a binomial process where each panel is classified as defective (or 1) or as conforming (or 0). The binomial rv, X, represents the number of nonconforming panels in a random sample of size n_i, where it is best to have at least $m > 20$ subgroups in order to construct the p-chart, where p is the FNC of the process. The sample FNC is given by $\hat{p} = X/n$, and if $n > 30$ and np and nq > 10, then the SMD of $\hat{p}$ is approximately normal with mean p and $se(\hat{p}) = \sqrt{pq/n}$, where $q = (1 - p)$ is the process fraction conforming (or process yield). The central line is given by

$$CNTL_p = \frac{\sum_{i=1}^{m} X_i}{\sum_{i=1}^{m} n_i} = \frac{\sum_{i=1}^{m} n_i\hat{p}_i}{N} = \overline{p}$$

where $N = \sum_{i=1}^{i=m} n_i$ is the total number of units inspected by attributes in all m samples, X_i represents the number of NC units in the ith subgroup, and $\hat{p}_i = X_i/n_i$ is the sample FNC of the ith subgroup. Since the estimate of the $se(\hat{p}_i) = \sqrt{\overline{p}(1 - \overline{p})/n_i}$, then the control limits for the ith subgroup is given by $LCL_i(p) = \overline{p} - 3\sqrt{\overline{p}(1 - \overline{p})/n_i}$, and $UCL_i(p) = \overline{p} + 3\sqrt{\overline{p}(1 - \overline{p})/n_i}$. Note that, when subgroup sizes differ on a Shewhart p-chart, then every sample FNC, $\hat{p}_i$, has its own control limit. If the difference between maximum and minimum sample sizes do not exceed 10 units, then a p-chart based on average sample size should be constructed for monitoring process FNC. In all cases the central line stays the same, but the average control limits simplify to

$$\overline{LCL}(p) = \overline{p} - 3\sqrt{\frac{\overline{p}(1 - \overline{p})}{\overline{n}}}, \quad \text{and} \quad \overline{UCL}(p) = \overline{p} + 3\sqrt{\frac{\overline{p}(1 - \overline{p})}{\overline{n}}},$$

where $\overline{n} = (1/m)\sum_{i=1}^{m} n_i$. The reader is cautioned to the fact that if a p-chart based on an average sample size is used to monitor process FNC, then all points (i.e. all sample FNCs) that are close to their average control limits (whether in or out of control) must be checked against their own limits to determine their control nature.

Table 2.15 DATA FOR TEXTILE PROCESS EXAMPLE

Sample number (i)	1	2	3	4	5	6	7	8	9	10
Square metres	180	150	120	90	150	160	120	140	130	175

SHEWHART CONTROL CHART FOR NUMBER OF NONCONFORMITIES PER UNIT (THE u-CHART)

Since the construction of the u-chart is not as straight forward as the others discussed thus far, we will describe the methodology through an example. In practice, it is best to have at least $m = 20$ subgroups, but herein for simplicity we will use $m = 10$ samples of differing sizes. Consider a textile process that produces oilcloth in lots of differing sizes, measured in square metres. An inspector selects $m = 10$ lots at random and counts the number of defects, c_i, in each lot (or sample). The data is displayed in Table 2.15.

Note that in Table 2.15, because of different square metres, we have arbitrarily let 100 square metres equal to one unit, although 50, or, 10, or any other convenient square metres would work just as well. Further, $u_i = c_i/n_i$ represents the number of defects per unit. Note that because of differing sample sizes, it would be erroneous to compute the average number of defects per unit from $(1/m) \sum_{i=1}^{m} u_i = 7.028\,9$, where this last formula would work only if all n_i's were identical. The correct formula for the central line is given by

$$\text{CNTL}_u = \bar{u} = \frac{\sum_{i=1}^{m} c_i}{\sum_{i=1}^{m} n_i} = \frac{\sum_{i=1}^{m} n_i u_i}{\sum_{i=1}^{i} n_i} = \frac{100}{14.15} = 7.067\,1$$

It is well known that the number of defects per unit, c, follows a Poisson process and hence its variance is also given by $E(c)$, i.e. $V(c)$ can be approximated by $\bar{u}$. Unfortunately, the terminology and notation for a u-chart has been somewhat confusing in statistical and QC literature and we anticipate no change. Therefore, herein we attempt to remedy the notational problem to some extent. First of all, the fifth row of Table 2.15 actually provides the average number of defects per unit for the ith sample, and hence the proper notation for the fifth row should be $\bar{u}_i$ (not u_i as is used in QC literature) because a bar is generally placed on averages in the field of statistics. This implies that a u-chart is actually a $\bar{u}$-chart because it is the average number of defects per unit that is plotted on this chart. Secondly, the central line should be called $\bar{\bar{u}}$ because the CNTL gives the grand average of all average number of defects per unit. These discussions lead to the fact that firstly $V(\bar{u}) = V(c)/n$, and secondly $V(\bar{u})$ can be estimated by $\bar{\bar{u}}/n$. Since we do not wish to deviate from QC literature terminology, we will stay with the existing notation and let u_i represent the average number of defects per unit with CNTL as $\bar{\bar{u}}$ and the $se(u) = \sqrt{\bar{u}/n_i}$. Thus, the $LCL_i(u) = \bar{u} - 3\sqrt{\bar{u}/n_i}$, and $UCL_i(u) = \bar{u} + 3\sqrt{\bar{u}/n_i}$. The values of control limits for all the $m = 10$ samples are provided in the last two rows of Table 2.15. Table 2.15 clearly shows that each u_i is well within its own control limits, implying that the process is in a state of excellent statistical control. Note that in all cases when the value of LCL became negative, a zero LCL was assigned in row 6 of Table 2.15.

This example provides a good illustration of a process that is in an excellent state of statistical control, but one that is in all pr not capable of meeting customer specifications due to the fact that $\bar{u} = 7.067\,1$ is too large and customers in today's global market will generally demand lower average number defects per unit. If this manufacturer does not improve its process capability through quality improvement (QI) methods, it may not survive very long in global competition.

Further, SPC is not a QI method but simply an on-line procedure to monitor process quality and to identify where the quality problems lie. After problems are identified, then off-line methods (DOE or Taguchi methods) can be applied to fine-tune a process.

*Atomic Weights of the Elements 1981, *Pure and Applied Chemistry* 1983, **55** (7), 1101–1136. A value given in brackets denotes the mass number of the isotope of longest known half-life. Because of natural variation in the relative abundance of the isotopes of some elements, their atomic weights may vary. Apart from this they are considered reliable to ±1 in the last digit, or ±3 if that digit is subscript.

Table 3.2   GENERAL PHYSICAL CONSTANTS

The probable errors of the various quantities may be obtained from the reference given at the end of the table.

Quantity	Symbol	Value	Units
Acceleration due to gravity (standard)	g_n	9.806 65	$m\,s^{-2}$
Atmospheric pressure (standard)	A_0	$1.013\,25 \times 10^5$	Pa

Table 3.3　MOMENTS OF INERTIA
Moment of inertia $= Mk^2$ where M is mass and k radius of gyration.

Body	Dimensions	Axis*	k^2
Uniform thin rod	length l	Through centre, perpendicular to rod	$l^2/12$
		Through end, perpendicular to rod	$l^2/3$
Rectangular lamina	sides a and b	Through centre, perpendicular to plane of lamina	$(a^2 + b^2)/12$
		Through centre, parallel to side b	$a^2/12$
Circular lamina	radius r	Through centre, perpendicular to plane of lamina	$r^2/2$
		Through any diameter	$r^2/4$
Annular lamina	radii r_1 and r_2	Through centre perpendicular to plane of lamina	$(r_1^2 + r_2^2)/2$
		Through any diameter	$(r_1^2 + r_2^2)/4$
Rectangular solid	sides a, b and c	Through centre, perpendicular to face ab	$(a^2 + b^2)/12$
Sphere	radius r	Through any diameter	$2r^2/5$
Spherical shell	radii r_1 and r_2	Through any diameter	$2(r_1^5 - r_2^5)/5(r_1^3 - r_2^3)$
Thin spherical shell	radius r	Through any diameter	$2r^2/3$
Right circular cylinder	radius r	Longitudinal axis through centre	$r^2/2$
	length l	Through centre perpendicular to longitudinal axis	$r^2/4 + l^2/12$
Hollow circular	radii r_1 and r_2	Longitudinal axis through centre	$(r_1^2 + r_2^2)/2$
cylinder	length l	Through centre perpendicular to longitudinal axis	$(r_1^2 + r_2^2)/4 + l^2/12$
Thin hollow circular	radius r	Longitudinal axis through centre	r^2
cylinder	length l	Through centre perpendicular to longitudinal axis	$r^2/2 + l^2/12$
Right circular cone	height h	Longitudinal axis through apex	$3r^2/10$
	base radius r	Through centre of gravity perpendicular to longitudinal axis	$3(r^2 + h^2/4)/20$
Ellipsoid	semi-axis a, n and c	Through centre along axis a	$(b^2 + c^2)/5$

*If the moment of inertia I_q about an axis through the centre of gravity is known, then the moment, I, about any other parallel axis may be obtained from

$$I = I_q + Mh^2$$

where h is the distance from the centre of gravity to the parallel axis.

4   X-ray analysis of metallic materials

4.1   Introduction and cross references

X-rays are very short wavelength electromagnetic waves. Their range encompasses the interatomic distances in crystalline materials, typically 0.5 to 2.5 Å, which permit the analysis of crystalline and to a lesser degree amorphous materials by X-ray diffraction (XRD). When atoms are irradiated with radiation of sufficient energy, they emit characteristic X-ray spectra, fluorescence, which are analysed in X-ray fluorescent analysis (XRF) to give element analysis. Individual electrons are emitted from an irradiated surface with energies related to the electron levels in the atom. The energies of these electrons are analysed in X-ray photoelectron spectroscopy (XPS) to provide an elemental analysis of surface atoms together with information on the chemical bonding between them.

This chapter reviews the applications of XRD to the investigation of metallic materials. The subject is well covered in detail in several standard textbooks including 'X-ray Metallography' by A. Taylor;[1] 'Structure of Metals' by C. S. Barrett and T. B. Massalski;[2] 'X-ray Diffraction Procedures' by H. P. Klug and L. E. Alexander.[3] 'Elements of X-ray Crystallography' by L. V. Azaroff,[4] 'Structure Determination by X-ray Crystallography' by M. F. C. Ladd and R. A. Palmer,[5] 'An Introduction to X-ray Crystallography' by M. M. Woolfson,[6] 'Elements of X-ray Diffraction' by B. D. Cullity and S. R. Stock,[7] and 'The Basics of Crystallography and Diffraction' by C. Hammond.[8]

Chapter 5 discusses crystallography and crystal structure data can be found in Chapter 6.

4.2   Excitation of X-rays

X-rays are produced (excited) when an electron experiences a sudden acceleration or (more commonly in practice) deceleration as, for example, when a beam of fast-moving electrons strikes an atom. The frequency ν or wavelength λ of the radiation produced as a result of energy loss E is given by the equation

$$E = h\nu = \frac{hc}{\lambda}$$

The maximum value of E, E_{max}, and corresponding smallest value of λ occurs when all the electron energy is lost on impact, i.e.

$$E_{max} = Ve = \frac{hc}{\lambda_{swl}}$$

where V = accelerating voltage and λ_{swl} = short wavelength limit or cut-off wavelength.

Substitution of numerical values gives

$$\lambda_{swl} = \frac{12.34}{V}$$

where λ_{swl} is expressed in Ångstrom units and V in kilovolts.

However, most electrons undergo repeated collisions of varying energy losses until finally stopped giving rise to a whole range of λ values – the so-called 'white' or 'Brehmstrallung' radiation.

If the intensity of the radiation is plotted against the wavelength, for relatively low applied voltages a curve is obtained rising from zero to a more or less pronounced maximum at a wavelength of about 4/3 λ_{swl}, falling again to a low value with increasing wavelength. It has been found that for this

curve of so-called 'white radiation' both the total radiation and the intensity of the peak are closely proportional to the atomic number of the target material. Thus if white radiation is required a target of one of the heavy metals should be selected, and since the total intensity (the area under the curve) is proportional to the square of the applied voltage the latter should be as high as possible.

On increasing the voltage beyond a certain limit, which is different for different targets, a line spectrum begins to appear, superimposed upon the continuous or white spectrum, the wavelengths of the lines being constant and characteristic of the target. The lowest critical voltage at which these lines appear is that which endows the bombarding electrons with just sufficient energy to eject electrons from one of the inner shells in the target atoms. Each vacancy as it occurs is filled by an electron jumping in from one of the outer shells, the jump being accompanied by an emission of energy of frequency ν given by the Bohr relationship

$$h\nu = W_1 - W_2$$

where $W_1 - W_2$ represents the change in potential energy of the system and h is Planck's constant.

The K series of lines is excited when electrons are ejected from the K shell and their places taken by electrons from the L, M or N shells. It consists principally of five lines $K\alpha_1$, $K\alpha_2$, $K\beta_1$, $K\beta_3$ and $K\beta_2$, the α lines being associated with jumps from the L shell, β_1 and β_3 with those from the M shell, and β_2 with those for the N shell. Other series of lines are emitted when the bombarding electrons eject electrons from the L, M or N shells. The K emissions which are the most intense are generally used in XRD while all the spectra are employed in XRF.

If V_0 is the critical voltage at which the K spectra first appear and e is the electron charge, then the energy needed to remove an electron from the K shell is $V_0 e$ which is equivalent to radiation of frequency ν_k and wavelength λ_k given by

$$V_0 e = h\nu_k = \frac{hc}{\lambda_k}$$

where c is the velocity of light. This critical wavelength λ_k, termed the K absorption edge of the material, together with slightly shorter wavelengths are heavily absorbed in the material. In XRD, to avoid fluorescence (high background) and low penetration into the sample a radiation is chosen which is on the long wavelength side of any absorption edge of the sample.

The empirical expression

$$I = K(V - V_0)^{1.7}$$

where K is a constant, relates the intensity, I, of the characteristic radiation to the difference between the tube voltage V and the critical voltage V_0 of the target material. It is found that the relative intensity of the characteristic radiation to that of the continuous wavelength (white) radiation is greatest for tube voltages of about four times the critical voltage. A method of achieving partial monochromatisation of the X-ray beam is to reduce the intensity of the K_β radiation with respect to that of the K_α by using a filter of an element with K absorption edge between the K_β and K_α wavelengths. The thickness of the filter is usually chosen to reduce the intensity of K_β to about 1/600 of the transmitted K_α. Generally, the element preceding the target element in the periodic table will act as a K_β filter. Filters cannot separate the α_1 and α_2 components and where they are not resolved in a diffraction pattern, d values are calculated using a weighted average wavelength where α_1, the stronger of the two, is given twice the weight of α_2. Full monochromatisation can be achieved with a single crystal monochromator oriented such that only $K\alpha_1$ component is diffracted. Monochromators in the form of a single crystal lamina bent to produce focusing are widely used in diffractometry to remove all unwanted radiation. Construction of focusing monochromators is described in 'International Tables for X-ray Crystallography'.[9]

Table 4.1 lists wavelengths, minimum excitation potentials and K_β filters for targets frequently used in XRD. Table 4.2 gives minimum excitation potentials for characteristic K, L, M, and N spectra while Tables 4.3 and 4.4 give K and L emission spectra and L_{111} absorption edges for all elements. Crystals suitable for monochromators are listed with comments on their performance in Table 4.5.

4.2.1 X-ray wavelengths

The X-unit defined by Siegbahn and very nearly equal to 10^{-3} Å was based on the atomic spacing in calcite as determined from the expression:

$$2d = \left(\frac{4M}{\rho NV} \right)^{1/3}$$

where M = molecular weight of calcite, ρ = density of calcite, N = Avogadro's number, V = volume of calcite rhombohedron with unit distance between the faces considered.

kX units were widely used up to about 1945 but were then gradually replaced by Ångström units as more precise methods for determining X-ray wavelengths were introduced. The nanometer (10^{-9} m) is now declared to be the standard unit for X-ray studies. However, in view of the much greater familiarity with Å, and the very simple conversion factor, in this edition the Ångström unit is used unless the contrary is stated.

1 kX unit = 1.002 02 Ångström units
1 Ångström unit, Å = 10^{-10} m or 10^{-1} nanometers

Emission lines are frequently quoted in keV

$$1\,\text{keV} = \frac{12.3975}{\text{Wavelength in Å}}$$

Table 4.5 CRYSTALS FOR PRODUCING MONOCHROMATIC X-RAYS

Crystal	Reflection	Spacing Å	Properties of reflection		Properties of crystal		Mechanical properties	Special uses
			Peak intensity	Breadth	Crystal imperfection	Stability		
β alumina	0 002 0 004	11.24 5.62	Weak Weak–medium	Moderate	Great	Perfect	Hard, brittle	For long wavelengths, but usable crystals hard to obtain
Mica	001 004	10.1 2.53	Weak	Small	Negligible for selected specimens	Fair	Flexible, easily cleaved	For point-focusing devices; exhibits irradiation effects
Gypsum	020	7.60	Medium–strong	Very small	Good specimens hard to find	Poor	Soft, flexible	For small-angle scattering; focusing long wavelengths
Pentaerythritol	002	4.40	Very strong	Moderate	Great	Poor	Soft, easily deformed	General purposes; exhibits irradiation effects
Quartz	1 011	3.35	Weak–medium	Very small	Negligible	Perfect	Can be elastically bent	For small-angle scattering; focusing
Potassium bromide	200	3.29	Medium–strong	Moderate	Negligible	Slightly deliquescent	—	—
Fluorite	111 220	3.16 1.94	Medium–strong Very strong	Moderate	Small	Perfect	Moderately hard	For eliminating harmonics; general purposes; short wavelengths
Urea nitrate	002	3.14	Strong	Very large	Very great	Very poor	Very easily deformed	For large specimens; soon decays
Calcite	200	3.04	Medium	Small	Negligible	Perfect	Moderately soft	For small-angle scattering; isolation of α_1 or α_2
Rock salt	200	2.82	Medium–strong	Large	Great	Slightly deliquescent	Can be plastically bent in warm supersaturated saline	For focusing
Aluminium	111	2.33	Very strong	Moderate to large	—	Good	Soft, can be seeded and grown to shape, then plastically shaped at room temperature	For focusing; diffuse scattering
Diamond	111	2.05	Weak	Very small	Negligible	Perfect	Very hard	For eliminating harmonics
Lithium fluoride	200	2.01	Very strong	Small-moderate	Negligible	Perfect	Hard, can be plastically bent at high temperature	For focusing; diffuse scattering; general purposes
Graphite	002	3.35	Very strong	Small	Negligible	Perfect	Easily shaped	Widely used for monochromators on diffractometers

4.3   X-ray techniques

The techniques, involving X-rays, which are commonly employed in the investigation of metallic materials are X-radiography, X-ray diffraction analysis, X-ray small angle scattering, X-ray fluorescence, and X-ray photoelectron spectroscopy (XPS). The basis of these techniques and their metallurgical applications are given in Table 4.6.

4.3.1   X-ray diffraction

Diffraction effects are produced when a beam of X-rays passes through the three-dimensional array of atoms which constitutes a crystal. Each atom scatters a fraction of the incident beams, and if certain conditions are fulfilled then the scattered waves reinforce to give a diffracted beam. These conditions are expressed by the Bragg equation:

$$n\lambda = 2d_{hkl} \sin\theta$$

where n is an integer, λ the wavelength of the incident beam, d_{hkl} the interplanar spacing of the *hkl* planes, and θ the angle of incidence on the *hkl* planes.

A randomly oriented single crystal irradiated with monochromatic radiation is unlikely to have any planes at the correct orientation to satisfy the Bragg equation. Hence when single crystals or more usually individual grains are examined they are either rotated in the X-ray beam or continuous wavelength (white) radiation is used as in the Laue technique.

In the case of powder or fine grained material sufficient crystals are irradiated for some to have planes oriented to satisfy the Bragg equation. The number is increased by rotating or translating the specimen. A series of concentric diffraction cones with semiapex angle 2θ are produced which intersect a narrow film placed around the specimen in a series of arcs, which is the diffraction pattern. This is either recorded on film or scanned with an electronic radiation detector.

4.3.1.1   *Experimental methods*

The experimental methods of X-ray diffraction and their common metallurgical applications are reviewed in Table 4.7. Film methods are included (only to illustrate particular applications) as they have virtually been replaced by computer automated diffractometer methods. Fully automated diffractometer systems are now commercially available for all XRD applications, ranging from routine rapid qualitative and quantitative analysis to detailed single crystal structure analysis.

With these systems, diffraction data are collected and processed automatically, peaks are identified and 2θ, d, peak intensity and width and integrated intensities are measured.

The data are stored in preparation for further evaluation specific to the applications, for example phase analysis and quantification, crystallite size and strain determination from peak breadths and crystallographic evaluations. These are obtained from the determination of unit cell, indexing of peaks and lattice parameter measurements.

The speed of data collection can be increased some 50 to 100 fold by replacing the scintillation counter previously supplied as the standard detector on conventional diffractometers with a Position Sensitive Detector (PSD). With this conversion a complete diffraction pattern can be obtained in a few minutes. The increase in speed is achieved by simultaneously recording diffractions over a 2θ range of about 12° as compared with only, typically, 0.05° with a conventional detector. There are two different modes of operation, stationary and scanning. In the stationary mode diffractions over a 2θ range of about 12° are simultaneously recorded, similar to, but much faster than recording on film. In the scanning mode, the detector is moved round the 2θ circle like a conventional detector. The scanning mode is often called Continuous Position Sensitive Proportional Counter (CPSC).[10]

Particular applications of each mode are:

> Stationary mode—small angle scattering
> > phase transition
> > residual stress determination
> Scanning mode—to produce a rapid throughput of specimens
> > phase transition where a complete diffraction pattern is needed
> > use with a high temperature chamber

Table 4.6   METALLURGICAL INVESTIGATION TECHNIQUES INVOLVING X-RAYS

Technique	Principle of technique	Metallurgical applications
X-radiography	Sample placed between divergent X-ray beam and detector (usually a photographic film). Dark areas on negative show regions of low X-ray absorption (i.e. low density in specimen such as cracks) and vice versa	Crack and other defect detection in castings, welded fabrications, etc. Very widely used inspection and quality assurance technique
X-ray diffraction	Beam of X-rays of specific wavelength (λ) diffracted at certain angles (θ) by crystal planes of appropriate spacing (d) which satisfies the Bragg equation, i.e.	Identification and quantitative analysis of crystalline chemical compounds (phase analysis and quantification, e.g. retained austenite determination)
	$$n\lambda = 2d \sin \theta$$	Crystal structure determination
	Angular position of diffraction peaks, shape of peaks, and intensity peaks give information on crystal structure and physical state	Residual macro- and micro-stress analysis and crystallite size
		Texture (preferred grain orientation) measurement Detection of cold work and imperfections (by stacking faults, etc.) N.B. All results obtained from thin (typically $50\,\mu m$) surface layer
Small angle X-ray scattering	Large regions (e.g. $10 \rightarrow 10\,000$ Å) of inhomogeneous electron density distributions (e.g. vacancy clusters or Guinier–Preston zones) cause scattered radiation pattern near main beam	Determination of size, shape and composition (in terms of electron density) of Guinier–Preston zones, vacancy clusters, etc. in metallic transmission technique therefore limited to thin samples—typically 10–$50\,\mu m$
X-ray fluorescence	Electrons ejected from inner shells of atoms cause emission of X-rays (fluorescence) characteristic of atomic species—exciting radiation may be photons (γ and X-rays), positive ions or electrons. Fluorescent X-rays analysed by wavelength or energy dispersive spectrometers.	Elemental analyses Na to U routine. C, N, O, F require specifically designed equipment. Hence used for routine analysis of composition of ores, semi-finished and finished metals and their alloys. Quantitative analysis normally employs calibrated standards. N.B. Results are obtained from surface layer of approx. $2\,\mu m$ thickness
X-ray photo-electron spectroscopy (XPS)	Electrons from inner shells of atoms are ejected by X-radiation of specific wavelength. Energy of ejected electron measured by spectrometer gives information on binding energy of electron shells	Qualitative and quantitative analysis of surface layers, XPS signals typically come from depths of less than 50 Å. Elemental analysis He to U including, C, N, O, F. Information on the state of bonding of analysed elements

Table 4.7   X-RAY DIFFRACTION TECHNIQUES

Experimental technique	Description	Metallurgical applications
Single crystal		
Single-crystal camera Weissenberg camera Precession camera Automated single crystal diffractometer	Small single crystal or metallic grains oriented on a two-axis goniometer with a prominent crystallographic axis along the goniometer axis. Crystal rotated in a monochromatic or filtered X-ray beam. Produces a spot diffraction pattern related to the symmetry of the crystal.	Determination of unit cell dimensions Crystal structure analysis (i.e. determination of atom positions and thermal vibrations) etc.
Back reflection or transmission Laue camera	Stationary sample, single crystal or polycrystalline irradiated with white, continuous wavelength radiation. The back scattered, (back reflection) and forward scattered transmission diffraction patterns are recorded on flat films perpendicular to the incident beam. The symmetry of the diffraction pattern is related to the symmetry of the crystal in the beam direction. The transmission pattern can be electronically recorded on large-area detectors.	Texture studies on deformed (worked) metallic materials Confirmation of crystal symmetry Determination of crystal orientation
Powder or fine-grained sample		
Debye-Scherrer camera	Cylindrical compact of powder or wire sample (approx. 5 mm long and 0.5–1 mm in diameter) rotated (to avoid texture effects) in monochromatic X-ray beam. Diffraction cones intersect narrow cylindrical film (coaxial with sample) to give line spectrum.	Phase identification Quantitative analysis of mixtures of chemical compounds usually with aid of calibrated standards Composition of alloy phases by correlation of lattice parameters with varying constituent elements
Glancing angle camera	Diffraction spectra obtained by irradiating surface or edge sample at glancing angle and recording one half of total diffraction spectra (other half absorbed by sample) on photographic film.	Examination of bulk samples, simultaneous detection and analysis of surface film (e.g. oxides) and parent metal substrate
Guinier camera	Flat sample positioned on the circumference of the camera is irradiated by a monochromatic or filtered beam of X-rays diverging from a film around the circumference.	Improved resolution and inherently low background aids identification and comparison of specimens with small differences of structure. Diffractions at low Bragg angles (high d values) can be studied

Diffractometry	Flat sample irradiated by a diverging beam of monochromatic or filtered X-rays. Detector rotated at twice the angular speed of the specimen to maintain the Bragg-Brentano focusing conditions.	Phase identification and quantification (usually with calibrated standards)
		Studies of crystal imperfections, e.g. stacking faults, microstrain, etc. by detailed measurement of spectra profiles
		With appropriate attachments the following are possible:
		  Residual stress measurement
		  Texture (preferred orientation) determination
		  Thermal expansion parameter measurement
		  Phase transition monitoring

4.3.1.2   *Accessory attachments for diffractometers*

The range of applications of diffractometers is increased by accessory attachments for particular applications. These include:

- Specimen holder with rotation and translation scanning for analysing coarse grained solid and powder samples.
- Specimen changers for the sequential analysis of up to 40 specimens.
- Chambers for high and low temperature measurement. Temperature control and data collection can be automated and with a CPSC, rapid data collection system, a 3D display of 2θ and intensity against temperature can be obtained in a few hours.
- Preferred orientation is measured with a Texture Attachment. Intensity data are automatically collected and results displayed as either a conventional pole figure or as orientation distribution functions (ODF).[11]
- Attachments for quantitatively measuring residual stress.
- Diffraction patterns can be obtained from thin surface films by irradiating the surface at a shallow angle to increase the effective thickness of the film.

4.3.2   **Specific applications**

4.3.2.1   *Phase identification and quantitative measurements*

Phase identification and quantification depend on the accurate measurement of the interplanar (*d*) spacings and relative intensities of the diffractions in a diffraction pattern. For routine phase identification the observed *d* spacings and relative intensities are compared with standard X-ray data listed in the X-ray Powder Diffraction File (PDF) published by the International Center for Diffraction Data (ICDD), formerly the Joint Committee on Powder Diffraction Standards (JCPDS).[12] The file contains data for over 90 000 materials and is regularly updated. It can be obtained on computer files for computer search and match procedures which have virtually replaced the previously used manual procedures.

Interactive graphic search programmes are commonly employed. After entering any chemical information, the PDF files are automatically searched and possible matches listed. These are subsequently subtracted from the unknown pattern and the residual displayed for further analysis. With a mixture, the intensities of the file patterns can be varied to produce the best fit.

In practice, the success in analysing a mixture often depends on the availability of additional information. For example chemical analysis of individual phases or particles carried out by EDAX in a SEM, or a manual separation of phases for separate XRD analysis. The patterns can then be subtracted from the unknown pattern.

Quantitive determinations are carried out by comparing integrated intensities of selected diffractions. In order to allow for absorption, powders are usually analysed by adding a known fraction of standard calibrating powder and comparing the intensities of a diffraction from the component to be analysed with the intensity of a diffraction from the internal standard. Methods are thoroughly discussed in references 3, 9, 10 and 11.

X-ray diffraction analysis is used for the identification of atmospheric pollutants. Examples include silica[13] and asbestos particles collected on multipore filters. The method requires the taking of an X-ray scan directly from the filter and determining the amount of pollutant by comparison with calibration curves prepared from similar filters containing known amounts of the pollutants. As little as $2\,\mu g\,cm^{-2}$ of silica can be detected by this method.

Most metallurgical samples of interest, however, are solid and cannot be analysed by the above methods. In this case either a calibration curve is constructed from well characterised standards, showing, for precisely defined diffraction conditions, the variation in intensity of a particular diffraction with percentage of the phase to be analysed. Alternatively, theoretical intensities are calculated for diffractions from each phase to be analysed and the ratios of their amounts determined from the observed intensity ratios. The method is illustrated below for the determination of retained austenite in steels but can be extended to other systems. X-ray data for calculating diffraction intensities are listed in Tables 4.8, 4.9, 4.10 and 4.11.

4.3.2.2 *Determination of retained austenite in steel*

An important example of quantitative phase analysis by X-ray diffraction is the determination of retained austenite in steels. The method is based on the comparison of the integrated diffracted X-ray intensities of selected (*hkl*) reflections of the martensite and austenite phases. The necessary formulae and reference data are given below; for more details of the experimental methods the definitive paper by Durnin and Ridal[14] should be consulted.

The integrated intensity of a diffraction line is given by the equation:

$$I_{(hkl)} = n^2\, Vm\,(LP)\, e^{-2m}\,(F)^2 \tag{4.1}$$

in which $I_{(hkl)}$ = integrated intensity for a special (*hkl*) reflection; n = number of cells in cm³; V = volume exposed to the X-ray beam; (LP) = Lorentz-Polarisation factor; m = multiplicity of (*hkl*); e^{-2m} = Debye–Waller temperature factor; F = structure factor (which includes f, the atomic scattering factor.)

For n^2V we may substitute V/v^2, in which v is the volume of the unit cell.

If the ratio between the integrated intensities of martensite and austenite is denoted by P:

$$P = \frac{I\text{ martensite }(\alpha)}{I\text{ austenite }(\gamma)} = \frac{V_\alpha v_\gamma^2 m_\alpha (LP)_\alpha e_\alpha^{-2m}(F_\alpha)^2}{V_\gamma v_\alpha^2 m_\gamma (LP)_\gamma e_\gamma^{-2m}(F_\gamma)^2} \tag{4.2}$$

Each factor is determined from the International Tables[9] and depends on the reflection used. A factor G is then determined for each combination of α and γ peaks used; hence:

$$P = \frac{V_\alpha}{V_\gamma} \times \frac{1}{G} \tag{4.3}$$

If α and γ are the only phases present:

$$V_\gamma = \frac{1}{1 + GP} \tag{4.4}$$

Hence, measurement of the ratio (P) of two diffraction peaks and calculation of the factor G will give the volume fraction of austenite V_γ.

The factors involved in the calculation of G for two steels—16.8%Ni–Fe(0.35%C) and NCMV (a Ni–Cr–Mo–V steel with composition wt % 0.43C; 0.31Si; 0.57Mn; 0.009S; 0.005P; 1.69Ni; 1.36Cr; 1.08Mo; 0.24V; 0.11Cu), Mo, Co and Cr radiation and a selection of *hkl* peaks have been extracted from the 'International Tables for X-Ray Crystallography'[9] by Durnin and Ridal[14] and are presented in Table 4.12.

These factors may be used to calculate G for different radiations and peaks. The results are presented in Table 4.13.

When the alloy compositions are being investigated the factors which make up G must be determined from the International Tables.[9]

Accuracy obtainable using a diffractometer is in the region of 0.5% for the range 1.5–38 volume percentage of austenite. X-ray diffraction determination accuracy thus compares favourably with other techniques such as metallography, dilatometry and saturation magnetisation intensity methods which are all inaccurate below 10% austenite content.

The main source of error in X-ray determination of retained austenite comes from overlapping carbide peaks. The carbides and their diffraction peaks most likely to cause problems are summarised in Table 4.14.

4.3.2.3 *X-ray residual stress measurements*

Residual stresses can be divided into two general categories, macrostresses where the strain is uniform over relatively large distances and microstresses produced by non-uniform strain over short distances, typically a few hundred Å. Both types of stress can be measured by X-ray diffraction techniques.

The basis of stress measurement by X-ray diffraction is the accurate measurement of changes in interplanar d spacing caused by the residual stress. When macrostresses are present the lattice plane spacing in the crystals (grains) change from their stress-free values to new values corresponding with the residual stress and the elastic constants of the material. This produces a shift in the position of the corresponding diffraction, i.e. a change in Bragg angle θ. Microstresses however give rise to non-uniform variations in interplanar spacing which broaden the diffractions rather than cause a shift in their position. Small crystal size also give rise to broadening.

Measurement of Macro-residual stress[1,2,3,7,15]

The working equation used in most X-ray stress analysis is

$$\sigma\phi = \frac{d_\psi d_\perp}{d_\perp} \times \frac{E}{1+v} \times \frac{1}{\sin^2 \psi} \tag{1}$$

where σ_ψ is the surface stress lying in a direction common to the surface and the plane defined by the surface normal and the incident X-ray beam. E and v are Young's modulus and Poisson's ratio respectively, d_ψ and $d_\perp$ are the interplanar spacings of planes with normals parallel to the surface normal and at an angle ψ to the surface normal. These angles are related to the direction of the incident X-ray beam, as shown in Fig. 4.1. Thus σ can be determined from two exposures, one with the incident beam inclined at θ to the surface to measure $d_\perp$ and the other at an angle ψ the first to measure d_ψ. This technique is known as the two-exposure technique.

Alternatively equation (1) can be rewritten as

$$d_\psi = d_\perp \left(\frac{1+v}{E} \right) \sigma\phi \sin^2 \psi + d_\perp \tag{2}$$

Figure 4.1

This shows that d_ψ is a linear function of $\sin^2 \psi$. The intercept on the d axis gives $d_\perp$ and the slope $d_\perp((1+v)E)\sigma\phi$. A positive slope corresponds to a tensile stress and a negative slope to compression. This technique takes advantage of measurements involving a number of d_ψ values.

The determination of interplanar spacings depends on the accurate measurement of the corresponding Bragg angle θ where

$$d_{hkl} = \frac{\lambda}{2 \sin \theta_{hkl}}$$

Back reflection diffractions are used as the highest sensitivity to changes in interplanar spacing are obtained as θ tends to 90°. In practice the specimen is rotated through ψ between exposures (or the tube and detector together through the same angle on portable systems for measuring large samples).

Due to the limited penetration of commonly used X-ray wavelengths, typically 4 μm for chromium radiation to 11 μm for molybdenum in steel, only surface stresses are measured. Stresses at lower depths in the sample are determined by repeating measurements after removing (electropolishing) layers of known thickness. The measured values are subsequently corrected for changes in stress resulting from the removal of upper layers.

Residual stress in small components can be measured on a converted diffractometer by adding a specimen support table with three orthogonal adjustments to permit the surface of the component to be brought into the beam. Fully automated portable systems are available for determining residual stress in large components.

Typical accuracy for steel is ± 1.5–3.0×10^7 Pa (± 1–2 ton in^{-2}).

MEASUREMENT OF MICROSTRESSES[2,16,17]

A worked surface gives rise to broadened diffractions due to a combination of microstresses and small crystallite size. An approximate method to separate the two effects is to assume that the breadth is the sum of the separate broadening from each effect.

The relationships between diffraction breadth β and average crystallite size ε and mean stress $\bar{\sigma}$ are:

1. Small crystallite alone

$$\beta_{\text{s.c.}} \simeq \frac{k\lambda}{\varepsilon_{hkl} \cos \Theta}$$

   where k is a constant $\simeq 1$ and ε_{hkl} is the linear dimension perpendicular to the measured *hkl* plane.

2. Microstresses alone

$$\beta_{\text{M.S.}} \simeq \frac{4\bar{\sigma} \tan \Theta}{E_{hkl}}$$

   where E_{hkl} is the elastic constant perpendicular to *hkl*.

When both effects are present, then

$$\beta = \beta_{\text{s.c.}} + \beta_{\text{M.S.}}$$

$$= \frac{\lambda}{\varepsilon_{hkl} \cos \Theta} + \frac{4\bar{\sigma} \tan \Theta}{E_{hkl}}$$

which can be rewritten in the form:

$$\frac{\beta \cos \Theta}{\lambda} = \frac{1}{\varepsilon_{hkl}} + \frac{4\bar{\sigma} \sin \Theta}{\lambda E_{hkl}}$$

If only these defects are present, then a plot of $\beta \cos \Theta / \lambda$ against $\sin \Theta$ should be a straight line, with intercept on the $\beta \cos \Theta / \lambda$ axis giving $1/\varepsilon_{hkl}$ and the slope $4\bar{\sigma}/\lambda E_{hkl}$.

For non-cubic materials, for example tetragonal and hexagonal, separate plots should be made for the hk0 and 001 results.

In the above formulae, diffraction breadth is measured as either the breadth in radians at half the peak height (HPHW) or as the integral breadth which is the integrated intensity of the diffraction divided by the peak height. It corresponds to the width of a rectangle having the same area and height as the diffraction. The latter is particularly useful in analysing peaks with partially resolved $\alpha_1 \alpha_2$ doublets. The measured breadths include the instrumental breadth which is independent of any crystal defects. This can be measured for subsequent subtraction from the measured breadths by running a scan from a defect-free specimen.

4.3.2.4   *Preferred orientation*

Preferred orientation can be represented in two ways, either as a convential pole figure or as an inverse pole figure. A conventional pole figure shows the distribution of a low-index pole—normal to a crystallographic plane, over the whole specimen. With a cubic metal, these are generally constructed for {100}, {110} and {111} planes while for hexagonal metals usually the basal (0001) planes {10$\bar{1}$0} or {10$\bar{1}$1} planes are selected. A high density of poles shows the preferred direction of the pole with respect to the sample.

An inverse pole figure on the other hand shows how the grains are distributed with respect to a particular direction in the sample. Inverse pole figures are usually constructed for the principal directions of the sample, for example the extrusion, radial, and tangential directions in extruded material. The method is rapid, and data for a single direction can be determined from a conventional diffractometer scan taken from a surface which is perpendicular to the required direction. The method is based on the fact that all diffractions recorded on a conventional scan come from planes which are parallel to the surface and their intensities are related to the number of grains (volume of material) which has this orientation. The diffraction intensities are compared to those from a sample having random orientation. These can be either theoretical calculated values or values measured directly from a corresponding scan taken from a sample with random orientation. These relative intensities are called texture coefficients (TC) and are expressed mathematically as

$$\text{TC}_{(hkl)} = \frac{I_{(hkl)}/I^0_{(hkl)}}{\frac{1}{n} \sum_0^n I_{(hkl)}/i^0_{(hkl)}}$$

where

I = measured integrated intensity of a given *hkl* diffraction
I^0 = corresponding intensity for the same *hkl* diffraction from a random sample
n = total number of diffractions measured.

The TC$_{hkl}$ values are proportional to the number of grains (volume of sample) which are oriented with an hkl plane parallel to the sample surface.

The values can be plotted on a partial sterographic projection and contour lines drawn through the plotted points to produce an 'Inverse Pole Figure' for that particular specimen direction. High values show the preferred grain orientation in the specimen direction.

4.3.2.5 *Specimen preparation*

Methods for preparing standard diffractometer specimens are discussed in references 1–3. The most common method is to pack loose powder into a flat cavity in an aluminium specimen holder, taking care not to introduce preferred orientation. Another method is to mix the powder into a slurry and smear some over a glass cover slip. Coarse powders which tend to slide out of the cavity during a scan can be mixed with petroleum jelly or gum tragacanth which themselves give negligible diffraction.

A problem when analysing a small amount of material is diffraction and scatter from the specimen holder. These effects are reduced by using a single crystal holder of a low element material which has been polished so the surface is just off a Bragg plane.

Most laboratories have developed procedures and specimen holders for non-standard applications. These have been surveyed by D. K. Smith and C. S. Barrett and the results published in 'Advances in X-ray Analysis'.[18] One application is the analysis of air-moisture reactive powders. A simple solution is to fill and seal the powder in thin walled glass quills inside a dry box. After removal from the glove box the quills are mounted in raft fashion across a recessed specimen holder. Sealed cells are also used to avoid handling delicate quills inside a glove box. One such method for lithium compounds was to load the powder inside a glove box into a recessed specimen holder and cover the powder with a flanged 0.001 in. thick aluminium foil dome. Petroleum jelly was lightly smeared round the flange to hold the dome on to the specimen holder and make a moisture seal.

Metal samples submitted for XRD analysis are generally metallurgically mounted and polished samples. Due to the limited penetration of the X-ray beam into the sample it is always advisable to first electropolish the surface. Useful electropolishes are listed in Chapter 10, Table 10.4. An electropolish frequently used in preparing specimens for retained austenite determinations is

    7 vol% perchloric acid
   69 vol% ethanol
   10 vol% glycerol
   14 vol% water

At a voltage of 23 V. Electrolyte maintained at temperature below 12°C.

EXTRACTION TECHNIQUES

Precipitates that are present at very low concentrations can be concentrated by dissolving away the matrix and collecting the residue. Typical solutions used for extraction are as follows.[19]

  (i) Carbides and certain intermetallic compounds
    (a) Immersion overnight in 5 or 10% bromine in methanol, or
    (b) Electrolytically in 10% hydrochloric acid in methanol at a current density of 0.07 A cm^{-2}. Extraction for 4 h provides sufficient powder residue.
     The intermetallic phases which can be extracted using these solutions are sigma phase, certain of the Laves phases, Fe$_3$Mo$_2$ etc.
 (ii) Gamma prime, eta phase, M(CN)
    (a) Electrolytically in 10% phosphoric acid in water at a current density of 10 A dm^{-2}. Time of extraction 4 h. It is sometimes necessary to add a small amount of tartaric acid in order to prevent the formation of tantalum and tungsten hydroxides,
     or
    (b) Electrolytically in 1% citric acid plus 1% ammonium sulphate in water. Current density 2 A dm^{-2}, duration 4 h. For quantitative work this solution is preferred to the phosphoric acid electrolyte.
     Certain of the Laves phases may also be extracted using either of these solutions.
(iii) Precipitates and intermetallic compounds in chromium
     Immersion overnight in 10% hydrochloric acid. This has been used to extract carbides and borides.

Precipitates can also be concentrated by heavily etching a surface to leave them proud of the surface as used to produce replicas in electron microscopy.[20]

4.3.2.6   *Formulae and crystallographic data*

Formulae for calculating interplanar d_{hkl} spacings from lattice parameters and data for calculating intensities together with other useful information on crystal symmetry are given in Tables 4.8, 4.9, 4.10, 4.11 and 4.15.

INTENSITIES

The relative intensities of diffractions recorded on a diffractometer scan are given by the formula

$$1 \propto \left(\frac{1 + \cos^2 2\theta}{\sin^2 \cos\theta}\right)|F|^2 \cdot \mathrm{T} \cdot \mathrm{p} \cdot \mathrm{A}$$

where $\left(\dfrac{1 + \cos^2 \theta}{\sin^2 \theta \cos\theta}\right)|F|^2 \cdot \mathrm{T} \cdot \mathrm{p} \cdot \mathrm{A} =$ Combined polarisation Lorentz factor (Table 4.11)

F = structure factor involving the summation of scattering from all atoms in the unit cell
T = temperature factor, $e^{-(B\sin^2\theta/\lambda^2)}$
p = multiplicity factor, Table 4.10
A = an absorption factor.

For a diffractometer specimen of effectively infinite thickness, $A = K/\mu$ where K is a constant and μ the linear absorption coefficient of the sample. A is therefore independent of θ. A criterion for this condition is that the thickness of the specimens is $> 3.2/\mu$.

Tables 4.16 and 4.17 give values of Mean Atomic Scattering Factors and Mass Absorption Coefficients, respectively.

4.4.2   Crystal structure

Crystal structural data for free elements are given in Table 4.25. The coordination number, that is the number of nearest neighbours in contact with an atom, is listed in column 4 and the distances in column 5. In complex structures, such as α Mn where the coordination is not exact, no symbol is used and the range of distances between near neighbours is given.

A co-ordination symbol x in column 4 indicates that each atom has x equidistant nearest neighbours, at a distance from it (in kX-units) specified in column 5. The symbol x, y indicates that a

From C. S. Barrett and T. B. Massalski, 'Structure of Metals', 1980.[2]

given atom has x equidistant nearest neighbours, and y equidistant neighbours lying a small distance further away. These distances are given in column 5. In complex structures, such as α-Mn, where the co-ordination is not exact, no symbol is used, and the range of distances between near neighbours is given in column 5.

The Goldschmidt atomic radii given in column 6 are the radii appropriate to 12-fold co-ordination. In the case of the f.c.c. and c.p.h. metals the radius given is one-half of the measured interatomic distance, or of the mean of the two distances for the hexagonal packing. In the case of the b.c.c. metals, where the measured interatomic distances are for 8-fold co-ordination, a numerical correction has been applied. In some cases, where the pure element crystallises in a structure having a low degree of co-ordination, or where the co-ordination is not exact, it is possible to find some compound or solid solution in which the element exists in 12-fold co-ordination, and hence to calculate its appropriate radius. In a few cases no correction for co-ordination has been attempted, and here the figures, given in parentheses, are one-half of the smallest interatomic distances. It should be emphasised that the Goldschmidt radii must not be regarded as constants subject only to correction for co-ordination and applicable to all alloy systems: they may vary with the solvent or with the degree of ionisation, and they depend to some extent on the filling of the Brillouin zones.

Ionic radii vary largely with the valency, and to a smaller extent with co-ordination. The values given in column 8 are appropriate to 6-fold co-ordination, and have been derived either by direct measurement or by methods similar to those outlined for the atomic radii. All are based, ultimately, on the value of 1.32 Å obtained for O^{2+} ions by Wasastjerna,[21] using refractivity measurements. Ionic radii are also affected by the charge on neighbouring ions: thus in CaF_2 the fluorine ion is 3% smaller than in KF, where the metal ion carries a smaller charge. It is not possible to give a simple correction factor, applicable to all ions: the effect is specific and is especially marked in structures of low co-ordination. Figures in arbitrary units indicating the power of one ion to bring about distortion in a neighbour (its 'polarising power'), and indicating the susceptibility of an ion to such distortion (its 'polarisability') are given in columns 9 and 10, respectively.

The crystal structures of alloys and compounds are listed in Chapter 6, Table 6.1. Other sources of data are references 12 and Pearson[22] which is particularly valuable as the variation of lattice parameters with composition as well as structure is given. Structures are generally referred to standard types which are listed in Pearson and in Table 6.2 in Chapter 6. Further information on crystallography can be obtained from International Tables for X-ray Crystallography.[9]

  parallel to surface.

The density of a material is calculated from crystallographic data with the relation

$$p_c = \frac{n\bar{A}}{VN}$$

where n is the number of atoms contained in the unit cell of volume V, A is Avogadro's constant and $\bar{A}$ is the mean atomic weight of the atoms. $\bar{A}$ is computed from the atomic percentages p_1, p_2, etc, of the elements forming the alloy and their atomic weights A_1, A_2, etc, using the formula

$$\bar{A} = \frac{p_1 A}{100} + \frac{p_2 A_2}{100} + \cdots$$

4.5 X-ray fluorescence

X-ray fluorescence occurs after an electron has been ejected from a shell surrounding the nucleus of an atom. The X-radiation is characteristic of the atom from which the electron has been ejected, and hence provides a means of identifying the atomic species. The ejection of an electron may be induced by irradiating the sample with photons (X or γ-rays) electrons, protons, charged particles or, indeed, any radiation capable of creating vacancies in the inner shells of the atoms of interest in the sample. The relative merits of each technique are given in Table 4.26. A further comparison of X-ray or radio-isotope sources for X-ray fluorescent spectroscopy is given in Table 4.27. Details of suitable available isotope sources are given in Table 4.28.[23]

Analysis of fluorescent X-rays is achieved by wavelength dispersion using crystal analyser (or several in a multichannel instrument), or by energy dispersion with solid-state detectors. Wavelength dispersion offers more accurate quantitative analysis, especially for the detection of small concentrations of elements where X-ray spectra from several elements overlap. Energy dispersion is preferred when rapid or quantitative analysis is required of an unknown sample.

Examples of the detection limits for X-ray excited samples are given in Tables 4.29 and 4.30, and for ion excited samples in Table 4.31.

Accuracy levels for elemental analysis are typically:

for X-ray excitation	better than 1%.
for electron and ion excitation	1–2%.

These values can be improved with very carefully calibrated standards, but are frequently much worse, especially when the specimen surface is rough. Unlike X-ray diffraction, powdered samples are the most difficult sample form to analyse.

Table 4.26   COMPARISON OF X-RAY FLUORESCENCE TECHNIQUES

Exciting radiation	*Advantages*	*Limitations*
Electrons	High-intensity energy-regulated sources easily produced Can be focused into submicron spot size Low cost Good light element detection	Specimen must be in vacuum with source Signal-to-background ratio relatively poor
Positive ions	Better signal-to-background ratio than electrons Can be focused Very sensitive to low concentrations	Specimens must be in vacuum with source Expensive equipment
Photons X-rays or γ-rays	Convenient—specimen need not be in vacuum Widely used Wavelength can be chosen for maximum sensitivity for element of interest	Cannot be focused Not as sensitive to small samples as positive ion excited methods Light elements (<Mg difficult)

Table 4.27   COMPARISON OF X-RAY AND RADIOACTIVE SOURCES FOR X-RAY FLUORESCENT SPECTROSCOPY

Radiation source	*Advantages*	*Limitations*
X-rays	Controllable high-intensity source which can be switched off when not required Intensity can be 10^2–10^4 times that of radioisotope source	Bulky, expensive equipment—requires high voltage generator
Radio isotopes	Cheaper, portable, and smaller than X-ray systems Can be built into process plant for local on-stream analysis	Permanent radioactive hazard Low intensity means long exposure times and/or larger samples Relatively small number of available isotopes (*see* Table 4.28)

5   Crystallography

5.1   The structure of crystals*

5.1.1   Translation groups

Metals and alloys, like most condensed matter, are aggregates of crystals; they are built up of units, consisting of small groups of atoms regularly and indefinitely repeated throughout the body by parallel translations. If the co-ordinates of the atoms within such a group are given, then three independent translations represented by vectors *a, b, c,* which are not all parallel to the same plane, suffice to specify the position of any other atom in the crystal. Let the vector from an arbitrary origin to an atom be

$$r = x\boldsymbol{a} + y\boldsymbol{b} + z\boldsymbol{c}$$

then atoms of the same kind will be found at all points

$$\boldsymbol{r}_n = (n_1 + x)\boldsymbol{a} + (n_2 + y)\boldsymbol{b} + (n_3 + z)\boldsymbol{c}$$

where n_1, n_2, n_3 may be any positive or negative integers. Such a succession of regularly arranged points in space constitutes a space lattice.

The lattice may be regarded either as a system of translations relating identical points in a structure, or as a system of points arranged in parallel and equidistant nets, each net consisting of series of parallel and equidistant rows in which the points are spaced at equal distances. The points of such an array can be arbitrarily arranged in an infinite number of ways in parallel equidistant linear rows or planar nets; they can, in other words, be referred to an infinite number of systems of three primitive vectors, but investigation has shown that any structure possessing the symmetry observed in crystals can be referred to one of 14 lattices, defined by its primitive vectors and by the character of its unit cell, the latter being the parallelepiped formed by the three translations selected as units. In general, unit translations are selected so as to give the simplest cell having edges as short as possible, but there are several cases in which a more complex cell is chosen so as to display the symmetry of the lattice, or its relation to other lattices, to greater advantage.

The system of three vectors *a, b, c,* is described by their lengths a, b, c and by the angles between them: $(bc) = \alpha, (ca) = \beta, (ab) = \gamma$. The face of the unit cell which is parallel to the plane of the (a) and (b) axes, and which therefore intersects the (c) axis at distance c from the origin is termed the c face. Similarly, the face parallel to the b–c axial plane is the a face, and that parallel to the a–c axial plane the b face.

The simplest cell, having points only at its corners, is termed 'primitive' and is given the symbol Γ (Schoenflies) or P (Hermann). Other cells, termed 'face centred', have points at the corners and at the centres of two or more of their faces, and are given symbols indicating the faces carrying these additional points. Thus A, B, C, F represent centring on the a, b, c and all faces respectively. Finally there is the 'body centred' cell, having points at its corners and one additional point at the intersection of the body diagonals. This is given the symbol I (Hermann). Centred cells are indicated by Schoenflies by dashes. The 14 space lattices are listed in Table 5.1.

---

* This chapter can be cross-referenced with chapters 4 (X-ray diffraction) and 6 (crystal chemistry), plus section 10.4 (electron microscopy).

Table 5.1   THE FOURTEEN SPACE LATTICES*

System	Axes	Angles	Unit cells	Symbols Schoenflies	Hermann
Triclinic	$a \neq b \neq c$	$\alpha \neq \beta \neq \gamma$	Primitive	Γtr	P
Monoclinic	$a \neq b \neq c$	$\alpha = \gamma = 90°$ β obtuse	*1* Primitive *2 c* face centred	Γm $\Gamma m'$	P C
Orthorhombic	$a \neq b \neq c$	$\alpha = \beta = \gamma = 90°$	*1* Primitive *2 c* Face centred *3* All face centred *4* Body centred	Γo $\Gamma o'(c)$ $\Gamma o''$ F'''	P C F I
Tetragonal	$a = b \neq c$	$\alpha = \beta = \gamma = 90°$	*1* Primitive *2* Body centred	Γt $\Gamma t'$	P I
Cubic	$a = b = c$	$\alpha = \beta = \gamma = 90°$	*1* Primitive *2* All face centred *3* Body centred	Γc $\Gamma c'$ $\Gamma c''$	P F I
Rhombohedral	$a = b = c$	$\alpha = \beta = \gamma \neq 90°$	Primitive	Γrh	R
Hexagonal	$a = b \neq c$	$\alpha = \beta = 90°$ $\gamma = 120°$	Primitive	Γh	C

* The 14 space lattices are also referred to as Bravais lattices (after Auguste Bravais 1811–63). The centred cells are chosen to display most clearly the symmetry of the lattice, but all space lattices may be represented by primitive cells. For example, the all-face and body-centred cubic lattices may be represented by rhombohedral unit cells having $\alpha = \beta = \gamma = 60°$ and 109.48° respectively. These are referred to as alternative settings of the unit cell of the lattice.

5.1.2   Symmetry elements

Symmetry elements may be classified as axes, planes, and centres. A body has an axis of symmetry when rotation through a definite angle about some line through it (the axis of rotation) causes it to assume its original aspect. Crystals can only have axes of 2-, 3-, 4- and 6-fold rotation, involving coincidence after rotation through 180°, 120°, 90° and 60° respectively. If a plane passes through a body such that every point on one side of the plane stands in mirror-image relationship to a corresponding point on the other side, the plane is said to be a reflecting plane or mirror plane of symmetry. A point within a body is a centre of symmetry or centre of inversion if a line drawn from any point of the body to the centre and extended to an equal distance beyond it encounters a corresponding point. Other symmetry operations are:

> *Rotoinversion (or inversion) axes of symmetry*, involving rotation through 180°, 120°, 90° and 60°, combined with an inversion through a centre of symmetry.
> *Screw axes of rotation*, combining rotation about a 2-, 3-, 4- or 6-fold axis with a translation of a specified length in the direction of the axis.
> *Glide planes*, combining reflection with a translation parallel to the plane of the mirror.

In the case of screw axes, the amount of the shift must be a rational fraction of the translation along the same axis, the denominator of the fraction being the multiplicity of the rotation. Thus for a 6-fold axis, the shift may be 1/6, 2/6, 3/6 … of the translation. In the case of the glide plane, the shift must be one half of some translation in that plane. Thus it may be $a/2$ or $b/2$ parallel to the a and b axes, or of half the face diagonal in the direction parallel to that diagonal. If the cell is centred on that particular face, the shift may be one half of the distance to the centre, i.e. of the face diagonal.

5.1.3   The point group

The point group may be defined as a group of symmetry elements distributed about a point in space, and may be conveniently visualised as an assembly of points generated by the operation of the symmetry elements in question upon a single point having co-ordinates xyz referred to specified axes, the symmetry elements passing through the origin. Thus a symmetry plane, passing through the origin and containing the x and y axes, will generate, from the point xyz, an equivalent point of which the co-ordinates are $xy\bar{z}$. These two points serve to characterise the point group.

The 32-point groups define all the ways in which axes, planes and centres of symmetry can be distributed so as to intersect in a point in space, and correspond to the 32 classes of morphological crystallography.

5.1.4   The space group

The space group may be defined as an extended network of symmetry elements distributed about the points of a space lattice, and may be visualised as an assembly of points generated by the operation of symmetry elements on a series of points situated identically in each cell of the lattice. Whereas in the point group the repeated operation of any symmetry element must ultimately bring each point back to its original position, in the space group an operation need only bring the point to an analogous position in the same or in another cell of the lattice. Thus in the space group the more complex symmetry operations of screw axes and glide planes are possible, combining translation with rotation and reflection respectively.

Point groups, placed at the points of space lattices belonging to the same system of symmetry, give rise to the simplest of the 230 space groups. The remainder are generated by replacing the simple planes and axes of the point group by glide planes and screw axes.

5.2   The Schoenflies system of point- and space-group notation

The symmetry elements chosen by Schoenflies are axes of n-fold rotation, reflection planes, rotore-flection (rather than rotoinversion) axes of symmetry and centres of inversion. The symbols assigned to the various point groups are as follows:

C_n = groups having a single n-fold axis;
C_n^h = groups having a single vertical n-fold axis, together with a horizontal reflection plane;
C_n^v = groups having a single vertical n-fold axis, together with n vertical reflection planes;
D_n = groups having an n-fold axis and n two-fold axes at right angles to it;
V = a symbol frequently used as an alternative to D_2;
O = the two cubic groups which possess the maximum possible number of rotation axes, namely three 4-fold axes parallel to the cube edges, four 3-fold axes parallel to the cube diagonals and six 2-fold axes parallel to the face diagonals;
T = the three remaining groups of the cubic system;
S_n = groups having an n-fold axis of rotary reflection.

The suffix i signifies a centre of inversion.
The suffix s signifies a single plane of symmetry.
The suffix d signifies a diagonal reflection plane, bisecting the angle between two horizontal axes.

The symbols for the space groups are simple modifications of those for the point groups: the index and subscript of the point group are combined to give the subscript of the space group symbol, and an index is added representing the order in which Schoenflies deduced the symmetry of the group. Thus C_{nh}^m represents the mth group derived from the point group C_n^h.

Table 5.2 gives the point groups, their symbols and elements of symmetry, the crystal classes with which they correspond, and the co-ordinates of equivalent points.

5.3   The Hermann–Mauguin system of point- and space-group notation

The symbols used by Hermann and Mauguin to indicate the various symmetry operations are as follows:

Rotation axes: the number 2, 3, 4 or 6 denoting the multiplicity.
Screw axes: the symbol denoting the multiplicity of rotation, with a subscript indicating the magnitude of the shift. The complete set of screw axes is 2_1; 3_1, 3_2; 4_1, 4_2, 4_3; 6_1, 6_2, 6_3, 6_4, 6_5.
Rotoinversion (or inversion) axes: $\bar{2}, \bar{3}, \bar{4}, \bar{6}$, the numeral indicating the multiplicity.
Centre of inversion: $\bar{1}$.
Reflection plane: m.
Glide plane: with shift in the a direction: a
with shift in the b direction: b
with shift of 1/2 the face diagonal: n
with shift of 1/2 the centring translation: d.

The full space group symbol consists of the translation (or lattice) symbol followed by symbols of the symmetry elements associated with specified crystallographic directions in a specified order.

Table 5.2   POINT-GROUP NOTATION (SCHOENFLIES)

System	Class no.	Schoenflies symbol	Crystal class		
			Schoenflies	Dana	Miers
Triclinic	1	C_1	Hemihedry	Asymmetric	Asymmetric
	2	C_i	Holohedry	Normal	Central
Monoclinic	3	$C_s = C_1^h$	Hemihedry	Clinohedral	Planar
	4	C_2	Hemimorphic hemihedry	Hemimorphic	Digonal polar
	5	C_2^h	Holohedry	Normal	Digonal equatorial
Orthorhombic	6	C_2^v	Hemimorphic hemihedry	Hemimorphic	Didigonal polar
	7	$V = D_2$	Enantiomorphic hemihedry	Sphenoidal	Digonal holoaxial
	8	$V^h = D_2^i$	Holohedry	Normal	Didigonal equatorial
Tetragonal	9	S_4	Tetartohedry of 2nd sort	Tetartohedral	Tetragonal alternating
	10	$V^4 = D_2^d$	Hemihedry of 2nd sort	Sphenoidal	Ditetragonal alternating
	11	C_4	Tetartohedry	Pyramidal hemimorphic	Tetragonal polar
	12	C_4^h	Paramorphic hemihedry	Pyramidal	Tetragonal equatorial
	13	C_4^v	Hemimorphic hemihedry	Hemimorphic	Ditetragonal polar
	14	D_4	Enantiomorphic hemihedry	Trapezohedral	Tetragonal holoaxial
	15	D_4^h	Holohedry	Normal	Ditetragonal equatorial
Cubic	16	T	Tetartohedry	Tetartohedral	Tesseral polar
	17	T^h	Paramorphic hemihedry	Pyritohedral	Tesseral central
	18	T^d	Hemimorphic hemihedry	Tetrahedral	Ditesseral polar
	19	O	Enantiomorphic hemihedry	Plagihedral	Tesseral holoaxial
	20	O^h	Holohedry	Normal	Ditesseral central
Rhombohedral	21	C_3	Tetartohedry	Not named	Trigonal polar
	22	$C_3^i = S_5$	Hexagonal tetartohedry of 2nd sort	Trirhombohedral	Hexagonal alternating
	23	C_3^v	Hemimorphic hemihedry	Ditrigonal pyramidal	Ditrigonal polar
	24	D_3	Enantiomorphic hemihedry	Trapezohedral	Trigonal holoaxial
	25	D_3^d	Holohedry	Rhombohedral	Dihexagonal alternating
Hexagonal	26	C_3^n	Trigonal paramorphic hemihedry	Not named	Trigonal equatorial
	27	D_3^h	Trigonal holohedry	Trigonotype	Ditrigonal equatorial
	28	C_6	Tetartohedry	Pyramidal hemimorphic	Hexagonal polar
	29	C_6^h	Paramorphic hemihedry	Pyramidal	Hexagonal equatorial
	30	C_6^v	Hemimorphic hemihedry	Hemimorphic	Dihexagonal polar
	31	D_6	Enantiomorphic hemihedry	Trapezohedral	Hexagonal holoaxial
	32	D_6^h	Holohedry	Normal	Dihexagonal equatorial

Typical example	*Symmetry elements*	*Co-ordinates of equivalent points*
—	None	xyz
Copper sulphate	Centre of inversion	$xyz, \bar{x}\bar{y}\bar{z}$
—	Horizontal reflecting plane	$xyz, xy\bar{z}$
Tartaric acid	2-fold axis	$xyz, \bar{x}\bar{y}z$
Gypsum	2-fold axis and horizontal plane	$xyz, \bar{x}\bar{y}z, xy\bar{z}, \bar{x}\bar{y}\bar{z}$
Topaz	2-fold axis and vertical plane	$xyz, \bar{x}\bar{y}z, \bar{x}yz, x\bar{y}z$
Sulphur	Three 2-fold axes	$xyz, x\bar{y}\bar{z}, \bar{x}y\bar{z}, \bar{x}\bar{y}z$
Barytes	Three 2-fold axes and horizontal plane	$xyz, x\bar{y}\bar{z}, \bar{x}y\bar{z}, \bar{x}\bar{y}z, xy\bar{z}, x\bar{y}z, \bar{x}yz, \bar{x}\bar{y}\bar{z}$
—	4-fold rotary reflection	$xyz, \bar{y}x\bar{z}, \bar{x}\bar{y}z, y\bar{x}\bar{z}$
Chalcopyrite	4-fold axis, two 2-fold axes and diagonal vertical plane	$xyz, x\bar{y}\bar{z}, \bar{x}y\bar{z}, \bar{x}\bar{y}z, yxz, \bar{y}x\bar{z}, y\bar{x}\bar{z}, \bar{y}\bar{x}z$
Wulfenite	4-fold axis	$xyz, \bar{y}xz, \bar{x}\bar{y}z, y\bar{x}z$
Scheelite	4-fold axis, horizontal plane	$xyz, \bar{y}xz, \bar{x}\bar{y}z, y\bar{x}z, xy\bar{z}, yx\bar{z}, \bar{x}\bar{y}\bar{z}, y\bar{x}\bar{z}$
—	4-fold axis, vertical plane	$xyz, \bar{y}xz, \bar{x}\bar{y}z, y\bar{x}z, \bar{x}yz, yxz, x\bar{y}z, \bar{y}\bar{x}z$
—	4-fold axis and four 2-fold axes	$xyz, \bar{y}xz, \bar{x}\bar{y}z, y\bar{x}z, x\bar{y}\bar{z}, \bar{y}\bar{x}\bar{z}, \bar{x}y\bar{z}, yx\bar{z}$
Zircon	4-fold axis, four 2-fold axes, horizontal plane	$xyz, \bar{y}xz, \bar{x}\bar{y}z, y\bar{x}z, x\bar{y}\bar{z}, \bar{y}\bar{x}\bar{z}, \bar{x}y\bar{z}, y x\bar{z}$ $xy\bar{z}, \bar{y}x\bar{z}, \bar{x}\bar{y}\bar{z}, y\bar{x}\bar{z}, \bar{x}yz, \bar{y}\bar{x}z, \bar{x}yz, yxz$
Ullmanite	Three 2-fold axes coincident with cube axes, *and* Four 3-fold axes coincident with cube diagonals	$xyz, x\bar{y}\bar{z}, \bar{x}y\bar{z}, \bar{x}\bar{y}z$ $zxy, \bar{z}x\bar{y}, \bar{z}\bar{x}y, z\bar{x}\bar{y}$ $yzx, \bar{y}\bar{z}x, y\bar{z}\bar{x}, \bar{y}z\bar{x}$
Pyrites	As for *T* plus a horizontal plane	Those of *T* plus $\begin{cases} xy\bar{z}, x\bar{y}z, \bar{x}yz, \bar{x}\bar{y}\bar{z} \\ z\bar{x}\bar{y}, zxy, \bar{z}\bar{x}\bar{y}, z\bar{x}y \\ yz\bar{x}, \bar{y}\bar{z}\bar{x}, y\bar{z}x, \bar{y}zx \end{cases}$
Blende	As for *T* plus a diagonal vertical plane	Those of *T* plus $\begin{cases} yxz, \bar{y}x\bar{z}, y\bar{x}\bar{z}, \bar{y}\bar{x}z \\ xzy, x\bar{z}\bar{y}, \bar{x}\bar{z}y, \bar{x}z\bar{y} \\ zyx, \bar{z}\bar{y}x, \bar{z}y\bar{x}, z\bar{y}\bar{x} \end{cases}$
Cuprite	As for *T* plus six 2-fold axes coincident with face diagonals thereby converting the three original 2-fold axes into 4-folds	Those of *T* plus $\begin{cases} \bar{y}\bar{x}z, y\bar{x}z, \bar{y}xz, yx\bar{z} \\ \bar{x}\bar{z}y, \bar{x}zy, xz\bar{y}, x\bar{z}y \\ \bar{z}\bar{y}x, zy\bar{x}, z\bar{y}x, \bar{z}yx \end{cases}$
Galena	As for *O* plus a horizontal plane	Those of all the four preceding classes
—	3-fold axis	xyz, zxy, yzx referred to rhombohedral axes
Dioptase	3-fold axis and centre of inversion	$xyz, zxy, yzx, \bar{x}\bar{y}\bar{z}, \bar{z}\bar{x}\bar{y}, \bar{y}\bar{z}\bar{x}$ (rhombohedral axes)
Tourmaline	3-fold axis and vertical plane	$xyz, zxy, yzx, yxz, xyz, zyx$ (rhombohedral axes)
Quartz	3-fold axis and three 2-fold axes	$xyz, zxy, yzx, \bar{y}x\bar{z}, \bar{x}\bar{z}\bar{y}, \bar{z}\bar{y}\bar{x}$ (rhombohedral axes)
Calcite	3-fold axis, three 2-fold axes and diagonal vertical planes	$xyz, zxy, yzx, \bar{y}x\bar{z}, \bar{x}\bar{z}\bar{y}, \bar{z}\bar{y}\bar{x}$ $\bar{x}\bar{y}\bar{z}, \bar{z}\bar{x}\bar{y}, \bar{y}\bar{z}\bar{x}, yxz, zyx, zyx$ (rhombohedral axes)
—	3-fold axis and horizontal plane	$xyz, (y-x)\bar{x}z, \bar{y}(x-y)z, xy\bar{z}, (y-x)\bar{x}\bar{z},$ $\bar{y}(x-y)\bar{z}$ (hexagonal axes)
—	3-fold axis, three 2-fold axes and horizontal plane	$xyz, (y-x)\bar{x}z, \bar{y}(x-y)z, (x-y)\bar{y}\bar{z}, yx\bar{z},$ $\bar{x}(y-x)\bar{z}$ $xy\bar{z}, (y-x)\bar{x}\bar{z}, \bar{y}(x-y)\bar{z}, (x-y)\bar{y}z, yxz,$ $\bar{x}(y-x)z$ (hexagonal axes)
Nepheline	6-fold axes	$xyz, y(y-x)z, (y-x)\bar{x}z, \bar{x}\bar{y}z, \bar{y}(x-y)z,$ $(x-y)xz$ (hexagonal axes)
Apatite	6-fold axis and horizontal plane	Those of C_6 plus $xy\bar{z}, y(y-x)\bar{z}, (y-x)\bar{x}\bar{z}, \bar{x}\bar{y}\bar{z},$ $\bar{y}(x-y)\bar{z}, (x-y)x\bar{z}$ (hexagonal axes)
Greenockite	6-fold axis and vertical plane	Those of C_6 plus $\bar{x}(y-x)z, (y-x)yz, yxz,$ $x(x-y)z, (x-y)\bar{y}z, \bar{y}\bar{x}z$ (hexagonal axes)
—	6-fold axis and six 2-fold axes	Those of C_6 plus $\bar{x}(y-x)\bar{z}, (y-x)y\bar{z},$ $xy\bar{z}, x(x-y)\bar{z}, (x-y)\bar{y}\bar{z}, \bar{y}\bar{x}z$ (hexagonal axes)
Beryl	6-fold axis, six 2-fold axes and horizontal plane	Those of all the four preceding classes

The direction associated with a reflection or glide plane is that of its normal: no direction can be specified for a centre of inversion.

The specified directions are:

Triclinic system: none
Monoclinic system: the **b** direction, i.e. the *b* axis.
Orthorhombic system: the **a, b, c** directions, in that order.

Tetragonal ⎫
Hexagonal ⎬ *systems*:   the **a**, **b**, and (**a** − **b**) directions, in that order. The direction represented by the vector difference is one of the diagonals of the
Rhombohedral ⎭   *c*-face.

Cubic system: the directions **c** (**a** + **b** + **c**), and (**a** − **b**), in that order, i.e. the *c*-axis the cube diagonal and a diagonal of the *c*-face.

If a symmetry axis has a symmetry plane normal to it, the two symbols are combined in the form of a fraction, thus $\frac{2}{m}$, $\frac{4_1}{d}$, alternatively written $2/m$, $4_1/d$.

If one of the specified crystallographic directions has no symmetry element associated with it, this is indicated by inserting the symbol 1 in the appropriate position in the space group symbol. The 1 may be omitted without risk of misunderstanding if it occurs at the end of the space group symbol. Symmetry symbols may also be omitted if they can be derived from those already indicated. These abbreviated symbols are termed 'short'.

As already explained, the symmetry of a space group can be derived from that of a point group by placing the latter at the points of the various lattices appropriate to the crystal system, and by using glide planes and screw axes as well as reflection planes and rotation axes. Thus the point group symbol will contain no symbol for the lattice; its symmetry planes will be indicated by *m* and its axes by numbers specifying the multiplicity and without subscripts. Thus the point group $2/m$ will be associated with the space groups $P(2/m)$; $P(2_1/m)$; $P(2/c)$; $P(2_1/c)$; $C(2/m)$; and $C(2/c)$.

5.3.1   Notes on the space-group tables

For a full description of the space groups, reference should be made to the *International Tables for Crystallography*, Vol. A (1983) published for the International Union of Crystallography by Kluwer Academic Publishers.

If there are *n* symmetry elements associated with any space group, their operation upon any single point having co-ordinates *xyz* will give rise to a total of *n* points which may be termed geometrically equivalent. If, however, the co-ordinates *xyz* are such that the point lies, say, on an axis or plane of symmetry, then the number of equivalent positions will be reduced, while if it lies at the intersection of two elements the number will be reduced still further. A knowledge of these so-called special positions is of importance, because experience has shown that they are the positions which are frequently occupied by the atoms or ions in an actual crystal. In sodium chloride, for example, the four sodium ions are situated in one set of four equivalent positions, those having co-ordinates 000, $\frac{1}{2}\frac{1}{2}0$, $\frac{1}{2}0\frac{1}{2}$, $0\frac{1}{2}\frac{1}{2}$, whilst the four chlorine ions are situated in another set of four points, having co-ordinates $\frac{1}{2}\frac{1}{2}\frac{1}{2}$, $00\frac{1}{2}$, $0\frac{1}{2}0$, $\frac{1}{2}00$. The co-ordinates of all the special positions for each space group were given by R. W. G. Wyckoff in *The Analytical Expression of the Results of the Theory of Space Groups* (Washington Carnegie Institution, 1930) and are also listed in the *International Tables*, Vol. A.

The last column of Table 5.3 gives the missing x-ray reflections characteristic of each space group. If the unit cell is centred on one or more faces, or is body centred, certain reflections will be absent, because in directions corresponding to the missing reflections the waves scattered by the atoms at the face or body centres will be exactly out of phase with those scattered by the atoms at the cell corners. In other words, the spacings of certain planes are halved, and odd-order reflections from these planes are destroyed. Thus with the body-centred lattice all reflections are absent for which $(h + k + l)$ is odd. Again, a glide plane halves the spacings in the direction of glide, and a 2-fold screw axis halves those along the axis. Consequently, odd order reflections are missing in these directions. Similarly with a 3-fold axis; the only reflections occurring in the direction of the axis are those for which (l) is a multiple of three.

In Table 5.3, x-ray reflections of the type indicated do not occur unless indices which are underlined are even, or unless the sum of indices joined together by brackets is even. Thus:

$00\underline{l}$ means that reflections will not occur unless *l* is even.
$0\underline{kl}$ means that reflections will not occur unless $(k + l)$ is even.
$\underline{hk}0$ means that reflections will not occur unless both *h* and *k* are even.
$\underline{hkl}$ means that reflections will not occur unless $(h + k + l)$ is even.

$h\underline{k}\underline{l}$ means that reflections will not occur unless the sums of any two indices are even.

$hh\underline{l}$ means that reflections will not occur if the first two indices are equal, unless the third index, l, is even.

A subscript 3, 4 or 6 means that the marked index, or the sum of the marked indices, must be a multiple of that number for reflections to occur. Thus

$0\underline{k}\underline{l}_4$ means that reflections will not occur unless $(k + l)$ is a multiple of 4.

$\underline{h}\underline{k}\underline{l}_3$ means that reflections will not occur unless $h + 2k + l$ is a multiple of 3.

6   Crystal chemistry

6.1   Structures of metals, metalloids and their compounds[†]

The elements have been arranged in the following order:

1. Group Ia—Li, Na, K, Rb, Cs
2. Group IIa—Be, Mg, Ca, Sr, Ba
3. Group IIIa—Sc, Y, La, Ce, Pr, Nd, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu, Ac
4. Group IVa—Ti, Zr, Hf, Th, Pa, U, Np, Pu, Am, Cm
5. Group Va—V, Nb, Ta
6. Group VIa—Cr, Mo, W
7. Group VIIa—Mn, Tc, Re
8. Group VIII—Fe, Co, Ni; Ru, Rh, Pd, Os, Ir, Pt
9. Group Ib—Cu, Ag, Au
10. Group IIb—Zn, Cd, Hg
11. Group IIIb—Al, Ga, In, Tl
12. Group IVb—Si, Ge, Sn, Pb
13. Group Vb—As, Sb, Bi
14. Metalloids etc.—B, C, P, N, Te, Se, S

A compound or solid solution composed of the elements ABCD . . . is placed under that element, A, B, C, D, . . . which occurs *last* in the above list. If there are several compounds containing this particular element, they are arranged in the following order:

(a) Compounds containing the same elements—in the order of increasing content of the second element.
(b) Compounds of different elements—in the order in which the other elements occur in the above list.

For example, Na_2K is described under K, because K comes after Na in the list; MgSr and Mg_2Sr are both entered under Sr, and are described in that order, in accordance with (a); Li_2Ca and Mg_2Ca are entered under Ca, and described in that order, in accordance with (b).

The second column of Table 6.1 gives the symbol for the structural type to which the element or compound is assigned, the notation used being that of *Strukturbericht*.[*] Detailed descriptions of the structural types are given in Table 6.2.

The third column of Table 6.1 gives the lattice constants of the various elements and compounds. For cubic crystals the single parameter a is given, in Å units; for tetragonal and hexagonal crystals a and c, in that order; for orthorhombic, a, b and c; for rhombohedral a, α; for monoclinic a, b, c, β.

Temperatures given in parentheses are those at which allotropic or polymorphic modifications are stable; figures such as $A = 28, M = 4$, also given in parentheses, refer to the number of atoms (A) or molecules (M) included in the unit cell; alternative structures are given where the available evidence is insufficient to permit of a decision being reached between them, and in such cases the authorities are quoted. Finally, it should be noted that in the case of the sulphides, only those having relatively simple structures have been included.

[†] For information on crystallography, see Chapter 5. Techniques that enable determination of crystal structure can be found in Chapter 4 and Section 10.4.

[*] Strukturbericht of *Z. Krystallographie*, Leipzig.

Although this system of classification is not used in any other compilation of intermetallic compounds, it has been retained as it has its own logic in keeping together compounds of similar systems in a Group; this would be lacking in a strictly alphabetical classification.

Since this compilation was first made, data on a very large number of intermetallic compounds have been published, far more than can be included in this list without extending it to over 1000 pages. Table 6.1 refers to the more frequently encountered compounds. Other compilations should be consulted for compounds not found in Table 6.1.

A comprehensive database is: 'Pearson's Handbook of Crystallographic Data for Intermetallic Phases' (4 volumes) by P. Villars and L. D. Calvert, published by A.S.M., Materials Park, OH, 1991. For an annually updated database, see the 'Powder Diffraction File', published by the International Center for Diffraction Data, Newtown Square, PA.

Pearson has introduced a new system of symbols based on the crystallography of the classes of isostructural compounds. This cannot be deduced readily from the Structurbericht Classification used in Table 6.1 and described in Table 6.2. Hence a comparison of the two nomenclatures is provided in Table 6.3.

The Pearson symbols take the form aBn, where:

a denotes the crystal system, i.e. cubic, hexagonal, etc.
B denotes the space lattice of the unit cells using the Hermann–Mauguin symbols, i.e. P, C, F, I, etc.
n denotes the number of atoms per unit cell.

The crystal systems are:

c = Cubic   o = Orthorhombic
h = Hexagonal   t = Tetragonal
m = Monoclinic

The space lattices of the unit cells are:

P = Simple   C = One face-centred*
F = All Face-centred+   R = Simple (rhombohedral)
I = Body-centred

*Monoclinic and Orthorhombic
+Cubic and Orthorhombic
e.g. A1(Cu) is cF4 and C14($MgZn_2$) is hP12.

As will be evident from Table 6.3, a Pearson symbol can be the same for several different structural types or prototypes. See note at end of references for sources of data.

*B*8 (α-NiAs type; β-Ni$_2$ In type)

Between the main types (α) and (β) there exist a number of intermediate arrangements due to the variation of the stoichiometric formulae. The axial ratio c/a may change from the value 1.75 (in type α) to 1.22 (in type β). Similarly, there is virtually a continuous change from the B8 type to the C6 type.

α-NiAs type (B8$_1$)

Hexagonal: D_{6h}^4–$P6_3/mmc$; $a = 3.619$, $c = 5.044$, $c/a = 1.39$; $A = 4$
Co-ordinates: $2\text{Ni}(D_{3d})$: $000; 00\frac{1}{2}$
    $2\text{As}(D_{3h})$: $\frac{1}{3}\frac{2}{3}\frac{1}{4}; \frac{2}{3}\frac{1}{3}\frac{3}{4}$

β-Ni$_2$ In type (B8$_2$)

Hexagonal: D_{6h}^4–$P6_3/mmc$; $a = 4.188\,9$, $c = 5.123\,0$, $c/a = 1.22$; $A = 6$
    $2\text{Ni}(D_{3d})$: $000; 00\frac{1}{2}$; $2\text{Ni}(D_{3h})$: $\frac{1}{3}\frac{2}{3}\frac{3}{4}; \frac{2}{3}\frac{1}{3}\frac{1}{4}$
    $2\text{In}(D_{3h})$: $\frac{1}{3}\frac{2}{3}\frac{1}{4}; \frac{2}{3}\frac{1}{3}\frac{3}{4}$

---

*B*9 [Cinnabar (HgS) type]

Hexagonal: D_3^4–$P3_121$ and D_3^6–$P3_221$; $a = 4.147\,9(7)$, $c = 9.499\,60(15)$; $A = 6$
Co-ordinates: $3\text{Hg}(C_2)$: $x00; \bar{x}\bar{x}\frac{1}{3}; 0x\frac{2}{3}; x = 0.33$
    $3\text{S}(C_2)$: $x0\frac{1}{2}; \bar{x}\bar{x}\frac{5}{6}; 0x\frac{1}{6}; x = 0.21$

---

*B*10 (LiOH type)

Tetragonal: D_{4h}^7–$P4/nmm$; $a = 3.552$, $c = 4.347$; $A = 4$
Co-ordinates: $2\text{Li}(D_{2d})$: $000; \frac{1}{2}\frac{1}{2}0$
    $2\text{OH}(C_{4v})$: $0\frac{1}{2}z; \frac{1}{2}0\bar{z}; z = 0.20$
For FeSe: $z = 0.26$

---

*B*11 (PbO type)

Tetragonal: D_{4h}^7–$P4/nmm$; $a = 3.974\,4(5)$, $c = 5.022\,0(5)$; $A = 4$
Co-ordinates: $2\text{Pb}(C_{4v})$: $0\frac{1}{2}z; \frac{1}{2}0\bar{z}; z = 0.24$
    $2\text{O}(C_{4v})$:   the same with $z = 0.74$
For γ-TiCu: $z(\text{Ti}) = 0.65; z(\text{Cu}) = 0.10$

---

*B*13 [Millerite (NiS) type]

Rhombohedral: C_{3v}^5–$R3m$; $a = 5.64$; $\alpha = 116°\ 35'$; $A = 6$
Co-ordinates: $3\text{Ni}(C_s)$: $xxz; \text{\textmusicalnote}); x = 0; z = 0.264$
    $3\text{S}(C_s)$:   the same with $x = 0.714; z = 0.361$

---

*B*16 (GeS type)

Orthorhombic: D_{2h}^{16}–$Pbnm$; $a = 4.306(4)$, $b = 10.449(9)$, $c = 3.653(4)$; $A = 8$
Co-ordinates: $4\text{Ge}(C_s)$: $\pm(xy\frac{1}{4}); \pm[(\frac{1}{2}-x)(\frac{1}{2}+x)\frac{1}{4}]; x = 0.167; y = 0.375$
    $4\text{S}(C_s)$:   the same with $x = 0.111; y = 0.139$

---

*B*17 [Cooperite (PtS) type]

Tetragonal: D_{4h}^9–$P4_2/mmc$; $a = 3.470\,1(3)$, $c = 6.109\,2(8)$; $A = 4$
Co-ordinates: $2\text{Pt}(D_{2h})$: $0\frac{1}{2}0; \frac{1}{2}0\frac{1}{2}$, $2\text{S}(D_{2d})$: $00\frac{1}{4}; 00\frac{3}{4}$

(continued)

Table 6.2   STRUCTURAL DETAILS—*continued*

---

*B*18 [Covellite (CuS) type]

Hexagonal: D_{6h}^4–$P6_3/mmc$; $a = 3.768(3)$, $c = 16.27(6)$; $A = 12$
Co-ordinates: $2\text{Cu}(D_{3h})$: $\pm(\frac{2}{3}\,\frac{1}{3}\,\frac{1}{4})$
            $4\text{Cu}(C_{3v})$: $\pm(\frac{1}{3}\,\frac{2}{3}z); \pm(\frac{1}{3}, \frac{2}{3}, \frac{1}{2} - z); z = 0.107$
            $2\text{S}(D_{3h})$: $\pm(\frac{1}{3}\,\frac{2}{3}\,\frac{1}{4})$
            $4\text{S}(C_{3v})$: $\pm(00z); \pm(0, 0, \frac{1}{2} - z); z = 0.063$

*B*19 (AuCd type)

Orthorhombic: D_{2h}^5–$Pmcm$; $a = 3.143\,7$, $b = 4.871\,7$, $c = 4.769\,0$; $A = 4$
Co-ordinates: $2\text{Au}(C_{2v})$: $\pm(0y\frac{1}{4}); y = 0.805$
            $2\text{Cd}(C_{2v})$: $\pm(\frac{1}{2}y\frac{1}{4}); y = 0.315$
For MgCd: $y(\text{Mg}) = 0.818; y(\text{Cd}) = 0.323$

*B*20 (FeSi type)

Cubic: T^4–$P2_13$; $a = 4.483$; $A = 8$
Co-ordinates: $4\text{Fe}(C_3)$: $xxx; (\frac{1}{2} + x)(\frac{1}{2} - x)\bar{x}; \text{♪}; x = 0.137$
            $4\text{Si}(C_3)$:   the same with $x = -0.158$
For BeAu: $x(\text{Be}) = -0.156; x(\text{Au}) = 0.150$
For RhSn: $x(\text{Rh}) = 0.142; x(\text{Sn}) = 0.159$

*B*27 (FeB type)

Orthorhombic: D_{2h}^{16}–$Pbnm$; $a = 4.064$, $b = 5.503$, $c = 2.946$; $A = 8$
Co-ordinates: $4\text{Fe}(C_s)$: $\pm(xy\frac{1}{4}); \pm(\frac{1}{2} - x, \frac{1}{2} + y, \frac{1}{4}); x = 0.125; y = 0.180$
            $4\text{B}(C_s)$:   the same with $x = 0.61; y = 0.036$
For MnB: $x(\text{Mn}) = 0.125; y(\text{Mn}) = 0.180; x(\text{B}) = 0.614; y(\text{B}) = 0.031$
For USi: $x(\text{U}) = 0.125; y(\text{U}) = 0.180; x(\text{Si}) = 0.611; y(\text{Si}) = 0.028$
For TiB: $x(\text{Ti}) = 0.123; y(\text{Ti}) = 0.177; x(\text{B}) = 0.603; y\text{B}) = 0.029$

*B*29 (SnS type)

Orthorhombic: D_{2h}^{16}–$Pmcn$; $a = 4.050(4)$, $b = 4.242(4)$, $c = 11.32(1)$; $A = 8$
Co-ordinates: $4\text{Sn}(C_s)$: $\pm(\frac{1}{4}yz); \pm(\frac{1}{4}, \frac{1}{2} - y, \frac{1}{2} + z); y = 0.115; z = 0.118$
            $4\text{S}(C_s)$:   the same with $y = 0.478; z = 0.850$
If this description, given in Strukturbericht vol. **3**, p. 14, is transformed to the following, it is virtually
identical with the B16 (GeS type).
Orthorhombic: D_{2h}^{16}–$Pbnm$; $a = 4.33$, $b = 11.18$, $c = 3.98$; $A = 8$
Co-ordinates: $4\text{Sn}(C_s) \pm (xy\frac{1}{4}); \pm(\frac{1}{2} - x, \frac{1}{2} + y, \frac{1}{4}); x = 0.115; y = 0.382$
            $4\text{S}(C_s)$:   the same with $x = 0.022; y = 0.150$

*B*31 (MnP type)

Orthorhombic: D_{2h}^{16}–$Pcmn$; $a = 5.902\,7(4)$, $b = 3.180\,6(2)$, $c = 5.240\,9(3)$; $A = 8$
Co-ordinates: $4\text{Mn}(C_s)$: $\pm(x\frac{1}{4}z); \pm(\frac{1}{2} - x, \frac{1}{4}, \frac{1}{2} + z); x = 0.20; z = 0.005$
            $4\text{P}(C_s)$:   the same with $x = 0.57; z = 0.19$
For AuGa: $x(\text{Au}) = 0.184; z(\text{Au}) = 0.010; x(\text{Ga}) = 0.590; z(\text{Ga}) = 0.195$
For PdSi: $x(\text{Pd}) = 0.190; z(\text{Pd}) = 0.070; x(\text{Si}) = 0.570; z(\text{Si}) = 0.190$
For PtSi: $x(\text{Pt}) = 0.195; z(\text{Pt}) = 0.010; x(\text{Si}) = 0.590; z(\text{Si}) = 0.195$
For NiGe: $x(\text{Ni}) = 0.190; z(\text{Ni}) = 0.005; x(\text{Ge}) = 0.583; z(\text{Ge}) = 0.188$
For PdGe: $x(\text{Pd}) = 0.188; z(\text{Pd}) = 0.005; x(\text{Ge}) = 0.595; z(\text{Ge}) = 0.190$
For IrGe: $x(\text{Ir}) = 0.192; z(\text{Ir}) = 0.010; x(\text{Ge}) = 0.590; z(\text{Ge}) = 0.185$
For PtGe: $x(\text{Pt}) = 0.195; z(\text{Pt}) = 0.010; x(\text{Ge}) = 0.590; z(\text{Ge}) = 0.195$
For PdSn: $x(\text{Pd}) = 0.182; z(\text{Pd}) = 0.007; x(\text{Sn}) = 0.590; z(\text{Sn}) = 0.182$
For RhSb: $x(\text{Rh}) = 0.192; z(\text{Rh}) = 0.010; x(\text{Sb}) = 0.590; z(\text{Sb}) = 0.195$
For NiSi: $x(\text{Ni}) = 0.184; z(\text{Ni}) = 0.006; x(\text{Si}) = 0.580; z(\text{Si}) = 0.170$

*B*32 (NaTl type)

Cubic: O_h^7–$Fd3m$; $a = 7.480(4)$; $A = 16$
Co-ordinates: $(000; \frac{1}{2}\,\frac{1}{2}\,0; \text{♪}) + 8\text{Na}(T_d)$: $000; \frac{1}{4}\,\frac{1}{4}\,\frac{1}{4}$
                    $+ 8\text{Tl}(T_d)$: $\frac{1}{2}\,\frac{1}{2}\,\frac{1}{2}; \frac{3}{4}\,\frac{3}{4}\,\frac{3}{4}$

(*continued*)

Table 6.2   STRUCTURAL DETAILS—*continued*

---

*B*34 (PdS type)

Tetragonal: C_{4h}^2–$P4_2/m$; $a = 6.429(2), c = 6.611(2); A = 16$
Co-ordinates: $2Pd(S_4)$: $00\frac{1}{4}; 00\frac{3}{4}; 2Pd(C_{2h})$: $0\frac{1}{2}0; \frac{1}{2}0\frac{1}{2}$
   $4Pd(C_s)$: $\pm(xy0); \pm(\bar{x}y\frac{1}{2}); x = 0.475; y = 0.250$
   $8S(C_1)$: $\pm(xyz); \pm(xy\bar{z}); \pm(y, \bar{x}, \frac{1}{2} + z); \pm(y, \bar{x}, \frac{1}{2} - z)$
   with $x = 0.20; y = 0.32; z = 0.22$

---

*B*35 (CoSn type)

Hexagonal: D_{6h}^1–$P6/mmm$; $a = 5.278, c = 4.258; A = 6$
Co-ordinates: $1Sn(D_{6h})$: $000; 2Sn(D_{3h})$: $\frac{1}{3}\frac{2}{3}\frac{1}{2}; \frac{2}{3}\frac{1}{3}\frac{1}{2}$
   $3Co(D_{2h})$: $\frac{1}{2}00; 0\frac{1}{2}0; \frac{1}{2}\frac{1}{2}0$

---

*B*37 (TlSe type)

Tetragonal: D_{4h}^{18}–$I4/mcm$; $a = 8.024, c = 7.18; A = 16$
Co-ordinates: $(000; \frac{1}{2}\frac{1}{2}\frac{1}{2}) + 4Tl(D_4)$: $00\frac{1}{4}; 00\frac{3}{4}; +4Tl(D_{2d})$: $\frac{1}{2}0\frac{1}{4}; \frac{1}{2}0\frac{3}{4}$
   $+8Se(C_{2v})$: $\pm(x, \frac{1}{2} + x, 0); \pm(\frac{1}{2} + x, \bar{x}, 0); x = 0.179$

B$_a$ (UCo type)

Cubic: T^5–$I2_13$; $a = 6.352\,5; A = 16$
Co-ordinates: $(000; \frac{1}{2}\frac{1}{2}\frac{1}{2}) + 8U(C_3)$: $xxx; (\frac{1}{2} + x)(\frac{1}{2} - x)\bar{x}; \,♪; x = 0.035$
   $+ 8Co(C_3)$:   the same with $x = 0.294$

B$_b$ (ζ-AgZn type)

Hexagonal: C_{3i}^1–$P\bar{3}$; $a = 7.636\,0; c = 2.819\,7; A = 9$
Co-ordinates: $1Zn(C_{3i})$: $000; +2Zn(C_3)$: $\frac{1}{3}\frac{2}{3}z; \frac{2}{3}\frac{1}{3}z; z \approx \frac{3}{4}$
   $(1.5Zn + 4.5Ag)(C_1)$: $\pm(xyz);$ $\pm(\bar{y}, x - y, z); \pm(y - x, \bar{x}, z)$ with $x = 0.350;$
   $y = 0.032; z = 0.750$

B$_c$ (CaSi type)

Orthorhombic: D_{2h}^{17}–$Cmmc$; $a = 3.90(3), b = 4.545(3), c = 10.728(10); A = 8$
Co-ordinates: $(000; 0\frac{1}{2}\frac{1}{2}) + 4Ca(C_{2v})$: $\pm(\frac{1}{4}0z); z = 0.36$
   $+4Si(C_{2v})$:   the same with $z = 0.07$
By choosing different axes and origin from those given in the original paper, this type becomes virtually identical with the *Bf* (CrB type):
   D_{2h}^{17}–$Cmcm$; $a = 4.59, b = 10.80, c = 3.91; y(Ca) = 0.14; y(Si) = 0.43$

B$_d$ (η-NiSi)

Orthorhombic: D_{2h}^{16}–$Pbnm$; $a = 5.628(2), b = 5.190(1), c = 3.330(1); A = 8$
Co-ordinates: $4Ni(C_s)$: $xy0; \bar{x}\bar{y}\frac{1}{2}; (\frac{1}{2} - x)(\frac{1}{2} + y)0; (\frac{1}{2} + x)(\frac{1}{2} - y)\frac{1}{2}; x = 0.184; y = 0.006$
   $4Si(C_s)$:   the same with $x = 0.080; y = 0.330$
By choosing different axes and origin from those given in the original paper, this type becomes identical with the *B*31(MnP type):
   D_{2h}^{16}–$Pcmn$; $A = 5.62, b = 3.34, c = 5.18; x(Ni) = 0.184; z(Ni) = 0.006; x(Si) = 0.580;$
   $z(Si) = 0.170$

B$_e$ (CdSb type)

Orthorhombic: D_{2h}^{15}–$Pbca$; $a = 6.476\,9(1), b = 8.251(2), c = 8.522(2); A = 16$
Co-ordinates: $8Sb(C_1)$: $\pm(xyz); \pm(\frac{1}{2} + x, \frac{1}{2} - y, \bar{z}); \pm(\bar{x}, \frac{1}{2} + y, \frac{1}{2} - z); \pm(\frac{1}{2} - x, \bar{y}, \frac{1}{2} + z)$
   $8Cd(C_1)$:   the same

	Sb			Cd *or* Zn		
	x	y	z	x	y	z
CdSb	0.136	0.072	0.108	0.456	0.119	−0.128
ZnSb	0.142	0.081	0.111	0.461	0.103	−0.122

(continued)

Table 6.2   STRUCTURAL DETAILS—*continued*

B_f (CrB type)

Orthorhombic: D_{2h}^{17}–$Cmcm$; $a = 2.970, b = 7.865, c = 2.936; A = 8$
Co-ordinates: $(000; \frac{1}{2}\frac{1}{2}0) + 4Cr(C_{2v})$: $\pm(0y\frac{1}{4}); y = 0.146$
$\qquad\qquad\qquad\qquad + 4B(C_{2v})$:   the same with $y = 0.440$
For NbB: $y(Nb) = 0.146; y(B) = 0.444$
For CaSi: $y(Ca) = 0.14; y(Si) = 0.43$ (cf. Bc type)

B_g (MoB type)

Tetragonal: D_{4h}^{19}–$I4/amd$; $a = 3.103, c = 16.95; A = 16$
Co-ordinates: $(000, \frac{1}{2}\frac{1}{2}\frac{1}{2}) + 8Mo(C_{2v})$: $\pm(00z); \pm(0, \frac{1}{2}, \frac{1}{4} + z); z = 0.197$
$\qquad\qquad\qquad\qquad + 8B(C_{2v})$:   the same with $z = 0.35$

B_h (WC type)

Hexagonal: D_{6h}^{1}–$P\bar{6}m2 = 2.906, c = 2.837; A = 2$
Co-ordinates: $1W(D_{6h})$: 000; $1C(D_{3h})$: $\frac{1}{3}\frac{2}{3}\frac{1}{2}; \frac{2}{3}\frac{1}{3}\frac{1}{2}$

B_i (γ'-MoC type)

Hexagonal: D_{6h}^{4}–$P6_3/mmc$; $a = 2.932, c = 10.97; A = 8$
Co-ordinates: $4Mo(C_{3h})$: $\frac{1}{3}\frac{2}{3}z; \frac{1}{3}\frac{2}{3}(\frac{1}{2} - z); \frac{2}{3}\frac{1}{3}(\frac{1}{2} + z); \frac{2}{3}\frac{1}{3}\bar{z}; z \approx \frac{1}{8}$
$\qquad\qquad 4C$:   in holes

B_l [Realgar (AsS) type]

Monoclinic: C_{2h}^{5}–$P2_1n$; $a = 9.994(6), b = 12.986(6), c = 7.153(4); \beta = 120.6°; A = 32$
Co-ordinates: 4 times $4As(C_1)$ and 4 times $4S(C_1)$ in:
$\qquad\qquad \pm(xyz); \pm(\frac{1}{2} + x, \frac{1}{2} - x, \frac{1}{2} + z)$

	As *I*	As *II*	As *III*	As *IV*	S *I*	S *II*	S *III*	S *IV*
x	0.118	0.425	0.318	0.038	0.346	0.213	0.245	0.115
y	0.024	−0.140	−0.127	−0.161	0.008	0.024	−0.225	−0.215
z	−0.241	−0.142	0.181	−0.290	−0.295	0.120	−0.363	0.048

B_m (TiB type)

Orthorhombic: D_{2h}^{16}–$Pnma$; $a = 6.105, b = 3.048, c = 4.551, A = 8$
Co-ordinates: $4Ti(C_s)$: $\pm(x\frac{1}{4}z); \pm(\frac{1}{2} - x, \frac{3}{4}, \frac{1}{2} + z); x = 0.177; z = 0.123$
$\qquad\qquad 4B(C_s)$:   the same with $x = 0.029; z = 0.603$
If the axes are changed from those of the original paper, this type becomes identical with the $B27$ (FeB) type:

$\qquad\qquad D_{2h}^{16}$–$Pbnm$; $a = 4.56, b = 6.12, c = 3.06; x(Ti) = 0.123; y(Ti) = 0.177;$
$\qquad\qquad x(B) = 0.603; y(B) = 0.029$

$C1$ (CaF$_2$ type—MgAgAs type)

(α) Cubic: O_h^5–$Fm3m$; $a = 5.462\ 6; A = 12$
$\qquad$Co-ordinates: $(000; \frac{1}{2}\frac{1}{2}0; \flat) + 4Ca(O_h)$: 000
$\qquad\qquad\qquad\qquad\qquad + 8F(T_d)$: $\pm(\frac{1}{4}\frac{1}{4}\frac{1}{4})$
In those cases in which the F-position is occupied by two components in an ordered fashion—for example in As(MgAg)—the space group is changed to
(β) Cubic: T_d^2–$F\bar{4}3m$; $a = 6.24; A = 12$
$\qquad$Co-ordinates: $(000; \frac{1}{2}\frac{1}{2}0; \flat) + 4As(T_d)$: 000
$\qquad\qquad\qquad\qquad\qquad + 4Ag(T_d)$: $\frac{1}{4}\frac{1}{4}\frac{1}{4}$
$\qquad\qquad\qquad\qquad\qquad + 4Mg(T_d)$: $\frac{3}{4}\frac{3}{4}\frac{3}{4}$

$C2$ [Pyrites (FeS$_2$) type]

Cubic: T_h^6–$Pa3$; $a = 5.293(2); A = 12$
Co-ordinates: $4Fe(S_{3i})$: $000; \frac{1}{2}\frac{1}{2}0; \flat$
$\qquad\qquad 8S(C_3)$: $\pm(xxx); \pm(\frac{1}{2} + x, \frac{1}{2} - x, \bar{x}; \flat); x = 0.386$
For MnS$_2$, $x = 0.401$; for CoAsS and NiAsS (random distribution of As and S) $x = 0.385$; for PtBi$_2$: $x = 0.38$.

Table 6.2 STRUCTURAL DETAILS—*continued*

---

*C*6 (CdI$_2$) type)

Hexagonal: D_{3d}^3–$P\bar{3}m1$; $a = 4.244$; $c = 6.859$; $A = 3$
Co-ordinates: 1Cd(D_{3d}): 000; 2I(c_{3v}): $\frac{1}{3}\frac{2}{3}z$; $\frac{2}{3}\frac{1}{3}\bar{z}$; $z \approx \frac{1}{4}$
There is virtually a continuous change from this type to the $B8$ type.

*C*7 (MoS$_2$ type)

Hexagonal: D_{6h}^4–$P6_3/mmc$; $a = 3.159(2)$, $c = 12.307(2)$; $A = 6$
Co-ordinates: 2Mo(D_{3h}): $\frac{1}{3}\frac{2}{3}\frac{1}{4}$; $\frac{2}{3}\frac{1}{3}\frac{1}{4}$.
  4S(C_{3v}): $\frac{1}{3}\frac{2}{3}z$; $\frac{2}{3}\frac{1}{3}\bar{z}$; $\frac{1}{3}\frac{2}{3}(\frac{1}{2} - z)$; $\frac{2}{3}\frac{1}{3}(\frac{1}{2} + z)$; $z = 0.62$

*C*11*a* (CaC$_2$ type)

Tetragonal: D_{4h}^{17}–$I4/mmm$; $a = 3.89(1)$, $c = 6.38(1)$, $c/a = 1.64$; $A = 6$
Co-ordinates: $(000; \frac{1}{2}\frac{1}{2}\frac{1}{2}) + 2$Ca($D_{4h}$): 000
  $+ 4$C(C_{4v}): $\pm(00z)$; $z = 0.38$

*C*11*b* (MoSi$_2$ type)

Tetragonal: D_{4h}^{17}–I/mmm; $a = 3.208$, $c = 7.900$, $c/a = 2.46$; $A = 6$
Co-ordinates: $(000; \frac{1}{2}\frac{1}{2}\frac{1}{2} + 2$Mo($D_{4h}$): 000
  $+4$Si(C_{4v}): $\pm(00z)$; $z \approx \frac{1}{3}$
This type is a superstructure of the Aα(Pa) type.

*C*12 (CaSi$_2$ type)

Rhombohedral: D_{3d}^5–$R\bar{3}m$; $a = 10.4$; $\alpha = 21°30'$; $A = 6$
Co-ordinates: 2Ca(C_{3v}): $\pm(xxx)$; $x = 0.083$
  2Si(C_{3v}): the same with $x = 0.185$
  2Si(C_{3v}): the same with $x = 0.352$
Hexagonal axes: $a = 3.88$, $c = 30.4$; $A = 18$
Co-ordinates: $(000; \frac{2}{3}\frac{1}{3}\frac{1}{3}; \frac{1}{3}\frac{2}{3}\frac{2}{3}) + 6$Ca($C_{3v}$): $\pm(00x)$; $x = 0.083$
  $+ 6$Si(C_{3v}): the same with $x = 0.185$
  $+ 6$Si(C_{3v}): the same with $x = 0.352$

*C*14 (MgZn$_2$ type)

Hexagonal: D_{6h}^4–$P6_3/mmc$; $c = 5.223(1)$, $c = 8.566(3)$; $A = 12$
Co-ordinates: 4Mg(C_{3v}): $\pm(\frac{1}{3}\frac{2}{3}z; \frac{1}{3}, \frac{2}{3}, \frac{1}{2} - z)$; $z \approx \frac{1}{16} = 0.062$
  2Zn(D_{3d}): 000; $00\frac{1}{2}$
  6Zn(C_{2v}): $\pm(x, 2x, \frac{1}{4}; 2\bar{x}, \bar{x}, \frac{1}{4}; x\bar{x}\frac{1}{4})$; $x \approx -\frac{1}{6} = -0.170$

*C*15 (MgCu$_2$ type)

Cubic: O_h^7–$Fd3m$; $a = 7.048$; $A = 24$
Co-ordinates: $(000; \frac{1}{2}\frac{1}{2}0; \downarrow) + 8$Mg($T_d$): 000; $\frac{1}{4}\frac{1}{4}\frac{1}{4}$
  $+ 16$Cu(D_{3d}): $\frac{5}{8}\frac{5}{8}\frac{5}{8}$; $\frac{7}{8}\frac{7}{8}\frac{5}{8}$;

*C*16 (CuAl$_2$ type)

Tetragonal: D_{4h}^{18}–$I4/mcm$; $a = 6.063(3)$, $c = 4.872(3)$; $A = 12$
Co-ordinates: $(000; \frac{1}{2}\frac{1}{2}\frac{1}{2}) + 4$Cu($D_4$): $\pm(00\frac{1}{4})$
  $+ 8$Al(C_{2v}): $\pm(x, \frac{1}{2} + x, 0; \frac{1}{2} + x, \bar{x}, 0)$; $x = 0.158$

	AuNa$_2$	MnSn$_2$	FeSn$_2$	CoSn$_2$	RhSn$_2$	TiSb$_2$	VSb$_2$	Ta$_2$B	Mo$_2$B	W$_2$B	Mn$_2$B
x	0.160	0.159	0.160	0.116	0.161	0.158	0.158	0.167	0.170	0.170	0.163

For the compounds FeGe$_2$, (Rh,Pd,Au)Pb$_2$ no deviation from $x = 0.158$ has been reported.

*C*18 [Marcasite (FeS$_2$) type]

Orthorhombic: D_{2h}^{12}–$Pnnm$; $a = 4.441$, $b = 5.425$, $c = 3.387$; $A = 6$
Co-ordinates: 2Fe(C_{2h}): 000; $\frac{1}{2}\frac{1}{2}\frac{1}{2}$
  4S(C_s): $\pm(xy0); \pm(\frac{1}{2} + x, \frac{1}{2} - y, \frac{1}{2})$; $x = 0.20$; $y = 0.38$
For FeAs$_2$: $x = 0.18$; $y = 0.36$
For NiAs$_2$: $x = 0.22$; $y = 0.37$

(*continued*)

Table 6.2   STRUCTURAL DETAILS—*continued*

For $SeSb_2$: $x = 0.18$; $y = 0.36$
For FeP_2: $x = 0.16$; $y = 0.37$
For $CoTe_2$: $x = 0.22$; $y = 0.36$
For $FeTe_2$: $x = 0.22$; $y = 0.36$
For $FeSe_2$: $x = 0.21$; $y = 0.37$

C22 (Fe_2P type)

Hexagonal: $P\bar{6}2m$; $a = 5.8644$, $c = 3.4560$; $A = 9$
Co-ordinates: $3Fe(C_2)$: $\bar{x}00$; $0\bar{x}0$; $xx0$; $x = 0.26$
              $3Fe(C_2)$: $x0\frac{1}{2}$; $0x\frac{1}{2}$; $\bar{x}x\frac{1}{2}$; $x = 0.40$
              $1P(D_3)$: $00\frac{1}{2}$
              $2P(C_3)$: $\pm(\frac{1}{3}\frac{2}{3}z)$; $z \approx \frac{1}{8} = 0.125$

C23 ($PbCl_2$ type)

Orthorhombic: D_{2h}^{16}–$Pmnb$; $a = 4.534$, $b = 7.622$, $c = 9.044$; $A = 12$
Co-ordinates: $4Pb(C_s)$: $\pm(\frac{1}{4}yz)$; $\pm(\frac{1}{4})\frac{1}{2} + y$, $\frac{1}{2} - z)$; $y = 0.246$; $z = 0.905$
              $4Cl(C_s)$:   the same with $y = 0.85$; $z = 0.93$
              $4Cl(C_s)$:   the same with $y = 0.95$; $z = 0.33$

For Co_2P, Ni_2Si* and ThS_2 the parameters are:

	P	Co	Co	Th	S	S	Si	Ni	Ni
y	0.250	0.862	0.970	0.250	0.850	0.965	0.236	0.825	0.958
z	0.900	0.930	0333	0.875	0.942	0.320	0.886	0.937	0.297

C32 (AlB_2 type)

Hexagonal: D_{6h}^1–$P6/mmm$; $a = 3.005$, $c = 3.257$; $A = 3$
Co-ordinates: $1Al(D_{6h})$: 000
              $2B(D_{3h})$: $\frac{1}{3}\frac{2}{3}\frac{1}{3}$; $\frac{2}{3}\frac{1}{3}\frac{1}{2}$

C33 (Bi_2Te_2S type)

Rhombohedral: D_{3d}^5–$R\bar{3}m$; $a = 10.31$; $\alpha = 24°10'$; $A = 5$
Co-ordinates: $2Bi(C_{3v})$: $\pm(xxx)$; $x = 0.392$
              $2Te(C_{3v})$:   the same with $x = 0.788$
              $1S(D_{3d})$: 000

C34 [Calaverite ($AuTe_2$) type]

Monoclinic: C_{2h}^3–$C2/m$; $a = 7.1947(4)$, $b = 4.4146(2)$, $c = 5.0703(3)$; $\beta = 90.038(4)$; $A = 6$
Co-ordinates: $(000$; $\frac{1}{2}\frac{1}{2}0) + 2Au(C_{2h})$: 000
                        $+4Te(C_s)$: $\pm(x0z)$; $x = 0.689$; $z = 0.280$

C36 ($MgNi_2$ type)

Hexagonal: D_{6h}^4–$P6_3/mmc$; $a = 4.807$, $c = 15.77$; $A = 24$
Co-ordinates: $4\,Mg(C3v)$: $+(\frac{12}{33}z)$; $\pm(\frac{2}{3}, \frac{1}{3}, \frac{1}{2} + z)$; $z \approx \frac{27}{32}$
              $4Mg(C_{3v})$: $\pm(00z)$; $\pm(0, 0, \frac{1}{2} + z)$; $z \approx \frac{3}{32}$
              $6Ni(C_{2h})$: $\frac{1}{2}00$; $0\frac{1}{2}0$; $\frac{1}{2}\frac{1}{2}0$; $\frac{1}{2}0\frac{1}{2}$; $0\frac{1}{2}\frac{1}{2}$; $\frac{1}{2}\frac{1}{2}\frac{1}{2}$
              $6Ni(C_{2v})$: $\pm(x, 2x, \frac{1}{4}$; $2\bar{x}, \bar{x}, \frac{1}{4}$; $x, \bar{x}, \frac{1}{4})$; $x \approx \frac{1}{6}$
              $4Ni(C_{3v})$: $\pm(\frac{1}{3}\frac{2}{3}z)$; $\pm(\frac{2}{3}, \frac{1}{3}, \frac{1}{2} + z)$; $z \approx \frac{1}{8}$

C37 (Co_2Si type)

Orthorhombic: D_{2h}^{16}–$Pbnm$; $a = 7.104$, $b = 4.919$, $c = 3.725$; $A = 12$
Co-ordinates: $4Si(C_s)$: $\pm(xy\frac{1}{4})$; $\pm(\frac{1}{2} - x, \frac{1}{2} + y, \frac{1}{4})$; $x = 0.440$; $y = 0.070$
              $4Co(C_s)$:   the same with $x = 0.103$; $y = 0.090$
              $4Co(C_s)$:   the same with $x = 0.772$; $y = 0.193$
With a different choice of axes and origin, a similarity to the $C23$ ($PbCl_2$ type) becomes apparent:
Orthorhombic: D_{2h}^{16}–$Pmnb$; $a = 3.73$, $b = 4.91$, $c = 7.10$; $A = 12$

---

* If Toman's[199] description of δ-Ni_2Si is charged from *Pbnm* to *Pmnb*, and if the origin is chosen differently, this compound belongs to the C23 type.

(*continued*)

Table 6.2   STRUCTURAL DETAILS—*continued*

Co-ordinates: $4Si(C_s)$: $\pm(\frac{1}{4}yz); \pm(\frac{1}{4}, \frac{1}{2}+y, \frac{1}{2}-z); y=0.07; z=0.94$
$\qquad\qquad\quad 4Co(C_s)$:   the same with $y=0.59; z=0.897$
$\qquad\qquad\quad 4Co(C_s)$:   the same with $y=0.693; z=0.228$

With this orientation the lattice constants are virtually identical with those of δ-Ni_2Si ($a=3.73, b=4.99$, $c=7.03$) which has the $C23$ type. A redetermination of the Co_2Si type might lead to a still closer similarity than that appearing in this description.

C38 (Cu_2Sb type)

Tetragonal: D_{4h}^7–$P4/nmm; a=4.0014, c=6.1044; A=6$
Co-ordinates: $2Cu(D_{2d})$: $000, \frac{1}{2}\frac{1}{2}0$
$\qquad\qquad\quad 2Cu(C_{4v})$: $0\frac{1}{2}z; \frac{1}{2}0\bar{z}; z=0.27$
$\qquad\qquad\quad 2Sb(C_{4v})$:   the same with $z=0.70$

For $Cu_{2-x}Te$; $z(Cu)=0.27; z(Te)=0.715$, with vacant sites in the $(0\frac{1}{2}z)$-position.
For Fe_2As and Cr_2As: $z(As)=0.735; z(Fe \text{ or } Cr)=0.33$. For $CuMgAs$: $z(As)=0.75; z(Cu, Mg)=0.335$.
For $AlNaSi_4$: $z(Si)=0.79; z(Na, Al)=0.37$.

   A very similar arrangement is shown by $CuGa_2$ with $a=2.83, c=5.84$. The 3 atoms per cell take the position $000; \frac{1}{2}\frac{1}{2}x; \frac{1}{2}\frac{1}{2}y$ with $x=0.70; y=0.27$. For comparison a larger cell with $a'=a\sqrt{2}$ can be chosen:

Tetragonal: C_{4v}^1–$P4\,mm; a'=4.03, c=5.84; A=6$
Co-ordinates: $2Ga(C_{4v})$: $000; \frac{1}{2}\frac{1}{2}0$
$\qquad\qquad\quad 2Ga(C_{4v})$: $0\frac{1}{2}z; \frac{1}{2}0z; z=0.70$
$\qquad\qquad\quad 2Cu(C_{4v})$: $0\frac{1}{2}z; \frac{1}{2}0z; z=0.27$

C40 ($CrSi_2$ type)

Hexagonal: D_6^4(or D_6^5)–$P6_222$ (or $P6_422$); $a=4.430(2), 6.365(5); A=9$
Co-ordinates: $3Cr(D_2)$: $\frac{1}{2}00; \frac{1}{2}\frac{1}{2}\frac{1}{3}; 0\frac{1}{2}\frac{2}{3}$
$\qquad\qquad\quad 6Si(C_2)$: $\pm(x, 2x, 0); x\bar{x}\frac{1}{3}; \bar{x}x\frac{1}{3}; 2x, x, \frac{2}{3}; 2\bar{x}, \bar{x}\frac{2}{3}; x\approx\frac{1}{6}$

C42 (SiS_2 type)

Orthorhombic: D_{2h}^{26}–$Icma; a=5.564(2); b=5.552(2); c=9.545(3); A=12$
Co-ordinates: $(000, \frac{1}{2}\frac{1}{2}\frac{1}{2})+4Si(D_2)$: $\pm(0\frac{1}{4}0)$
$\qquad\qquad\quad +8S(C_s)$: $\pm(x0z); \pm(x\frac{1}{2}\bar{z}); x=0.208; z=0.119$

C44 (GeS_2 type)

Orthorhombic: C_{2v}^{19}–$Fdd2; a=11.691(8), b=22.341(3); c=6.68(1); A=72$
Co-ordinates: $(000, \frac{1}{2}\frac{1}{2}0)+8Ge(C_2)$: $000; \frac{1}{4}\frac{1}{4}\frac{1}{4}$
$\qquad\qquad\quad +16Ge(C_1)$: $xyz; x\bar{y}z; (\frac{1}{4}-x)(\frac{1}{4}+y)(\frac{1}{4}+z); (\frac{1}{4}+x)(\frac{1}{4}-y)(\frac{1}{4}+z)$ with $x=0.125; y=0.139; z=0.00$
$\qquad\qquad\quad +16S(C_1)$:   the same with $x=0.022; y=0.081; z=0.183$
$\qquad\qquad\quad +16S(C_1)$:   the same with $x=0.153; y=-0.014; z=-0.183$
$\qquad\qquad\quad +16S(C_1)$:   the same with $x=0.063; y=0.125; z=-0.278$

C46 [Krennerite ($AuTe_2$) type]

Orthorhombic: C_{2v}^4–$Pma2; a=16.51(3), b=8.80(3), c=4.45(3); A=24$
Co-ordinates: $2Au(C_2)$: $00z; \frac{1}{2}0z; z=0$
$\qquad\qquad\quad 2Au(C_s)$: $\frac{1}{4}yz; \frac{3}{4}z; y=0.319; z=0.014$
$\qquad\qquad\quad 4Au(C_1)$: $xyz; x\bar{y}z; (\frac{1}{2}-;x)yz; (\frac{1}{2}+x)\bar{y}z; x=0.124; y=0.666; z=0.500$
$\qquad\qquad\quad 2Te(C_s)$: $\frac{1}{4}yz; \frac{3}{4}\bar{y}z; y=0.018; z=0.042$
$\qquad\qquad\quad 2Te(C_s)$:   the same with $y=0.617; z=0.042$
$\qquad\qquad\quad 4Te(C_1)$:   as $4Au$ (C_1) with $x=0.003; y=0.699; z=0.042$
$\qquad\qquad\quad 4Te(C_1)$:   the same with $x=0.132; y=0.364; z=0.500$
$\qquad\qquad\quad 4Te(C_1)$:   the same with $x=0.119; y=0.964; z=0.500$

C49 ($ZrSi_2$ type)

Orthorhombic: D_{2h}^{17}–$Cmcm; a=3.725, b=14.774, c=3.664; A=12$
Co-ordinates: $(000, \frac{1}{2}\frac{1}{2}0)$ $+4Zr(C_{2v})$: $\pm(0y\frac{1}{4}); y=0.106$
$\qquad\qquad\qquad\qquad\qquad +4Si(C_{2v})$:   the same with $y=0.750$
$\qquad\qquad\qquad\qquad\qquad +4Si(C_{2v})$:   the same with $y=0.355$

Table 6.2 STRUCTURAL DETAILS—*continued*

$\underline{C54 \ (TiSi_2 \ type)}$

Orthorhombic: D_{2h}^{24}–$Fddd$; $a = 8.2671(9)$, $b = 4.800(5)$, $c = 8.5505(11)$; $A = 24$

Co-ordinates: $(000, \frac{1}{2}\frac{1}{2}0; \, \natural)$ $+ 8Ti(D_2)$: $000; \frac{1}{4}\frac{1}{4}\frac{1}{4}$
$+ 16Si(C_2)$: $\pm(x00); (\frac{1}{4} + x)\frac{1}{4}\frac{1}{4}; (\frac{1}{4} - x)\frac{1}{4}\frac{1}{4}; x \approx \frac{1}{3}$

Data updated in this edition of Smithells is from 'Pearson's Handbook of Crystallographic Data for Intermetallic Phases' (4 volumes) by P. Villars and L. D. Calvert, published by ASM, International Materials Park OH, 1991.

Supplemented by checking of selected phases not present in the above (NaCl, CsCl, LiOH, $PbCl_2$, P) using the Powder Diffraction File, International Center for Diffraction Data, Newton Square, PA, 2001.

7 Metallurgically important minerals

Table 7.1 gives data on the minerals from which the more widely used metallic and non-metallic elements and their compounds are extracted. The elements in this table are given in alphabetical order for easy reference. A 'mineral' is a naturally occurring, homogenous, inorganic solid material that has a definite, but not always fixed, chemical composition. It may be crystalline or amorphous and may have formed, in nature, by inorganic or biological processes.

Most elements form more minerals than those listed; minerals of primary importance are shown in bold type in column 2. Not all elements cited are metals although they have widespread utility in metallurgical and materials processing applications. For example silicon (Si) is a non-metal used in semiconductor (computer chip) applications, while chlorine and bromine are utilised in metal-extraction technologies. Some elements are hardly ever used as such but rather in compound forms. For example, boron (B) compounds have hundreds of uses in the form of B_2O_3, H_3BO_3, or $Na_2B_4O_7$ etc. Many elements, such as germanium (Ge)—an important component of semiconductor devices, are normally extracted as by-product of sphalerite (ZnS) or bauxite processing residues.

Extraction technologies often incorporate a number of process steps including concentration (flotation), smelting (pyro-metallurgy), and leaching (hydro-metallurgy). Parentheses indicate that the element or its compounds are recovered as by-products from the extraction residues of other primary materials. The mineral-producing countries are listed in order of decreasing production volume in column 5 while major end product sources are given in column 6. When data are not available or not certain, US import sources are cited in column 6. The figure for abundance given in column 1 is the concentration of the element (in p.p.m., parts per million) in the crustal rocks of the earth. The figure for metal production in column 7 refers to recovered primary element production except where indicated as contained quantities in produced ores or concentrates or as secondary refining production. *Salines* is used to include all salt waters, bitter lakes and the sea.

Abbreviations used in the table:

p.p.m. : Parts per million (or gram per metric ton)
m.t.   : Metric ton = 1 000 kg = tonne
N/A   : Not available or not disclosed due to strategic or proprietary reasons
Equiv. : Equivalent
Est.   : Estimated

Table 7.1   MINERALS, SOURCES, AND USES

Element: symbol and abundance (p.p.m.)	Minerals	Formulae	Density (g cm^{-3})	Major mineral sources	Major sources	1999/2000 World production (m. t.)	Primary uses and applications
1	2	3	4	5	6	7	8
Aluminium Al 81 300	**Bauxite** **Gibbsite** Kyanite	(ore with Fe, Ti, clay impurities) $Al_2(OH)_6$ Al_2SiO_5	2–2.55 2.35 3.55–3.66	Australia, Guinea, Brazil Jamaica	USA, Russia, China, Canada	23.1×10^6	Containers, construction, electrical, machinery, equipment, aerospace
Antimony Sb 0.2–1	Senarmotite Valentinite Kermesite **Stibnite**	Sb_2O_3 Sb_2O_3 Sb_2S_2O Sb_2S_3	5.3 5.6 4.6 4.5–4.6	China S. Africa Russia Bolivia	China Mexico Australia	118×10^3	Flame retardant, lead-alloys, plastics filler, ceramics, glass, corrosion resistance
Arsenic As 1.8–5	**Arsenopyrite** Orpiment **Realgar**	FeAsS As_2S_3 AsS	6.07 3.49 3.48	China, Chile, Ghana, Mexico	China, Chile, Ghana, Mexico	In the form of As_2O_3 36.9×10^3	Wood preservation, glass additive, pesticides, Cu-Alloy
Barium Ba 4 000	**Barite** (or barites) Witherite	$BaSO_4$ $BaCO_3$	4.5 4.3	China, India, USA, Morocco	China, India, USA, Morocco	In the form of $BaSO_4$ 6.2×10^6	Chemicals, filler/extender, glass, well drilling
Beryllium Be 2–6	**Bertrandite** **Beryl**	$B_4Si_2O_7(OH)_2$ $B_3Al_2Si_6O_{18}$	2.59–.66 2.7	USA, Russia, Kazakhstan	USA	Metal Equiv.: 226	Electronics, alloy with Cu, defence applications
Bismuth Bi 0.2	**Native** (in PbS) **Bismuthinite**	Bi Bi_2S_3	9.7–9.8 6.4–6.5	China, Mexico, Peru	China, Mexico, Peru, Belgium	4.37×10^3	Alloys, solders, pharmaceuticals, glazes chemicals
Boron B 10	**Colemanite** **Tincal (Borax)** **Ulexite**	$Ca_2B_6O_{11} \cdot 5H_2O$ $Na_2B_4O_7 \cdot 10H_2O$ $NaCaB_5O_9 \cdot 8H_2O$	2.42 1.7 1.65	USA, Turkey, Russia	USA, Turkey, Russia	B_2O_3 Equiv.: 4.47×10^6	Glasses, insulators, soaps/detergents, chemicals, refining flux
Bromine Br 2.5	Bromyrite Embolite (also **NaBr, KBr in salines**)	AgBr Ag(Cl, Br)	6.5 5.3–5.4	USA, Israel, United Kingdom, China	USA, Israel, United Kingdom, China	542×10^3	Fire retardants, drilling, pesticides, water-treatment, photography, rubber

Cadmium Cd 0.17	Greenockite (also from **ZnS** processing)	CdS	5.00	China, Australia, USA, Mexico	Japan, China, USA, Belgium	19.7×10^3	Batteries, pigments, coatings, plastics
Calcium Ca 36300	**Calcite** **(limestone)** **Aragonite** Gypsum	$CaCO_3$ (Hex.) $CaCO_3$ (Orth.) $CaSO_4 \cdot 2H_2O$	2.71 2.94 2.3	All countries	Limestone, cement and dolomite: USA, Canada, China, Australia	Extensive; US- usage calcite: 998×10^6 dolomite: 101×10^6	Minerals used in cement making, roads, construction- aggregates, agriculture, chemicals
Carbon C 200	**Graphite** Diamond	C (Hex.) C (Cub.)	2–2.3 3.52	China, India, Brazil, N. Korea	China, Brazil, Mexico, USA	602×10^3	Batteries, lubricants, electrodes, refractories
Cerium Ce 60–78	**Bastnazite** **Monazite**	$(Ce,La,Di)(CO_3)F$ $(Ce,La,Y,Th)PO_4$	4.9–5.2 4.6–5.4	China, Brazil, India, USA,	China, France, Japan, USA	Est. compounds: 6500	Lighters, lanterns, catalysts, glass
Caesium Cs 3	Pollucite	$CsAlSi_2O_6 \cdot H_2O$	2.9	Canada, Namibia, Zimbabwe	Canada, Germany, UK	N/A Est.: 20	Electronics, photoelectric, medical
Chlorine Cl 130	**Halite** Sylvite Carnalite	NaCl KCl $KCl.MgCl_2 \cdot 6H_2O$	2.2 2.0 1.6	USA, China, Germany, France, Canada	USA, European Union, Canada, China	Est.: 50×10^6	Polymer production, pesticides, pulp/paper bleaching, water treatment
Chromium Cr 167	**Chromite**	$FeCr_2O_4$	4.5–4.8	S. Africa, Kazakhstan, India, Zimbabwe	S. Africa, Kazakhstan, India, Zimbabwe	Ores: Cr-Equiv.: content 4.32×10^6	Stainless steel, refractories, metal plating, chemicals
Cobalt Co 25	**Smaltite** **Linnaeite** **Erythrite** **Cobaltite**	$CoAs_2$ Co_3S_4 $Co_3As_2O_8 \cdot 8H_2O$ CoAsS	6.4 4.85 2.95 6–6.3	As byproduct of Cu and Ni: Australia, Canada, Cuba, Congo	Congo, Finland, Norway, Zambia, S. Africa	35×10^3	Superalloys, magnets, corrosion resistant alloys, tools, catalysts

(*continued*)

Table 7.1   MINERALS, SOURCES, AND USES—*continued*

Element: symbol and abundance (p.p.m.)	Minerals	Formulae	Density ($g\,cm^{-3}$)	Major mineral sources	Major sources	1999/2000 World production (m. t.)	Primary uses and applications
1	*2*	*3*	*4*	*5*	*6*	*7*	*8*
Copper Cu 55–70	**Native Cu** **Chalcopyrite** **Malachite** **Azurite** **Covellite** Chrysocolla	Cu $CuFeS_2$ $Cu_2(OH)_2$ $Cu_3(OH)_2(CO_3)_2$ CuS $CuSiO_3 \cdot 2H_2O$	8.95 4.1–4.3 4.05 3.77 4.6–4.76 2–2.2	Chile, USA, Indonesia, Australia	Chile, Japan, USA, China	11.4×10^6	Conductor (wires), ingots/rods, brasses, bronzes
Fluorine F 625	**Fluorite** Cryolite	CaF_2 Na_3AlF_6	3.0–3.25 2.97	China, S. Africa, Mexico, Brazil	China, S. Africa, Mexico, Brazil	As CaF_2 4.52×10^6	Mainly as CaF_2 in HF production, ceramics, enamels, glass, steel-flux
Gallium Ga 15	Gallite (in **Bauxite, sphalerite, and fly-ash**)	$CuGaS_2$	4.2	Australia, Germany, Japan, Kazakhstan	France, Kazakhstan, Russia	Est.: 40–60	Photo-electric devices, electronics
Germanium Ge 1.5–7	Renierite Germanite (in **bauxite and fly-ash**)	$(Cu,Zn)_{11}(Ge,As)_2$ Fe_4S_{16} $Cu_{26}Fe_4Ge_4S_{32}$	4.3 4.4–4.6	China, USA, Belgium, Russia	China, USA, Belgium, Russia	Est.: 70	Fibre optics, infrared optics, polymerisation, electrical/solar
Gold Au 0.005	**Native** Calaverite Krennerite Petzite	Au Au_2Te_4 (Mon.) Au_8Te_{16} (Orth.) Ag_3AuTe_2	19.3 9.2–9.3 8.62 8.7–9.0	S. Africa, USA, Australia, China, Canada	S. Africa, USA, Australia, China, Canada	2 550	Jewellery, conductor in electronics, finance
Hafnium Hf 3–4.5	In **Zircon** at a concentration of (Zr:Hf) = 50:1	Zircon: $ZrSiO_4$	See Zircon	France, Germany, Japan, Canada	France, Germany, Belgium	Est.: 12	Neutron absorber, reactor-rods, lanterns, refractories
Indium In 0.1	Mainly with **sphalerite** at p.p.m. levels	Sphalerite: ZnS	See Sphalerite	China, Canada, France	Belgium, Canada, China, France	220	Low melting point solders, alkaline batteries

Element	Mineral	Formula	S.G.				Uses
Iodine I 0.5	Iodyrite Lautarite Marshite (Iodine: from **caliche, salines, oil wells**)	AgI $Ca(IO_3)_2$ CuI	5.69 4.59 5.68	Chile, Japan, USA, China	Chile, Japan, USA, China	18×10^3	Pharmaceuticals, sanitation, animal feed, catalysts, photography
Iridium Ir 0.001	Native: see Platinum group metals (**PGM**)	Ir	22.65	See PGM	See PGM	Est.: 4	See PGM
Iron Fe 50 000	**Haematite** Magnetite **Pyrite** Siderite Limonite	Fe_2O_3 Fe_3O_4 FeS_2 $FeCO_3$ $2Fe_2O_3 \cdot 3H_2O$	4.9–5.3 5.18 4.8–5.1 3.7–3.9 3.6–4.0	China, Brazil, Australia, India	China, Brazil, Australia, India, USA	Fe Equiv.: 635×10^6; ore 92×10^6	Cast iron, steels, pigments, chemicals
Lanthanum La 30	**Monazite** **Bastnazite** **Xenotime**	$(Ce,La,Y,Th)PO_4$ $(Ce,La,Di)(CO_3)F$ YPO_4 (also has La)	5.27 4.9–5.2 4.46–5.1	China, USA, India, Russia	China, France, Japan, India, USA,	N/A Est.: less than 1000	Catalytic converters, ceramics, magnets, catalysts, TV screens
Lead Pb 13–16	**Galena** **Cerussite** **Anglesite**	PbS $PbCO_3$ $PbSO_4$	7.4–7.6 6.55 6.38	Australia, China, USA, Peru	USA, Australia, Canada, China	Mine output: 310×10^3	Acid batteries, solders
Lithium Li 20–65	**Spodumene** **Amblygonite** **Petalite**	$LiAlSi_2O_6$ $Li(F,OH)AlPO_4$ $Li(AlSi_4)O_{10}$	3.13–3.20 3–3.1 2.4	Chile, USA, Argentina, Australia	Chile, USA, Argentina	Minerals and brines: 37 000	Ceramics, glass, batteries
Magnesium Mg 20 900	**Magnesite** **Dolomite** Epsomite (also in **salines**)	$MgCO_3$ $CaMg(CO_3)_2$ $MgSO_4 \cdot 7H_2O$	2.8–3.0 2.8–2.9 1.67	Russia, China, USA, Slovakia	China, Australia, Canada	Compounds MgO Equiv.: 11.1×10^6	Compounds as refractories, flue-gas treatment, and as metal in aircraft
Manganese Mn 1 000	**Pyrolusite** **Rhodochrosite** **Manganite** **Psilomelane**	MnO_2 $MnCO_3$ $MnO(OH)$ $BaMn_{10}O_{16}(OH)_4$	4.4–5.0 3.7 4.3 4.7	S. Africa, Ukraine, Brazil, Gabon	China, S. Africa, Ukraine, France, Gabon	Ores: metal Equiv.: 7.28×10^6	Steel, batteries, chemicals

Table 7.1   MINERALS, SOURCES, AND USES—*continued*

Element: symbol and abundance (p.p.m.)	Minerals	Formulae	Density (g cm^{-3})	Major mineral sources	Major sources	1999/2000 World production (m. t.)	Primary uses and applications
1	2	3	4	5	6	7	8
Mercury Hg 0.05–0.5	**Cinnabar**	HgS	8.09	Kyrgyzstan, Spain, Algeria, China	India, Singapore, Spain, UK	Mine output: minimum 1 640	Electrolytic Cl$_2$ and NaOH production, dentistry, gold amalgamation
Molybdenum Mo 1–15	**Molybdenite** Wulfenite Molybdite	MoS$_2$ PbMoO$_4$ Fe$_2$O$_3$ · 3Mo$_3$ · 8H$_2$O	4.7–4.8 6.3–7.0 4.5	USA, Chile, China, Mexico	USA, Chile, China, Mexico	129 × 10^3	Stainless steel, catalysts, lubricants
Nickel Ni 78	**Pentlandite** **Garnierite** **Millerite**	(Fe,Ni)S (Ni,Mg)SiO$_4$ NiS	5.0 2.2–2.8 5.3–5.6	Russia, Canada, Australia, New Caledonia	Russia, Japan, Canada, Australia	1.12 × 10^6	Steels, corrosion resistant coatings, Cu-alloys, magnets
Niobium (Nb) or Columbium 23	**Columbite** **Pyrochlore** also in **tin slags**	(Fe,Mn)(Nb,Ta)$_2$O$_6$ NaCb$_2$O$_6$F	5.2–6.4 4.45	Brazil, Canada, Australia	Brazil, Canada, Germany	32.6 × 10^3	Steel, jet engines, carbides
Osmium Os 0.005	Native in **Pt or Ir alloys**	Os	22.61	See PGM	See PGM	Est.: 22	See Platinum group metals (PGM)
Palladium Pd 0.01	Native in **Pt alloys and Cu-Ni ores**	Pd	12.02	Russia, S. Africa, USA, Canada	Russia, S. Africa, USA, Canada	174	See Platinum group metals (PGM)
Phosphorus P 1000	Apatite with F, Cl and/or OH: **Fluorapatite** **Hydroxylapatite**	(F,Cl,OH) Ca$_5$(PO4)$_3$	3.1–3.2	USA, Morocco, China, Russia,	USA, Morocco, China, Russia,	P$_2$O$_5$ Equiv.: 42 × 10^6; ore: 133 × 10^6	Fertilisers, phosphoric acid, chemicals
Platinum Pt 0.01	**Native Pt** **Sperrylite** **Braggite** **Cooperite**	Pt PtAs$_2$ PtS and (Pt,Pd,Ni)S PtS	21.45 10.6 10.0 9.5–10.2	S. Africa, Russia, Canada, USA	S. Africa, Russia, Canada, USA	155	See Platinum group metals (PGM)

Platinum group metals (PGM) 0.03	**Native and in alloys with Pt or PtS/PtAs$_2$, in Chromite (FeCr$_2$O$_4$)**	Pt, Pd, Rh, Ir, Os, Ru	see individual elements	S. Africa, Russia, Canada, USA	S. Africa, Russia, Canada, USA	365	Catalytic converters, petroleum refining catalysts, jewellery, ceramics, electronics
Potassium K 25 900	**Sylvite** **Carnalite** Nitre	KCl KCl $\cdot$ MgCl$_2$ $\cdot$ 6H$_2$O KNO$_3$	2 1.6 2.1	Canada, Russia, Germany, Belarus	Canada, Russia, Belarus, Germany	K$_2$O Equiv.: 25 $\times$ 10^6	Fertilisers, chemicals
Rhenium Re 0.001	Rheinite (in **Cu, Mo-ores**)	ReS$_2$	7.5	USA, Peru, Kazakhstan, Chile	USA, Chile, Germany, Russia	Mine output: 28.4	Catalysts, Mo-Ni-and W—Alloys, heat-sensors, electronics
Selenium Se 0.08	Clausthalite Berzelianite Naumannite (from **Cu-anode slimes**)	PbSe Cu$_2$Se Ag$_2$Se	7.8–8.08 6.71–7.23 7.0–8.0	Japan, Canada, Belgium Germany	Canada, Philippines, Korea, Australia,	1 460	Glass, metallurgy, electronics, agriculture
Silicon Si 277 200	**Quartz** Opal and numerous silicates	SiO$_2$ SiO$_2$ $\cdot$ nH$_2$O	2.65 2–2.25	China, Russia, Ukraine, USA, Brazil	China, Russia, Ukraine, USA, Brazil	Ferro-silicon: 4.3 $\times$ 10^6; Si: 7.2 $\times$ 10^6	Steels (as ferrosilicon additive) and computer chips as silicon
Silver Ag 0.085	**Native Ag** **Argentite** Pyrargyrite Hessite (also **gold recovery byproduct**)	Ag Ag$_2$S Ag$_3$SbS$_3$ Ag$_2$Te	10.5 7.19–7.36 5.7–5.9 8.4	Mexico, Peru, Australia, USA	Mexico, Peru, Australia, USA	18.3 $\times$ 10^3	Photography, batteries, electrical, electronics, catalysts
Sodium Na 28 300	**Halite** Mirabilite (Galuber's salt) **Trona** (also from **salines** as NaCl)	NaCl Na$_2$SO$_4$.10H$_2$O Na$_2$CO$_3$ $\cdot$ NaHCO$_3$ $\cdot$ 2H$_2$O	2.2 1.48 2.13	USA, China, Mexico, Germany, Russia, India	USA, China, Mexico, Germany, Russia, India	Na Equiv.: 100.23 $\times$ 10^6	Glass, soaps and detergents, textiles, household, pulp and paper. Use pattern: NaCl: 83.9% Na$_2$CO$_3$: 14.9% Na$_2$SO$_4$: 1.29%

Table 7.1   MINERALS, SOURCES, AND USES—*continued*

Element: symbol and abundance (p.p.m.)	Minerals	Formulae	Density (g cm^{-3})	Major mineral sources	Major sources	1999/2000 World production (m. t.)	Primary uses and applications
1	2	3	4	5	6	7	8
Strontium Sr 375	**Celestine (or Celestite)** **Strontianite**	$SrSO_4$ $SrCO_3$	3.96 3.6–3.7	Mexico, Spain, Turkey, China, Russia	Mexico, Germany, China, France	Sr Equiv.: 139×10^3 China and Russia: N/A	TV tubes, magnets, fire-works
Sulphur S 260	**Native Sulphur** **Pyrite** **Chalcopyrite** **Galena** **Sphalerite** (also from **crude oil**)	S FeS_2 $CuFeS_2$ PbS ZnS	2.07 4.8–5.1 4.1–4.3 7.4–7.6 3.9–4.2	USA, Canada, China, Russia	USA, Russia, Saudi Arabia, Poland, UAE	57.2×10^6	Sulphuric acid, (phosphate fertilisers, oil refining, copper ore leaching)
Tantalum Ta 2.05	**Tantalite**	$(Fe, Mn)Ta_2O_6$	5.7–7.3	Australia, Brazil, Congo, Canada	Australia, Nigeria, Japan, China	836	Electronics, aerospace, carbides, heat- exchangers
Tellurium Te 0.06	**Tellurite** **Hessite** **Sylvanite** **Calaverite**	TeO_2 Ag_2Te $AuAgTe_2$ Au_2Te_4 (Mon.)	5.9 8.4 8–8.2 9.2–9.3	Japan, Peru, Canada	UK, Philippines, Belgium, Canada	Est. 140 (USA numbers N/A)	Steel additive, catalysts, chemicals, photoelectric devices
Thallium Tl 0.7	Carlinite Avicennite Fangite Lorandite (byproduct of **Pb, Zn, Cu ores**)	Tl_2S Tl_2O_3 Tl_3AsS_4 $TlAsS_2$	8.1 9.57 6.18 5.53	Canada, Belgium, Mexico	Belgium, Germany, Mexico, UK	Est.: 0.5	Electronics, radiation detection equipment, catalysts, medical
Thorium Th 10.2	**Monazite** Thorianite Thorite	$(Ce,La,Y,Th)PO_4$ ThO_2 $ThSiO_4$	5.27 9.7 5.3	Australia, India, Norway, Brazil,	France, Switzerland	6.2×10^3 (monazite concentrate)	Welding, catalysts, refractories, radar, microwave ovens
Tin Sn 2–40	**Cassiterite** Stannite	SnO_2 Cu_2SnFeS_4	6.8–71 4.4	China, Indonesia, Peru, Brazil, Bolivia, Australia	Peru, China, Bolivia, Brazil	238×10^3	Electrical, bronzes, solders, cans-containers, chemicals

Titanium Ti 4 400	**Rutile** **Ilmenite** Sphene Leucoxene	TiO_2 $FeTiO_3$ $CaTiSiO_5$ Variant of Ilmenite	4.2 4.5–5.0	Australia, Brazil, India, China, Norway	Australia, Canada, Norway, S. Africa	Ti Equiv.: Est.: 1.493×10^6 as (ilmenite: 88.8%, rutile:11.2%)	Pigments (for paper, coatings, plastics), aerospace, armour, medical tools
Tungsten W 1.5–69	**Scheelite** **Wolframite** Ferberite Huebnerite	$CaWO_4$ $(Fe,Mn)WO_4$ $FeWO_4$ $MnWO_4$	5.9–6.1 7.1–7.9 7–7.5 7.0	Russia, China, Austria, Portugal	Russia, China, Austria, Portugal	37.4×10^3	Carbides, tools, armaments, steels, catalysts, high temperature applications
Uranium U 1.8–4	**Pitchblende** (or Uraninite) Torbernite **Carnotite**	$2UO_3 \cdot UO_2$ $Cu(UO_2)_2P_2O_8 \cdot 12H_2O$ $K_2O \cdot 2U_2O_3 \cdot$ $V_2O_5 \cdot 2H_2O$	6.4 3.5 4.7–5.0	Canada, Australia, Niger, Namibia	Canada, Australia, USA Niger, Namibia	Mine output: 31 172	Nuclear fuels, weapons, medicine
Vanadium V 145	Patronite Vanadinite Carnotite (also Rascoelite **U-ore processing** **byproduct)**	VS_4 $Pb_4Cl(VO4)_3$ $K_2O \cdot 2U_2O_3 \cdot$ $V_2O_5 \cdot 2H_2O$ $3V_2O_5 \cdot 10SiO_2 \cdot 4H_2O$	2.82 6.9 4.7–5.0 2.97	S. Africa, China, Russia, Kazakhstan	China, Russia, S. Africa	43×10^3	Steels, catalysts, ceramics
Yttrium Y 33	**Monazite** **Xenotime**	$(Ce,La,Y,Th)PO_4$ YPO_4	5.27 4.46–5.1	China, India, Canada	China, France, UK, Japan	Mine output Y_2O_3 Equiv.: 2 400	TV monitors, fluorescence, lasers, jet engines, ceramics
Zinc Zn 50–132	**Sphalerite** **Smithsonite** Hemimorphite Willemite	ZnS $ZnCO_3$ $Zn_4Si_2O_7(OH)_2 \cdot H_2O$ $ZnSiO_4$	3.9–4.2 4–4.5 3.45 4.0–4.1	China, Australia, Peru, USA	China, Australia, Canada, Kazakhstan	Mine output: 8.73×10^6	Galvanising, alloys, brasses and bronzes
Zirconium Zr 165–220	**Zircon** **Baddeleyite**	$ZrSiO_4$ ZrO_2	4.68 5.4–6.02	Australia, S. Africa, USA,	France, Germany, Japan USA	760×10^3 (mineral concentrate) excludes USA	Nuclear reactors, heat exchangers,

8   Thermochemical data

Except where otherwise indicated, the data given in these tables have been selected from three main sources: 'Selected Values of the Thermodynamic Properties of the Elements', by R. Hultgren, P. O. Desai, D. T. Hawkins, M. Gleiser and K. K. Kelley, and by the same authors, 'Selected Values of the Thermodynamic Properties of Binary Alloys'; also 'Metallurgical Thermochemistry', 5th edn., by O. Kubaschewski and C. B. Alcock.* These works represent authoritative compilations of critically assessed data presently available, to which reference should be made for original sources or details of assessment.

See also the following: 'NIST-JANAF Thermochemical Tables', 4th edn., by M. W. Chase, Jr.

8.1   Symbols

θ_m = melting point in °C
θ_e = boiling or sublimation point in °C at 760 mmHg
θ_t = transition temperature in °C
θ_s = sublimation point in °C
T = absolute temperature in K
L_m = latent heat of fusion
L_e = latent heat of vaporisation
L_t = latent heat of transition
L_s = latent heat of sublimation

$\left.\right\}$ in kJ mol^{-1} (or kJ g-atom^{-1}) or in Jg^{-1}

ΔV_m = volume change during melting $[(V_{liq} - V_{solid})/V_{solid}]\%$
ΔH_{298} = heat of formation at 298 K (25°C) in kJ mol^{-1} (or kJ g-atom^{-1}) or in Jg^{-1}.
(The value of a heat evolved during a reaction is taken to be negative)
ΔG = maximum work (change of free energy) in kJ mol^{-1} (or kJ g-atom^{-1})
S_{298} = standard entropy at 298 K (25°C) in J K^{-1} mol^{-1} (or J g-atom^{-1})
p (mmHg) = vapour or dissociation pressure in mmHg
N_1 = mol fraction of the first component
N_2 = mol fraction of the second component
C_p = specific heat in J K^{-1} mol^{-1}
c_p = specific heat in J g^{-1} k^{-1}

---

* Now called 'Materials Thermochemistry', 6th edn., with P. J. Spencer added as an author.

8.2   Changes of phase (phase diagrams may be found in Chapter 11)

Table 8.2a INTERMETALLIC COMPOUNDS

Latent heats and temperatures of fusion.

If an intermetallic phase is completely disordered, the entropy of fusion (L_m/T_m) can generally be calculated additively from the entropies of fusion of the components. If it is completely ordered, $-19.146\,(N_1 \log N_1 + N_2 \log N_2)$ is as a rule to be added to the calculated entropy of fusion.

Phase	N_2 10^{-2}	θ_m °C	L_m kJ g-atom⁻¹	L_m Jg⁻¹

The above values of the heat of formation ΔH were measured calorimetrically at room temperature or at about 600°C, or have been calculated from measurements of vapour pressure or electromotive force at different temperatures. They are probably correct to within $\pm 10\%$. As the molar heats of alloys are obtained nearly additively from the atomic heats of the components (Neumann and Kopp's rule) all the heats of formation (even if measured at higher temperatures) are probably valid also at room temperature within the limits of error mentioned above. The formulae of the compounds are given only to indicate composition, independent of whether the phases form a broad or narrow homogeneous field, or are ordered or disordered.

ΔS = entropy of formation. N_2 = mol fraction of second component.   s.s. = solid solution.

8.4   Metallic systems of unlimited mutual solubility

While mutual solubility in the solid state is usually limited, that in the liquid state is frequently unlimited. Thus, the curves of concentration against integral heat, free energy and entropy of formation are convex with a maximum or a minimum. The thermochemical values at the concentrations corresponding to these maxima and minima are given in Table 8.6.

According to van Laar the form of the heat of mixing curve may be represented by

$$\Delta H = \frac{aN_2(1 - N_2)}{1 + b \cdot N_2}$$

where N_2 is the mol fraction of the second component and a and b are constants for each binary system.

For a system, completely disordered, the entropy of formation is often represented by this equation:

$$\Delta S = -19.155(N_1 \log N_1 + N_2 \log N_2) \, \mathrm{J\,K^{-1}\,g\text{-}atom^{-1}}$$

which has a maximum value of 5.78 $\mathrm{J\,K^{-1}}$ at $N_1 = N_2 = 0.5$. Some deviations from this value may be due to experimental errors, but others are real.

For more detailed discussions *see* refs 1–3.

* Note standard state for metal *C*.

8.5   Metallurgically important compounds

In Tables 8.8a to 8.8j values of the heats and free energies of formation from the constituent elements are given throughout in kJ mol^{-1} of compound and standard entropies in J K^{-1} mol^{-1} of compound. It is to be noted that the minus signs appear in the captions, and therefore positive numerical values denote exothermic formation.

The standard state of a reactant element is the most stable form at the temperature indicated unless otherwise stated in the headings; the ideal diatomic gases were used as the standard states for sulphur, bromine and iodine in computing the free energy values at room temperature. The standard state of the compounds is the ideal stoichiometric proportion, and the state of aggregation where necessary is indicated by s = solid, m = liquid and g = gaseous. Many compounds are stable with slight deviations from stoichiometric proportion. Compounds which may exist over a range of composition are indicated by an asterisk (*). For such compounds thermochemical values must be used with caution; dissociation pressures calculated from the free energy values may show considerable deviations from measured dissociation pressures.

Free energy values are given at five temperatures; further values can be obtained by linear interpolation provided that no change in the state of aggregation occurs in the interval. Even then, a linear interpolation will generally give a value within the accuracy of the data. The limits of accuracy are given in the last column of the tables; they apply to the values of the heat and free energy of formation below, say, 1 500 K. The errors may be greater at 2 000 K.

Dissociation pressures of sulphides and phosphides have only been determined for parts of many systems, the data for the lowest oxidation steps often being absent. No total thermochemical values for the formation of the compounds from the elements can therefore be given in Tables 8.8f and 8.8j but dissociation pressures of the compounds rich in sulphur or phosphorus appear in Tables 8.9a and 8.9b, respectively.

The thermochemical values for the metal borides and carbides suggested below can only be used as a guide. They are not sufficiently reliable for accurate calculations—mainly for two reasons: (1) transition metals do not form stoichiometric compounds with boron and carbon but rather extensively homogeneity ranges of which the investigators have taken too little heed. Thus the data below are oversimplifications. (2) it is very doubtful whether the experimental zero-point entropies of borides and carbides are generally zero. More likely, 'frozen-in disorder' of the substances studied accounted for substantial zero-point entropies, so that the values in column 3 when obtained from low-temperature heat capacities are not truly 'standard entropies'.

Table 8.8f SULPHIDES

Heats and free energies of formation in kJ and standard entropies.
In calculating the heats of formation, rhombic sulphur is taken as the standard state. For the free energies of formation the perfect diatomic gas S$_2$ is taken as the standard state at all temperatures.

Table 8.8h SILICATES AND CARBONATES

Heats and free energies of formation from the constituent oxides in kJ and standard entropies.
The standard state of carbon dioxide is the perfect gas under 1 atm pressure; that of silica is quartz.

GeP	27.2	61.1	11				

The standard state is white phosphorus and for P white → P red, $\Delta H = -17.4$ kJ g-atom^{-1}. With respect to red phosphorus, heats of formation are thus less negative per g-atom P by this amount.

8.6   Molar heat capacities and specific heats

Table 8.10   ELEMENTS

Molar heat capacities.

The molar heat capacity C_p may be given empirically by an equation of the form:

$$C_p = 4.186\,8(a + 10^{-3}bT + 10^5 cT^{-2})\,\text{J K}^{-1}\,\text{mol}^{-1}$$

where a, b and c are constants and T = temperature in K.
   The values of the constants are given below.

Table 8.11   ALLOY PHASES AND INTERMETALLIC COMPOUNDS

Molar heat capacities and specific heats.

Generally, Neumann and Kopp's rule applies better to intermetallic compounds than to inorganic salts. Thus, the molar heat capacity of an alloy may be calculated additively from the atomic heat capacities of the components. This relationship is useful as only a few specific heats of alloys have been measured.

In the following cases Neumann–Kopp's rule is obeyed to within ±3% in the temperature range 0–500°C:
Ag–Au; Ag$_3$Al; γ-Ag–Al; β-Ag–Mg; AlCu; Al$_2$Cu; AlCu$_3$; Al$_3$Mg$_4$; Bi–Cd; Co$_2$Sn; Cu$_2$Mg; MgZn$_2$; Mg$_2$Si; Pd–Sb

The heat capacities of heterogeneous alloys must always be calculated additively from those of the components.

In other cases the calculated values differ from the determined values by more than 3%. This result may be due in part to experimental errors.

C_p may be represented empirically by an equation of the form:

$$C_p = 4.1868(a + 10^{-3}bT + 10^5 cT^{-2})\,\mathrm{J\,K^{-1}\,mol^{-1}}$$

where a, b and c are constants and T is the temperature in K. The values of the constants are given below.

8.7 Vapour pressures

Table 8.13 ELEMENTS

Vapour pressures.

The vapour pressure p (mmHg) of an element may be represented by an equation of the type:

$$\log p = -\frac{A}{T} + B + C \log T + 10^{-3}DT$$

The values of the constants A, B, C and D in this equation are given below.

Element	A	B	C	D	Temp. range K
Ag	14 710	11.66	−0.755	—	298–1 234
	14 260	12.23	−1.055	—	1 234–2 400
Al	16 450	12.36	−1.023	—	1 200–2 800

9 Physical properties of molten salts

In the following tables are given densities, electrical conductivities, surface tensions and coefficients of viscosity of pure molten salts, molten binary salt systems and other ionic melts. For comprehensive data and treatment, reference should be made to G. J. Janz, 'Molten Salts Handbook', 1967, Academic Press, New York/London.

Table 9.1   DENSITY OF PURE MOLTEN SALTS

The density of most pure molten salts varies almost linearly with temperature, and may be represented by the equation:

$$d_t = a - 10^{-3} \cdot bt$$

where d_t is the density in g cm^{-3}, a and b are constants, and t is the temperature in °C over appreciable ranges of temperature. Values of the constants and the appropriate temperature ranges are given below. Principal references are in **bold type**.

Table 9.2   DENSITIES OF MOLTEN BINARY SALT SYSTEMS AND OTHER MIXED IONIC MELTS

The density (g cm^{-3}) at temperature t(°C) and composition p(wt. %) of the first-named constituent is given as d_t, or the constants a and b in the equation $d_t = a - 10^{-3} bt$ or A, B and C in the equation $d_t = 10^6 A t^{-2} - 10^3 B t^{-1} + C$ are given together with the temperature range r(°C). Principal references are in **bold type**.

Table 9.4 ELECTRICAL CONDUCTIVITY OF PURE MOLTEN SALTS

The conductivity in Ω^{-1} cm^{-1} is given at the melting point θ_m, and at 50° intervals beginning at θ, or as an equation in the temperature t, or at the temperatures given in brackets. All temperatures are in °C. Extrapolated conductivities are also bracketed. Principal references are in **bold type**.

Table 9.5   ELECTRICAL CONDUCTIVITY OF MOLTEN BINARY SALT SYSTEMS AND OTHER MIXED IONIC MELTS

The electrical conductivity in $\Omega^{-1}\,cm^{-1}$ at temperature $t(°C)$ and composition p (wt.%) of the first-named constituent is given as κ_t, or empirical equations for κ as a function of temperature within the stated range are given at each composition. Principal references are in **bold type**.

Table 9.6   SURFACE TENSION OF PURE MOLTEN SALTS

The surface tension (mNm^{-1}) at temperature t (°C) is given as γ_t, or the constants a, b and t_0 in the equation $\gamma_t = a - b(t - t_0)$ are given for the temperature range r. Principal references are in **bold type**.

Table 9.7　SURFACE TENSION OF MOLTEN BINARY SALT SYSTEMS AND OTHER MIXED IONIC MELTS

The surface tension ($mN\,m^{-1}$) at temperature t (°C) and composition p (wt.%) of the first-named constituent is given as γ_t (or σ_t), or the constants a, b and t_0 in the equation $\gamma_t = a - b(t - t_0)$ are given for the temperature range r. Principal references are in **bold type**.

Table 9.8 VISCOSITY OF PURE MOLTEN SALTS

The viscosity (centipoise) at temperature t (°C) is given as η_t, or the constants a and b in the equation $\log \eta_t = a + b/(t + 273)$ are given for the temperature range r. Principal references are in **bold type**.

Table 9.9   VISCOSITY OF MOLTEN BINARY SALT SYSTEMS AND OTHER MIXED IONIC MELTS

The viscosity (centipoise) at temperature t (°C) and composition p (wt. %) of the first-named constituent is given as η_t, or the constants a and b in the equation $\log \eta_t = a + b/(t + 273)$ are given for the temperature range r. Principal references are in **bold type**.

10   Metallography

Metallography is the branch of science dealing with the study of the constitution and structure of metals and alloys, its control through processing, and its influence on properties and behaviour. The original implementation of this science was limited by the resolution of the reflected light microscope used to study specimens. This limitation has been overcome by the development of transmission and scanning electron microscopies (TEM and SEM). The analysis of X-rays generated by the interaction of electron beams with atoms at or near the surface, with wavelength or energy-dispersive spectroscopy (WDS, EDS) with SEM, electron microprobe analysis (EMPA) or TEM has added quantitative determination of local compositions, e.g., of intermediate phases, to the deductions based upon observations. Introduction of metrological and stereological methods, and the development of computer-aided image analysers, permits measurement of microstructural features. Crystallographic data can be obtained using classic X-ray diffraction methods using a diffractometer, or diffraction analysis can be performed with the TEM using selected area or convergent-beam electron diffraction (SAD and CBD) techniques, and more recently with the SEM with the orientation-imaging (EBSD) procedure. There is a wide variety of very sophisticated electron or ion devices that can be utilised to characterise surfaces and interfaces, but these devices are generally restricted in availability due to their high cost.

Conventional light-optical techniques are still the most widely used and are capable of providing the information needed to solve most problems. Examination by light optical microscopy (LOM) should always be performed before use of electron metallographic instruments. LOM image contrast mechanisms are different from electron microscopy (EM) imaging modes. Natural colour can not be seen with EM devices. Microstructures are easier to study at low magnification with the LOM than with the SEM. The LOM examination may indicate the need for SEM or TEM analysis and determine the locations for such work. Interpretation of LOM examination results is enhanced and reinforced by the use of electron metallographic techniques. The SEM has become ubiquitous in the metallographic laboratory.

Important Safety Note: The metallographic laboratory can involve a number of serious hazards, that can lead potentially to fatalities. For example, many of the reagents used in the preparation of metallographic etchants are highly corrosive (hydrofluoric acid severely attacks the bone) and/or extremely toxic. These reagents are frequently inflammable and in some cases are explosive (e.g., picric acid). It is especially important to understand that, often, the etchant can possess hazards that are greater and/or different from those of the reagents from which it was prepared (e.g., some perchloric acid based solutions pose a much greater explosion risk than others). Some etchants (e.g., those containing hydrofluoric acid) can be extremely hazardous even when dilute. All etchants have a limited shelf life and some require special storage precautions. In some cases (e.g., glyceregia), etchants cannot be stored safely and must be made up freshly at each use. Identifying a safe and legal method of disposal of used or discarded etchants requires consideration of all of their ingredients.

Given the risks involved, metallographic specimen preparation requires both suitable operating conditions/safety equipment and appropriate training for the metallographer. This chapter points out some of the hazards associated with specific etchants, but is not intended as a substitute for either a detailed laboratory safety manual or reading of the regulations in force in the metallographer's location. A discussion of etchant safety may be found in Petzow[1] and various other references given in the present section.

10.1   Macroscopic examination

For examination of large-scale features, known as macrostructure[2] which are visible with the unaided eye, discs are cut from cast or wrought products (in the case of wrought products, usually before extensive hot deformation is performed). The discs must be representative of the product and are taken usually from prescribed test locations. Mechanical sawing or abrasive sectioning is used to obtain the disc, which may be ground to various surface finish levels, depending upon the nature of the detail that must be observed. The discs are cleaned and hot acid etched to reveal the solidification structure, deformation structure, segregation, soundness, etc. Discs may also be subjected to contact printing methods, such as sulphur printing (see 2, ASTM E 1180 and ISO 4968).

The required disc is obtained by sawing, abrasive sectioning or machining with adequate cooling and lubrication, and is finished normally by grinding. Due to the size of these discs, workshop (machine shop) grinders are used. In the case of a small section, laboratory practices may be utilised. Grinding on abrasive cloth or paper, such as an 'endless belt grinder', is often used, but the platen beneath the belt must be kept flat. For most macroexamination work, a ground surface is adequate. In a few cases, chiefly dependant upon the nature of the examination and the desired etchant, a polished surface is required. Conventional metallographic procedures are adequate. The main problem is obtaining flatness over a section area that is rather large compared to standard metallographic specimens. But, with modern grinder/polisher devices, this can be accomplished readily.

Capturing images of macroetched components can be quite difficult due to the need for obtaining proper uniform illumination, especially if the surface is as-polished, as might be the case when documenting porosity, cracks or other voids in sections. Although film-based documentation is becoming less common, compared to digital imaging, film is still preferred at this time in failure analysis work involving litigation. Regardless of the technology used, illumination still must be uniform. With an as-polished surface, 'hot spots' and reflections are a major problem that can be overcome by a variety of 'tricks' utilising vertical illumination and passing light through translucent material.

Etching reagents for macroscopic work are given in many national and international standards, such as ASTM E 340, and textbooks.[2] The commonly used reagents are listed in Table 10.1. Directions for sulphur-printing are given in ISO 4968 and ASTM E 1180. This technique is used to show the distribution of sulphur in steel and is also described in Table 10.1.

Table 10.1   ETCHING REAGENTS FOR MACROSCOPIC EXAMINATION

See general safety note at the start of this Chapter.

Material	Reagent*		Remarks
A. *Aluminium base*			
1. Aluminium and its alloys	(a) Concentrated Keller's Reagent Nitric acid (1.40) Hydrochloric acid (1.19) Hydrofluoric acid (40%)§	100 ml 50 ml 1½ ml	Can be diluted with up to 50 ml water
	(b) Nitric acid (1.40) Hydrochloric acid (1.19) 2% conc. Hydrofluoric acid§	30 ml 30 ml 30 ml	Widely applicable, but very vigorous
	(c) Tucker's Reagent Nitric acid (1.40) Hydrochloric acid (1.19) Hydrofluoric acid (40%)§ Water	15 ml 45 ml 15 ml 25 ml	Use fresh
	(d) 10% sodium hydroxide in water		Use at 60–70°C
2. Unalloyed Aluminium and Al–Cn alloys	(e) Flick's Reagent Hydrochloric acid Hydrofluoric acid§ Water	15 ml 10 ml 90 ml	Wash in warm water after etching and clear by dipping in concentrated nitric acid
3. Aluminium– silicon	(f) Hume-Rothery's Reagent Cupric chloride Water	15 g 100 ml	For high-silicon alloys Fine polish undesirable. Immerse specimen 5–10s, remove, and brush

(continued)

Table 10.1 ETCHING REAGENTS FOR MACROSCOPIC EXAMINATION—*continued*

Material	Reagent*		Remarks
			away deposited copper or remove it with 50% nitric acid in water
4. Aluminium–copper	(g) Keller's Reagent 2½ % nitric acid (1.40) 1½ % hydrochloric acid (1.19) ½ % hydrofluoric acid (40%)§ Remaining water		More frequently used as micro-etch
5. Aluminium–magnesium	(h) 5% cupric chloride 3% nitric acid (1.40) Remaining water		Clear surface with strong nitric acid
6. Aluminium–copper–silicon	(g) Keller's Reagent (as above) (i) Nitric acid (1.40) Hydrochloric acid (1.19) Hydrofluoric acid (40%)§ Water	 15 ml 10 ml 5 ml 70 ml	
7. Aluminium–copper–magnesium–nickel	(j) Zeerleder's Reagent Hydrochloric acid (1.19) Nitric acid (1.40) Hydrofluoric acid (40%)§ Water	 20 ml 15 ml 5 ml 60 ml	
B. *Copper base* 1. Copper and copper alloys generally	(a) Alcoholic ferric chloride Ethanol Ferric chloride (anhydrous) Hydrochloric acid (1.19)	 96 ml 59 g 2 ml	Avoid use of water for washing, or staining may result. Use alcohol or acetone instead. Grain contrast
	(b) Acid aqueous ferric chloride Ferric chloride Hydrochloric acid (1.40) Water	 25 g 25 ml 100 ml	(a) and (b) require moderately high standard of surface finish
	(c) Concentrated nitric acid (1.40) Nitric acid (1.40) Water	50 ml 50 ml 10 ml	A rapid etch, suitable for roughly prepared surfaces. Addition of a trace of silver nitrate (5%) enhances contrast
	(d) 10% ferric chloride in water 5% chromium trioxide in saturated brine 20% acetic acid in water	10 ml 10 ml 20 ml	To reveal strains in brasses
	(e) A. 1% mercuric nitrate in distilled water B. 1% nitric acid (1.40) in water. Mix A and B in equal proportions		Time required to induce cracks is indication of residual stress
	(f) Chromium trioxide Ammonium chloride Nitric acid (1.40) Sulphuric acid (1.84) Distilled water	40 g 7.5 g 50 ml 8 ml 100 ml	Good for alloys with silicon and silicon bronzes
C. *Iron and steel*	(a) 50% hydrochloric acid in water		Use hot (70–80°C) for up to 1 h. Shows segregation porosity, cracks; useful for examination of welds for soundness
	(b) 20% sulphuric acid in water		Use hot (80°C) for 10–20 min. Scrub lightly to remove carbonaceous deposit. Purpose

Table 10.1   ETCHING REAGENTS FOR MACROSCOPIC EXAMINATION—*continued*

Material	Reagent*		Remarks
Iron and steel—continued			
			as (a). Mixtures of (a) and (b) are also used similarly
(c)	25% nitric acid in water		Purposes as (a) and (b). May be used cold if more convenient
(d)	10% ammonium persulphate in water		Grain contrast etch. Apply with swab. Reveals grain growth and recrystallisation at welds
(e)	Stead's Reagent Cupric chloride Magnesium chloride Hydrochloric acid (1.19) Alcohol to 1 litre	10 g 40 g 20 ml	For revealing phosphorus segregation and primary dendritic structure of cast steels. Dissolve the salts in the acid with addition of a minimum of water. Phosphorus segregate unattacked, also eutectic cells in cast iron
(f)	Fry's Reagent Cupric chloride Hydrochloric acid Water	90 g 120 ml 100 ml	To reveal strain lines in mild steel. Heat to 150–250°C for 15–30 min before etching specimen. Etch for 1–3 min while rubbing with a soft cloth. Rinse with alcohol.
(g)	Humphrey's Reagent Copper ammonium chloride Hydrochloric acid (1.19) Water	120 g 50 ml 1 litre	Reveals dendritic structure of cast steels. First treat surface with 8% copper ammonium chloride solution and then with (g) for ½–1½ h. Remove copper deposit (loosely adherent), dry and rub surface lightly with abrasive
(h)	5–10% nitric acid in alcohol		Etch for up to ½ h. Reveals cracks and carbon segregation. More controlled than aqueous acids
(j)	Sulphur printing 3% sulphuric acid in water		Soak photographic printing paper in the acid and remove surplus acid with blotting paper. Lay paper face down on the clean steel surface and 'squeegee' into close contact. After 2 min remove paper, wash it and fix in 6% sodium thiosulphate in water. Brown colouration on the paper indicates local segregation of sulphides
(k)	Dithizone process for lead distribution		*See* p. **10**–49, *Lead in steels*. Analogous to sulphur printing
(l)	Marble's Reagent Hydrochloric acid (1.19) Saturated aqueous solution of cupric sulphate	50 ml 25 ml	Austenitic steels. High temperature steels. Fe–Cr–Ni casting alloys. Also shows depth of nitriding
(m)	Oberhoffer's Reagent Hydrochloric acid (1.19) Ferric chloride Stannous chloride	42 ml 30 g 0.5 g	Good surface preparation needed. Steel castings. Darkens Fe-rich areas, reveals segregation and

(*continued*)

Table 10.1   ETCHING REAGENTS FOR MACROSCOPIC EXAMINATION—*continued*

Material	Reagent*		Remarks
Iron and steel—continued	Water	500 ml	primary cast structure
	Ethanol (acid added last)	500 ml	
	Rinse in 20% hydrochloric acid in ethanol		
	(n) Klemm's Reagent		Phosphorus distribution in cast steel and cast iron. Grain contrast
	Saturated aqueous solution of sodium thiosulphate	50 ml	
	Sodium metabisulphite (can be increased for contrast)	1 g	
D. *Lead base* Lead and lead alloys generally	(a) Russell's Reagent A. 80 ml nitric acid (1.40) in 220 ml water B. 45 g ammonium molybdate in 300 ml water		Grain contrast etch; removes deformed layer Mix equal parts of A and B immediately before use. Swab for 10–30 s. Rinse in water
	(b) Ammonium molybdate	10 g	Bright etch revealing grain structure, defects, etc.
	Citric acid	25 g	
	Water	100 ml	
	(c) Worner and Worner's Reagent		Chemical polish revealing defects, etc. Specimen must be dry and water content of solution as low as possible *N.B.*— Avoid all heating, as lead alloys recrystallise very readily
	Acetic acid, glacial '100 vol.'	75 ml	
	Hydrogen peroxide (30% conc.)	25 ml	
	(d) Nitric acid (1.40)	20 ml	Immerse 5–10 min. Grain contrast, laminations, welds. Up to 50% nitric acid can be used
	Water (distilled)	80 ml	
	(e) Glacial acetic acid	20 ml	Macrostructure of alloy with Ca, Sb and Sn. Use fresh only. Several minutes needed
	Nitric acid (1.40)	20 ml	
	Glycerol	80 ml	
	(f) Glacial acetic acid	20 ml	2–10 s by swabbing. Good for alloys with Bi, Te or Ni
	Nitric acid (1.40)	20 ml	
	Hydrogen peroxide (30%)	20 ml	
	Water (distilled)	50 ml	
E. *Magnesium base*	(a) Picric acid‡ (64%) saturated in ethanol (96%)	50 ml	Grain size. Flow lines in forging (wash precipitate in hot water). Etch for up to 3 min
	Glacial acetic acid	20 ml	
	Distilled water	20 ml	
	(b) Ammonium persulphate	2 ml	Flow lines in forgings
	Distilled water	98 ml	
	(c) Nitric acid (1.40)	20 ml	Internal defects in casts. Useful for Mg–Mn and Mg–Zr. Etch for up to 3 min
	Water	80 ml	
	(d) Glacial acetic acid	10 ml	General defects; flow lines, segregation. Etch for up to 3 min
	Water	90 ml	
F. *Nickel base*	(a) Nitric acid (1.40)	50 ml	Welds, Ni–Cr–Fe alloys
	Acetic acid	50 ml	
	(b) Aqua regia		As (a)
	Nitric acid (1.19)	25 ml	
	Hydrochloric acid (1.19)	75 ml	

(*continued*)

Table 10.1 ETCHING REAGENTS FOR MACROSCOPIC EXAMINATION—*continued*

Material	Reagent*		Remarks
G. *Tin base*			
	(a) Sat. soln of ammonium polysulphide in water (wipe off surface film)		Grain structure; suitable most tin alloys (etching time 20–30 min)
	(b) FeCl	10 g	Sn–Sb alloys (up to 3 min)
	Hydrochloric acid (1.18)	2 ml	
	Water	100 ml	
H. *Zinc base*			
Zinc and zinc alloys	(a) Concentrated hydrochloric acid (1.19)		Good grain contrast
Zinc-rich alloys	(b) 5% hydrochloric acid in alcohol		HCl can be increased to 50% Wash under running water to remove reaction product
	(c) Sodium sulphate (3.5 g if hydrated)	1.5 g	Better than above for Zn–Cu alloys
	Chromium trioxide	20 g	
	Water	100 ml	
I. *Other metals*			
Many of these require etching in aggressive solutions comprising various mixtures of HCl, HNO$_3$ and HF	(a) Hydrochloric acid (1.18)	50 ml	Platinum metals group, especially Ru, Os, Rh
	Nitric acid (1.40)	20 ml	
	Hydrofluoric acid (40%)§	30 ml	
	(b) Hydrochloric acid (1.19)	30 ml	Cr, Mo, W, V, Nb, Ta
	Nitric acid (1.40)	15 ml	
	Hydrofluoric acid (40%)§	30 ml	
Nitric acid/HF etches: These do not appear to be very sensitive to composition. HF should be 5–10%. Heating to 60–80°C will accelerate etching, e.g., for Ti	(c) Nitric acid (1.40)	30–45 ml	Highly alloyed Ti, Hf, Zr; also Cr, W, Mo, V
	Hydrofluoric acid (40%)§	10 ml	
	Water	60–45 ml	
Aqueous HCl, HNO$_3$ etches. The reactivity can be reduced by adding water	(d) Hydrochloric acid (1.19)	66 ml	Au, Pt, Pd. Used for Co alloy if added to 34 ml water
	Nitric acid (1.40)	34 ml	
Acidified hydrogen peroxide etch	(e) Hydrofluoric acid§	10 ml	Dilute Ti, Hf, and Zr alloys
	Hydrogen peroxide (30%)	45–60 ml	
	Water	45–30 ml	
Nitric acid in alcohol ('Nital')	(f) Nitric acid (1.40)	10 ml	Silver. (*Note*: It is dangerous to *store* more than 5% HNO$_3$ in ethanol in a tightly stoppered bottled or >33% HNO$_3$ in methanol). In an open dish, 5% or 10% HNO$_3$ in ethanol is safe.
	Methanol	90 ml	
Hydrochloric acid etches	(g) Hydrochloric acid (1.19)	10 ml	Be and its alloys, especially for large grain sizes
	Water	90 ml	
	Ammonium chloride	2 or 4 g	
	Picric acid‡	2 g	
	(h) Hydrochloric acid (1.19)	50 ml	Cobalt alloys
	Water	50 ml	
	60–80°C for 30–60 min		

* Acids are concentrated, unless otherwise indicated, e.g., with specific gravity.

‡ Special handling is required for picric acid to avoid the risk of fire and/or explosion and local regulations must be consulted before use of this reagent.

§ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

10.2   Microscopic examination

Metallographic specimens are normally prepared for examination with the light microscope by cutting out the piece to be examined (preferably not more than about 30 mm diameter) using a laboratory abrasive cut-off machine or a precision saw. Sometimes, specimens are cut in the shop or in the field using more aggressive methods, such as power hacksaws, dry abrasive cutting, and even by flame cutting. These techniques introduce a great deal of damage into the structure adjacent to the cut. It is generally best to re-section the specimen with a laboratory abrasive cut-off machine, rather than to try to grind through the damaged layer. In many cases, the specimen is encapsulated in a polymeric compound, either a compression mounting resin or a castable resin. Larger specimens of uniform shape may be prepared without mounting, but the edge retention may not be adequate for examination above 100X. The specimens are then subjected to at least one grinding step and one or more diamond abrasive steps, followed by one or more polishing steps with other abrasives, such as alumina or colloidal silica. However, the steps must be designed to remove the damage from sectioning. Moreover, each abrasive does produce damage proportional to its particle size. So, each step must remove the damage from the previous step, so that at the final step, the damage depth is so thin that etching will remove it. At the same time, the preparation procedure must keep the specimen surface flat and other problems (e.g., pull out, drag, smear, embedding, etc.) are prevented. The surface must be more than just reflective in nature if the true microstructure is to be revealed.

For some purposes, e.g., the study of slip processes involving individual dislocations using transmission electron microscopical studies of fine structure, and microindentation hardness testing under light loads, electropolishing has been considered in the past to be almost indispensable (specimen preparation for nanoindentation techniques is beyond the scope of the present section). In the case of microindentation, this is certainly unnecessary today with proper mechanical preparation methods. Preparation of specimens for replica work requires a proper metallographic preparation procedure, but this can be done mechanically. Preparation of TEM thin foils normally employs jet-electropolishing (or similar alternative procedures) to perforate the specimen. But, this is the final step after initial mechanical grinding. Electropolishing does have certain advantages, but also disadvantages. It is best for single phase metals, particularly for relatively pure metals. In alloys containing two or more phases, the rate of electropolishing varies for each phase and flat surfaces may be difficult to obtain. Even for single phase metals, the surface is often wavy rather than flat which makes high magnification examination difficult or impossible. Electropolishing solutions are often quite aggressive chemically, and may be dangerous, even potentially explosive under certain operating conditions, or under careless operating procedures.

The most frequent problems are: failure to completely remove the distorted metal produced at the original cut surface; alteration of the structure by overheating the specimen; contamination of the succeeding steps by carrying abrasives over, due to poor cleaning practices, from a coarse stage of polishing, to a finer one; and, the development of false structures by staining through faulty drying after etching or bleed out from shrinkage gaps between the specimen and mounting material. Preparation of an unfamiliar material should be guided by checking the progress of the grinding and polishing steps during the preparation sequence to determine if the scratches from the previous step have been removed and to detect any problems, such as pull out, drag, embedding, and so forth. After the preparation has been completed, through to about a 1 μm abrasive size, the specimen can be etched (or examined with polarised light if it is an optically anisotropic metal) to examine the development of the structure. This will aid the metallographer in determining if the preparation sequence has been adequate. Hard metals and ceramics or sintered carbides can often be adequately examined after preparing down to only a 1 μm finish, although going to a finer abrasive size will yield improved results.

Many metals and alloys can be prepared with essentially the same procedure with more than adequate results. However, there are many metals and alloys, and non-metallic materials, that do require quite different preparation approaches. These will be described in the text where appropriate. Etching, however, is quite specific to the metal under examination and the feature of the structure to be investigated. There are no truly universal etchants, although a few have wide applicability. However, because of the specific corrosion aspects of different metals and alloys, it is unlikely that any universal etch would produce optimal results for more than a very limited range of compositions.

MOUNTING

Specimens that are of irregular shape, or are fragile or small in size are best encapsulated or 'mounted' in polymeric materials. Several specimens, if of similar materials, may be prepared in the same mount, with a saving of time, although etching may become a problem. In general, it is best to prepare as small a specimen as feasible, for example a 100 mm^2 square area is ideal. With the introduction of

automated equipment, specimen sizes have gradually become larger due to the ease of preparation compared to manual preparation. To obtain flatness out to the extreme edge, e.g., for examination of platings, coatings and other surface treatments, mounting is required. The preparation process can be optimised for obtaining good edge retention ('edge preservation'). Compression mounting resins, particularly thermosetting resins, yield best results. A modern press that cools the specimen automatically to near ambient temperature after polymerisation has been completed, yields much better results than the former 'hot ejection' method because shrinkage gaps are reduced. If a shrinkage gap is formed between specimen and mounting compound, a 'free edge' exists and it will become bevelled by abrasives getting into the gap. This is one reason why a protective plating, such as electroless nickel, is effective in providing good edge retention. Modern automated polishing devices yield better edge retention than manual polishing. Rigid grinding discs used with coarse diamond abrasives and hard, woven, napless clothes for the subsequent polishing steps, yield much better flatness than the older clothes, such as canvas, felt or billiard cloth.

Modern mounting presses have the heating elements and cooling channels built in so that one no longer needs to remove the heating element from around the mould cylinder after the polymerisation cycle has been completed (thermosetting resin) or after the resin melts (thermoplastic resin) and place copper chill blocks around the cylinder, required for a thermoplastic resin, for cooling the polymer to below 70°C under pressure. These presses were introduced in the mid 1970s, chiefly to facilitate moulding of thermoplastic resins. It was not until the 1990s that metallographers realised that cooling a thermosetting mount, already polymerised, towards ambient temperature under pressure helped reduce shrinkage gap formation which greatly improved edge retention.

To mount a specimen, the specimen is placed on the lower ram which is lowered into the cylinder about 25 mm (1 inch). The desired powdered resin (see Table 10.2) is added to a depth of at least 25–37 mm (1–1.5 inches). The ram is lowered all the way to the bottom and the top ram is placed into the cylinder hole and pushed downward and locked in place. The press is then turned on. Modern presses recognise the mould size (25, 30, 40 or 50 mm or 1, 1.25, 1.5 or 2 inches in diameter) and are set to the required pressure and temperature for either thermosetting or thermoplastic resins. Further, many can be set to have a pre-heat cycle where the temperature is brought up to the set point without applied pressure. This is helpful for more delicate specimens that might be folded over of bent by the initial application of pressure. The cooling cycle is controlled by either setting a cooling time, or a desired final temperature. Upon reaching this time or temperature, the cooling will be stopped, a bell rings, and the press is turned off automatically.

It is essential to verify that the structure of the metal will not be materially affected by any heat and pressure applied in forming the mount. In cases where the temperature of moulding, typically

Table 10.2   PLASTICS USED FOR MOUNTING

Plastics	Type	Remarks
Phenolic	Thermosetting	Needs controlled heat and pressure. Sufficiently inert to most solvents. Normal grades good for general work but have high shrinkage; mineral-filled type preferable for edge sections. If curing insufficient, e.g., too low a temperature, the mount is soft and is attacked by acetone. Badly degraded by high temperature etchants. Least expensive thermosetting resin.
Epoxy resin	Thermosetting	Cures under heat and pressure yielding excellent mounts with superior edge retention and resistance to solvents and boiling reagents. Good polishing characteristics, low shrinkage.
Diallyl phthalate	Thermosetting	Needs controlled heat (130–140°C) and pressure. Low shrinkage, good polishing characteristics.[3] Expensive resin, provides only marginal improvement over phenolics.
Methyl methacrylate	Thermoplastic*	Needs controlled heat and pressure. Gives clear mount. Attacked by acetone. Rather soft. High shrinkage.
Acrylic resins	'Cold' setting	Mix resin and hardener; cures very quickly (<10 min.). Cheap but poor edge retention. High shrinkage.
Polyester	'Cold' setting	Several ingredients to be mixed for each batch. Not used commonly today. Inert to usual solvents.
Epoxy resins	'Cold' setting	Liquid resin and hardener are mixed; gives good mounts without heat or pressure. Inert to usual solvents, although the surface can become sticky in alcohol.

* Must be cooled under pressure to low temperature to solidify before ejection.

about 150°C, cannot be tolerated (e.g., low-melting point metals and alloys, alloys where aging will occur, etc.), the so called 'cold' mounting resins are used. It must be pointed out that obtaining a very low exotherm (from the heat of polymerisation) is not automatic when using these resins. Acrylic resins are used widely because they are very inexpensive and they cure very quickly, usually in 5–8 minutes. However, they can generate considerable heat during polymerisation, enough to burn the metallographer's hand. Polyester materials are not utilised much in metallography. Cast epoxy resins are quite popular due to several characteristics, although they are relatively expensive and do have a shelf life of about a year. The shelf life can be improved by storing resin and hardener in a refrigerator (but do not freeze the resin or hardener). It is best to buy only a quantity that is expected to be used in about six months. The epoxy resin and hardener are mixed, usually on a weight basis (more accurate than by volume), stirred gently for about a minute, then poured into a mould in which the specimen resides face down. Moulds can be made of plastic, phenolic ring forms, silicone rubber, glass or metal. The phenolic ring forms are usually allowed to adhere to the polymer, while the others are coated with a mould release agent and removed after the mount cures. Low viscosity epoxy can be drawn into cracks and voids in specimens under vacuum. This greatly facilitates specimen preparation as the voids are supported by the epoxy and liquids cannot enter the openings and bleed out later.

Some plastics used for encapsulation, and their characteristics, are listed in Table 10.2.

Thermoplastics, such as methyl methacrylate, and thermosetting resins, such as phenolic, are convenient for routine work because they are available as powders immediately ready for use, but they require a press, and normally only one size of cylindrical mould may be available. On some presses, it is rather simple to change moulds, while on others it may take more time and effort. Cold-setting resins may be formed simply in a container consisting of a short piece of tube standing on a glass plate, and are therefore suitable for occasional use and odd shapes and sizes.

To examine a surface edge on a cross section, use the best mounting compound (thermosetting epoxy containing a filler, e.g., Epomet® resin). The edge can be protected by plating (e.g., with copper or electroless nickel) or, if that is not possible, by applying an evaporated coating before mounting. Mount specimens with a press that incorporates water cooling after the polymerisation cycle to minimise or eliminate shrinkage gaps between specimen and mount. If a 'cold' mounting compound must be used, use epoxy, never an acrylic or a polyester. Use a slow curing epoxy, rather than a fast curing epoxy. Soft (about 750–800 HV) ceramic shot ('flat-edge filler' shot) can be added to the epoxy at the polishing face to reduce shrinkage and help support the edge. Hard ceramic shot, such as made from alumina, is incompatible in grinding and polishing characteristics with metals and should be avoided. Use automated grinding/polishing equipment with central force loading, use 'hard' napless cloths or pads or rigid grinding discs (usually with coarse diamond abrasive sizes), and use proper loads and times. Do not use napped cloths, especially with diamond abrasive, except in the final step with a very fine abrasive.

Conductive mounting resins have also been developed to simplify electrolytic polishing and etching and for SEM or EMPA work. Copper-filled resins have been used for some time, although they are rather expensive. For example, Probemet™ conductive resin consists of very fine thermosetting epoxy with a silica filler mixed about equally with very fine copper flake. Flake shaped particles are better for conductivity than spherical particles. This resin, besides exhibiting zero resistance between specimen and mount, also yields excellent edge retention. Carbon-filled phenolic resins provide a lower-cost alternative, but are not as conductive and do not provide as good edge retention. Conductive nickel flake can be added to cast resins, such as epoxy, for conductivity.

GRINDING

Silicon carbide abrasive bonded to waterproof paper is used commonly for grinding. Silicon carbide paper is preferred over emery paper because SiC is harder, has sharper particles and cuts at a faster rate. The simplest technique, used generally only by students, employs rolled strips about 50 mm wide where a portion is unrolled and laid flat on a hard, tilted surface and held mechanically along the edges. Water is run onto the top end of the paper to wet the surface. The specimen is rubbed up and down on the paper strip. Simple devices exist to hold four or five rolls of graded paper, for example, 120 (P120), 240 (P280), 320 (P400), 400 (P800) and 600 (P1200) grit sizes. Usually, grinding begins with the coarsest grit, and the specimen is rubbed until all traces from cutting are removed. Then, turn the specimen 45–90° and rub the specimen with the next finer grit until the first set of scratches are removed. Repeat at least once, because the depth of the deformed layer is several times the depth of the residual scratches. Then, progress to the next finer paper or cloth, turning the specimen through 45–90°, and again rub until the previous scratches are removed, then to the next finer paper similarly, until grade 600 silicon carbide paper is reached. Some soft metals are prone

to embedding problems, that is, the finer SiC particle sizes will break off the paper and become embedded in the alloy surface. This is a particular problem with the low melting point alloys of lead, tin, bismuth and cadmium. To counter this tendency, wax can be rubbed onto the paper surface before grinding. Candle wax appears to be better for embedding prevention than bee's wax.

A more suitable grinding practice is to use round SiC paper discs attached to a platen, usually made from aluminium. Copper-based alloys have been used in the past, but they are more expensive and are unsuitable when attack polishing agents are used in the polishing stage. The discs can be applied to the platen using a pressure-sensitive adhesive (psa) backing.* This is an excellent practice as the disc will not move under the applied force during grinding. The other main alternative is to use plain-backed SiC paper discs. Water is placed on the platen surface. The disc is placed over the wet platen and a hold down ring is placed around the periphery of the platen. The motor-driven platen is turned on and set to 240–300 rpm, in most cases. When the specimen is forced against the SiC disc, the disc stalls for a few seconds until suction builds up and holds the disc against the platen. This method is satisfactory for manual polishing but has some disadvantages in automated polishing. With an automated specimen holder, the holder must be positioned over the platen so that its periphery does not strike the hold down ring. This restricts grinding out to the edge and prevents the user from setting up the head position so that it cannot sweep slightly over the edge of the SiC paper on the platen. This type of hold down system generally eliminates use of smaller diameter platen formats, e.g., an 200 mm (8 inch) diameter platen system cannot be effectively used as the holder must be made smaller than 100 mm (4 inch) diameter, so that grinding and polishing can be performed inside the hold down ring without crossing the centre of the platen (when that happens, differential grinding and polishing results and specimens are not flat). If the holder must be <100 mm (4 inch) in diameter, it cannot hold many specimens and the specimen diameters must be quite small. Thus, the metallographer must choose a larger diameter platen system where the cost of consumables is higher.

For very hard metals, sintered carbides and ceramics, diamond hones[4] and laps[5] have been used for grinding, although today different products are more common. The original metal-bonded diamond discs used a metal plate over which diamond of a specific size was spread and was held in place with electroless nickel. While these discs would provide effective cutting, they could not be used manually as the surface tension between specimen and disc was so great that the specimen could not be hand held. These discs were largely unsuitable for metals, except the very hardest, but they worked adequately for sintered carbides and ceramics. Lapping discs became popular for a period and they work well as long as the surface remains flat. Their use requires a careful adjustment of the specimen holder so that the entire lap surface is in contact with the specimens. In the majority of cases, diamond slurries or suspensions were used. Procedures using one or two 'lapping' stages were developed. It must be stated that these lapping platens were not actually lapping in the true sense of the word. Lapping implies that the abrasive is free to roll between the lap surface and the sample surface. But, with these laps, the abrasive would become embedded in the lap surface soon after being sprayed onto the platen. Hence, cutting resulted rather than true lapping (lapped surfaces appear to be 'hammered' by the abrasive, that is, the surface is made flat and specular more by deformation than by cutting, and this is not desired as the true microstructure will not be observed).

In recent years, the rigid grinding disc (RGD) has been introduced. These are basically quite similar to the former laps that were popular from about 1975–1990, except that they are thinner and some extra relief has been introduced to reduce surface tension. The RGD costs less to produce and, because it is thin, usually wears out before it becomes too non-planar to use. One disc style incorporates round spots of epoxy containing fine particles of Fe and Cu with a fair amount of the disc surface not covered by the spots. This reduces the surface tension (specimens can be easily held manually using this disc) while actually providing a higher removal rate than a similar disc with greater surface coverage. Such a disc is used for rough polishing with diamond abrasive and sizes from 45 to 3 μm have been used on specimens with a hardness of about 150 HV or higher. Although sheet metal specimens softer than this have been successfully prepared using a RGD in the practice, and their hardness is well below 150 HV, some deformation may persist when somewhat harder solution annealed stainless steel or nickel-based superalloys are prepared. While titanium alloys can be prepared with such a disc, commercial purity titanium cannot, unless extra steps are taken to remove the damage. Consequently, a second disc was developed using a different epoxy and the filler is fine particles of tin, much softer than Fe and Cu. This disc is less aggressive than the previous disc and can prepare softer metals, but is still useful for very hard metals, sintered carbides and ceramics. The RGD can be used to replace the rough grinding step with SiC, or after the initial grinding step with SiC abrasive, or for the first and second steps. Specimens prepared using RGDs in one or more steps are noted for exceptional flatness and edge retention. However,

---

 * Magnetic platens are also available and allow rapid exchange of the grinding/polishing disc.

the scratch pattern produced using diamond of a specific size with a RGD is more pronounced than when the same diamond is used on a hard, woven cloth or a chemotextile pad. The latter are less aggressive in removal rate than the RGD. There are other alternatives to grinding with SiC papers. Alumina abrasive can be obtained on waterproof backings, such as paper or Mylar. Alumina is a better abrasive for Fe-based metals than SiC, but these papers are less readily available and more expensive. Alumina is slightly softer than SiC (about 2000 versus 2200 HV, respectively), but is more than hard enough to grind any steel. Alumina is also tougher and less prone to embed in soft metals, such as Pb, Sn, Bi or Cd.

MECHANICAL POLISHING

Mechanical polishing is often done in two stages, with coarse and fine abrasives (one or more of each may be used). The division between coarse and fine is somewhat arbitrary, but is usually at 3 µm. The coarse polishing stage is carried out at 150 rpm, or less, and uses a napless cloth such as selected silk, nylon, polyester or a synthetic chemotextile pad. Napped cloths should not be used, except in the final step, as they promote poor edge retention, relief at constituents and problems such as pull-out or drag and smearing. Napped cloths, such as canvas, felt, synthetic suede and others, were used with coarse and fine diamond abrasives for both rough and fine polishing, but in more recent years they have been shown to be poor for all but the final step. In coarse polishing, the cloth is charged with an abrasive, chiefly diamond (except for those metals where diamond is not very effective). The author of this section prefers to charge a cloth with diamond paste first. The amount added must be sufficient to obtain good cutting; many people add far too little diamond. Turn the platen on (with the cloth attached using a psa backing, not stretched, as it will be easily ripped using an automated specimen holder) to a speed of 120–150 rpm. Hold the diamond syringe against the centre of the cloth and press on the applicator to squeeze diamond paste out of the tube onto the centre of the cloth. Then, while pressing on the syringe, pull the tip towards the periphery of the cloth, while 'laying' a concentric track of diamond paste. Turn off the platen. Take the tip of the index finger (which must be clean) and spread the diamond over the cloth surface. Then, squirt on some of the lubricant, that is compatible with the diamond carrier paste, and start polishing. This gets the cutting action started quickly. If, on the other hand, a fresh cloth is charged with a liquid diamond slurry or suspension of the same particle size, the cutting rate will be much lower until the diamond particles become embedded in the cloth and start cutting. If the polishing step is more than a minute or two, add some slurry or suspension to the cloth periodically during the cycle to keep the cutting rate high. The cloth must be kept moist during polishing. If a slurry or suspension is not added during the cycle (these have the lubricant built in), then the lubricant must be added periodically. If the cloth gets too dry, smear, drag and pull-outs may result. If it gets too wet, the cutting rate can drop due to hydroplaning effects, but this does not damage the structure.

Fine polishing is carried out with abrasives smaller than 3 µm in diameter and includes diamond, alumina and amorphous colloidal silica, plus some proprietary blends. MgO, used formerly to final polish Al and Mg alloys is employed rarely today, as it is very difficult to use. MgO is available usually only down to a 1 µm size and getting really good quality MgO for polishing is difficult. Further, magnesium carbonates will form in the cloth after use, which ruins the cloth, unless the cloth is soaked in a dilute HCl solution, which is quite inconvenient. Iron oxides and chromium oxides have been used occasionally in metallography, but they have little overall value. Cerium oxide has been used to polish glass but has little value with metals. Polishing is conducted at a lower rotational speed (80–150 rpm) than for grinding using medium or low-nap cloths, such as synthetic suede bonded to a waterproof backing, or with napless polyurethane pads. The polishing agent should have a cutting action but it may produce a 'flowed' layer on the surface or both. The author of this section has made Laue patterns of coarse grained specimens and seen the sharpness of the diffraction spots decrease after final polishing with alumina slurries, indicating that some smearing is occurring. Because of this, it is common practice to etch the specimen after final polishing. If the final step is repeated, the re-etched structure will appear to be sharper and crisper in detail due to removal of the smeared metal. As an alternative, the specimen can be given a final polish using a vibratory polisher with the same cloth and abrasive as used for the final step. As little as 20 minutes is required with this device. Vibratory polishing is noted for producing excellent, deformation-free surfaces without sacrificing edge retention and relief control. However, if carried out too long, relief will be observed.

Some metals or coatings are readily stained or corroded in the presence of water, and for these a non-aqueous polishing mixture is preferred. Diamond abrasives suspended in oil are available and are effective, but cleaning is more difficult. Oil-based diamond is very effective as the oil is a fine lubricant. Final polishing can be performed with alumina powder suspended in alcohol, purified kerosene or mineral spirits. Again, cleaning is more difficult than with water-based products. A few

proprietary abrasive suspensions are available that have a low water content and appear to work satisfactorily with magnesium alloys where water-based products are best avoided, at least in the final step. Galvanised steel and cadmium-plated steels cannot be final polished with aqueous suspensions. If they are, the coating is attacked heavily. Non-aqueous abrasives must be used in the final step, perhaps with some loss of fine scratch control. Some specimens are prone to staining around inclusions, such as sulphides. In this case, the use of distilled water, rather than tap water, helps to avoid staining. Also, water temperature may be important. Hot water is more reactive than cooler water.

Colloidal silica containing amorphous, spherical silica particles in a basic suspension (pH of 9.5 to 10, usually), has become a very popular final polishing abrasive and has replaced MgO as the final polish for aluminium and its alloys. Because the particles are nearly spherical, its action is more chemical than mechanical and measurements of its removal rate reveal very low values. However, it does often produce the best final polished surfaces. Its use is not without problems. If the cloth is allowed to dry out, the silica becomes crystalline and the cloth is ruined. So, after use, the cloth must be cleaned carefully. Also, specimen surfaces can be more difficult to clean as the colloid contains ions, such as sodium ions. A whitish smut may be seen on the surface when the specimen is not cleaned carefully. This will make etching a disaster. To counter these problems, when using an automated system, stop adding colloidal silica with about 20 s left in the polishing step. With 10 s left, direct the water jet onto the platen surface. This will wash off the cloth and clean the specimen simultaneously. Then, the specimens can be rinsed under running water, wet with ethanol, and blow dried under warm air without retaining the surface smut. A similar approach can be used for manual work.

Metallographers may notice that etch response can be different when using colloidal silica. This can be good or bad. Colour etchants used with Cu-based alloys generally show softer, more pastel-like colours after using colloidal silica and more gaudy, harsher colours after using standard alumina suspensions. Experiments with specimens such as Fe–Ni alloys reveals a change in etch nature with repeated use of colloidal silica. For example, an Fe—36% Ni specimen was prepared and etched with Marble's reagent after final polishing with colloidal silica. The specimen exhibited a grain-contrast etch appearance, that is, light and dark grain twin areas. With repeated final polishing steps and re-etching, the grain contrast appearance changed to a flat, grain boundary/twin boundary etch. This switch has been observed with other metals. Detrimental effects of colloidal silica can be obtained using austenitic stainless steels or duplex stainless steels. After final polishing, etchants such as glyceregia or Vilella's reagent may be used and the etch response is generally rather slow. However, sometimes after final polishing with colloidal silica, etching is extremely rapid. As soon as the cotton swab touches the surface, it darkens. This effect is called 'flashing' by metallographers. Examination of the surface reveals a heavily crazed scratch pattern and the scratches are far too deep to remove with the final polishing agent. Instead, the specimen must be completely reprepared. This appears to be due to surface passivation, probably by the ions in the colloidal silica adhering to the polished stainless steel surface. Flashing never occurs when electrolytic etching is performed. A properly electrolytically etched surface can then be etched with glyceregia or Kalling's No. 2 reagent, for example, and it may flash. Flashing appears to be most common in etchants that contain Cl^- ions and careful cleaning appears to reduce its occurrence. To prevent this problem, the author of this section uses a two-step final polishing procedure. A timer is set for 3 minutes. Polishing begins with colloidal silica. After about 90 s, direct a water jet onto the cloth and flush off most of the colloidal silica; then add alumina. The present author has used a special 0.05 μm alumina suspension made by the sol-gel process (called Masterprep™ alumina). Unlike calcined aluminas, it is totally free of agglomerates. Polishing continues until about 10 s remaining. At this point, direct the water jet onto the cloth and wash both the cloth and the specimens before the platen stops. Then, etching can be conducted without flashing and the benefits of both polishing agents are obtained.

Over the years a generic preparation practice was developed that is commonly called the 'traditional method' today. It consists of the following steps and can be performed manually or with automated grinder/polisher units:

The 'Traditional Method'

1. Grind with waterproof SiC abrasive paper starting with 120 grit (P120) paper, water cooled, 240–300 rpm, 25 or 30 N (6 lb) pressure/specimen until the cutting damage is removed and all specimens in the holder are at the same plane.
2. Grind with 220 or 240 grit (P240 or P280) SiC paper, as in step 1, for 1 minute.
3. Grind with 320 grit (P400) SiC paper, as in step 2.
4. Grind with 400 grit (P800) SiC paper, as in step 2.
5. Grind with 600 grit (P1200) SiC paper, as in step 2.
6. Rough polish with 6 μm diamond paste on canvas, 150 rpm, 25 or 30 N (6 lb) per specimen, for 2 minutes. Use complementary motion with an automated device but contrarotation with manual work. Some people used 3 μm diamond rather than 6 μm, and others used nylon cloths.

7. Fine polish with 1 μm diamond paste on felt or billiard cloth, as in step 6. This step is not used by all metallographers.
8. Fine polish with 0.3 μm α-alumina aqueous slurry on a synthetic suede cloth at 150 rpm, 25–30 N (6 lbf) load per specimen, for 2 minutes. Head/platen directions as in step 6. This was often an optional step if 7 was used.
9. Fine polish with 0.05 μm γ-alumina aqueous slurry, as in step 8.

In this method, complementary means that the head and platen are both rotating in the counter clockwise direction while contra means that the head and platen rotate in opposite directions. Complementary rotation cannot be done manually. This method works reasonably well for many materials, but not all. It is slow because of the many steps. It is not adequate for edge retention and may lead to excessive relief. As a result, 'contemporary' preparation methods are largely replacing the traditional method, because they are more efficient and yield better control of flatness.

The following is a generic example of a contemporary preparation practice. It requires use of a good laboratory sectioning machine with the proper wheel to minimise cutting damage.

The 'Contemporary Preparation Method'

1. Grind with waterproof SiC paper as fine as possible, usually 180, 220, 240 or 320 grit (P180, P240, P280, or P400), at 240–300 rpm, 25–30 N (6 lbf) load per specimen with water cooling, until the cutting damage is removed and the specimens are at the same plane.
2. Rough polish with 9 μm polycrystalline diamond on a psa-backed selected silk cloth (e.g., an Ultra-Pol™ cloth) at 150 rpm, 25–30 N (6 lbf) per specimen, complementary or contrarotation, for 5 min.
3. Rough polish with 3 μm polycrystalline diamond on a psa-backed chemotextile pad (e.g., a Texmet® 1000 pad), as in step 2, but for 4 min.
4. Fine polish with 1 μm polycrystalline diamond on a psa-backed polyester woven cloth (e.g., a Trident™ cloth), as in step 2, but for 3 min. This is often an optional step but is used for more difficult specimens.
5. Fine polish with 0.05 μm colloidal silica or sol-gel alumina (Masterprep™ alumina) slurries, on a synthetic suede (rayon) cloth (e.g., a Microcloth® pad) or a polyurethane pad (e.g., a Chemomet® pad), as in step 2, but for 2–3 min. Contrarotation is preferred for this step (see note in the next paragraph about head speed).

Choice of the final polishing solution in step 5 is often a matter of personal preference, although there are some materials that are not prepared properly with colloidal silica (Mg alloys tend to be etched, precious metals are not affected, even if an attack polish agent is added; pearlitic cast irons often have small etch spots; and, austenitic stainless steels and Ni-base superalloys may 'flash' when etched, as discussed above). Contrarotation should not be used when the head speed is >100 rpm, as the abrasive will be thrown off the wheel and will hit the metallographer and walls. If the head speed is 60 rpm or less, the abrasive stays nicely on the work surface. Contra is slightly more aggressive than complementary rotation.

Variations can be made to the contemporary method in each step depending upon personal preferences and what is available for use. Several alternatives, mentioned above, exist for the first step using SiC. Rigid grinding discs can be substituted for either step one or two. For some materials, it is possible to use as little as three steps with excellent results. These modifications are discussed when dealing with the individual metals and alloys.

After polishing by any method, the specimen must be thoroughly washed and dried. It is best to etch immediately after polishing, particularly for those metals and alloys that form a tight oxide (or other film) on the surface with air exposure, for example, Al, Cr, Nb, Ni, stainless steels, Ti and some precious metals. After the specimen is washed under running water, it may be necessary to scrub the surface carefully with cotton soaked in a soapy solution. A mild dish washing detergent can often be used, or a proprietary detergent such as liquid alconox. Then, wash again with clean running water, rinse with ethanol to displace the water, and dry with a blast of hot air. If the etch contains HF, it is best to rinse the surface in a neutralising bath to remove any adherent HF that might damage the microscope optics (see ASTM E 407).

Attack polishing is a method of improving polishing action by the addition of a dilute etching agent to the abrasive suspension. For instance, ammonia may be used with advantage on the pad in polishing copper alloys. Hydrogen peroxide (30% conc.) is useful for refractory metals and precious metals to improve metal removal. Not only is the damaged layer at the surface removed more effectively, but also scratch control in these metals is enhanced over final polishing with the same abrasive without the added chemical attack. Table 10.3 gives reagents for use with various metals by this method. Several solutions have also been proposed for magnesium alloys.[6] Attack polishing is often performed using polyurethane pads or with synthetic suede cloths (the latter do not hold up as well, however).

Table 10.3   ATTACK POLISHING CONDITIONS FOR VARIOUS METALS AND ALLOYS

See general safety note at the start of this Chapter.

Material	Solution*		Time (min)	Remarks
Uranium	CrO_3 H_2O HNO_3 (1.40)	50 g 100 ml 100 ml	20–30	Medium contrast under polarised light, no pitting, good resistance to oxidation
Zirconium	HNO_3 (1.40) Glycerol	50 ml 150 ml	1–10	Good contrast under polarised light. Slight grain relief
Bismuth	HNO_3 (1.40) Glycerol	50 ml 150 ml	3–5	Good contrast under polarised light. Requires less pressure than usual
Chromium	Oxalic acid H_2O	15 g 150 ml	5–10	Bright polish revealing oxides, etc.
Molybdenum and tungsten	Pot. Ferricyanide Sodium hydroxide Water	3.5 g 1 g 300 ml		

* Acids are concentrated, unless otherwise indicated, e.g., with specific gravity.

ELECTROLYTIC POLISHING

Extensive reviews have been given by Jacquet,[7] Tegart,[8] Petzow[1] and Vander Voort[2] which may be consulted for individual references (see also ASTM E 1558). A comparison with mechanical methods has been made by Samuels.[9]

The specimen is made the anode in a suitable solution, and conditions are adjusted so that the hills on the surface are dissolved much more rapidly than the valleys. When enough metal has been removed a smooth surface is obtained. The condition for polishing often corresponds to a nearly flat (i.e., constant current) region in the curve for cell current versus voltage. As the voltage is increased (see Figure 10.1), etching (AB) is replaced by film formation (BC). The voltage then increases and the current falls slightly as the film disappears and polishing conditions are established (CD). At higher voltages, gas evolution occurs with pitting. Near E gas evolution is rapid and polishing continues but the region just below D is preferred. By reducing the voltage to below B, the specimen

can be etched in the same operation. For many specimens, electropolishing leads to a great saving in time, and it reliably produces surfaces free from strain provided sufficient metal is removed in the process. It tends to exaggerate porosity and is unsuitable for highly porous specimens. Inclusions are often removed, though not invariably, and their place taken by severe pits. Many two-phase and complex alloys, however, can be successfully polished.

Apparatus. To cover the widest range of applications, a d.c. supply of 4–5 A at voltages variable up to at least 60 V is required, but some solutions require only 2 V. Accurate voltage regulation is essential, and a rectifier set fed from a variac, a tapped battery or a potentiometer circuit across a constant d.c. source is recommended. Published recommendations for particular solutions sometimes state the voltage, and sometimes the current density, required. It is preferable to work on voltage, as the current density for a given electrode condition is much affected by temperature and other variables. If both are stated, but cannot be simultaneously obtained, the solution is probably wrong; if it is not, the current density should be disregarded. Two general cell arrangements are used: with electrodes in a beaker of still or gently stirred solution and with flowing or pumped electrolyte.[10–12] The first arrangement is easily set up and often suffices; the second is more powerful but requires more complicated apparatus (obtainable commercially, however). The characteristics are quite different: with flowing electrolyte a good polish may be obtained with more strongly conducting solutions, and hence with higher current densities, and it is therefore frequently possible to remove more metal in polishing and to start with a more roughly prepared surface. A small area of an article may be electropolished by the use of electrolyte flowing from a vertical jet above the article, the jet itself containing a projecting wire to act as cathode.[12] In suitable conditions, polishing of an area already ground with SiC paper may be completed in 3–10 s. Apparatus for this method is also available commercially.

Jacquet has described a device (the 'Ellapol') in which an electrolyte is applied to the surface by a small swab surrounding the cathode. The device can conveniently be used to polish a small area of a large component *in situ* (*see* e.g., refs. 13–15).

Solutions for electropolishing particular metals are listed in Table 10.4 [*see also* refs. 1, 2, 7, 8 and ASTM E 1558]. Table 10.4 is not a complete list, but should cover most requirements. Minor differences between solutions are often a consequence of the cell used. The most widely useful solutions are methanol—nitric acid mixtures, strong solutions of phosphoric acid and mixtures of perchloric acid with alcohol, acetic acid or acetic anhydride. Mixtures of perchloric acid with acetic anhydride, although frequently the best polishing agents, can be explosive and should be avoided. Electrolytes containing perchloric acid must be kept cold in use; plastics (especially cellulose) and bismuth must be kept away from them, as they may cause explosions, and they must not be stored in the laboratory as they are liable to explode without apparent reason. Note that the safe use of perchloric acid requires a dedicated fume hood, designed specifically for perchloric acid work, with an uninterrupted vertical stack and a stack wash down system. Quantities larger than a few hundred millilitres should not be used, in order to minimise the effects of an explosion, if one was to occur. The limits of the dangerous mixtures, according to Jacquet, the originator,[7,16] are indicated in Figure 10.2. Perchloric acid must always be added to the acetic anhydride-water mixture to avoid compositions in the detonation zone. Explosions outside the danger zone in this diagram have occurred. Consequently, the use of perchloric acid-acetic anhydride based electrolytes should be avoided (their use is forbidden by law in some locations). Safe operating practices in the metallography laboratory is a complex subject. In general, the metallography laboratory is a reasonably safe place, when well managed, but problems can occur, particularly in 'open' laboratories and at schools, where the personnel may not be as well versed in safe operating practices. It is impossible to list all possible safety issues in any text, as no one can envision all of the potential mis-uses that humans can create. Each laboratory must develop a comprehensive safety program based upon the materials that they use, their equipment, their particular circumstances and relevant regulatory requirements. The basic aspects of safe metallographic practices are given in references 2, 17, 18 and ASTM E 2014.

Because of the considerable number of solutions published in the literature, a selection has been made on the basis of (a) wide usage, (b) simplicity of composition, and (c) least danger. Temperatures should be in the range 15–35°C (or below). Cooling should be used to avoid temperatures above 35°C unless stated otherwise.

CHEMICAL POLISHING

Chemical polishing is adopted usually as a quick method of obtaining a passable result, rather than as a method of preparing a perfect surface. However, where it is difficult to prepare a deformation-free surface by other means, as with some very soft metals or where other difficulties are encountered, it may provide the best method of preliminary or final preparation. Chemical polishing of refractory

Table 10.4a   ELECTROLYTIC POLISHING SOLUTIONS FOR VARIOUS METALS AND ALLOYS

See general safety note at the start of this Chapter. Because of the considerable number of solutions published in the literature, a selection has been made on the basis of (a) wide usage, (b) simplicity of composition, and (c) least danger. Temperatures should be in the range 15–35°C (or below). Cooling should be used to avoid temperatures above 35°C unless stated otherwise.

	Composition of solution		Usage	Cell voltage	Time	Cathode
1	Ethanol	800 ml	Al alloys (not Al–Si)	30–80	15–60 s	Stainless steel

‡ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

§ A specially designed, dedicated fume hood, with a vertical stack and a wash down system is required for perchloric acid. Note that some solutions containing perchloric acid present grave explosion hazards and there are restrictions on the use of these solutions in some locations.

metals is often performed after mechanical polishing to improve polarised light response (e.g., for Zr, Hf), or to remove minor deformation (e.g., Nb, Ta, V).

In general, a ground specimen is immersed in the polishing agent, or swabbed with the solution, until a polish is obtained, and it is then etched or washed and dried, as appropriate. Reagents are listed in Table 10.5.

Table 10.5   REAGENTS FOR CHEMICAL POLISHING[1,2,8,19]

Metal	Reagent*		Time	Temp. (°C)	Remarks
Aluminium and alloys	Sulphuric acid (1.84) Orthophosphoric acid Nitric acid	25 ml 70 ml 5 ml	30 s–2 min	85	Very useful for studying alloys containing intermetallic compounds, e.g., Al–Cu, Al–Fe and Al–Si alloys
Beryllium	Sulphuric acid (1.84) Orthophosphoric acid (1.75) Chromic acid Water	1 ml 14 ml 20 g 100 ml	Several min	49–50	Rate of metal removal is approx. $1\,\mu\mathrm{m\,min}^{-1}$. Passive film formed may be removed by immersion for 15–30 s in 10% sulphuric acid
Cadmium	Nitric acid (1.4) Water	75 ml 25 ml	5–10 s	20	Cycles of dipping for a few seconds, followed immediately by washing in a rapid stream of water are used until a bright surface is obtained
Copper	Nitric acid Orthophosphoric acid Glacial acetic acid	33 ml 33 ml 33 ml	1–2 min	60–70	Finish is better when copper oxide is absent
Copper alloys	Nitric acid Hydrochloric acid Orthophosphoric acid Glacial acetic acid	30 ml 10 ml 10 ml 50 ml	1–2 min	70–80	Specimen should be agitated
Copper–zinc alloys	Nitric acid (1.40) Water	80 ml 20 ml	5 s	40	Use periods of 5 s immersion followed immediately by washing in a rapid stream of water. Slight variations in composition are needed for α–β and β–γ brasses to prevent differential attack. With β–γ alloys, a dull film forms and this can be removed by immersion in a saturated solution of chromic acid in fuming nitric acid for a few seconds followed by washing
Germanium	Hydrofluoric acid‡ Nitric acid Glacial acetic acid	15 ml 25 ml 15 ml	5–10 s	20	—
Hafnium	Nitric acid Water Hydrofluoric acid‡	45 ml 45 ml 8–10 ml	5–10 s	20	As for zirconium
Iron	Nitric acid Hydrofluoric acid (40%)‡ Water	3 ml 7 ml 30 ml	2–3 min	60–70	Dense brown viscous layer forms on surface; layer is soluble in solution. Low carbon steels can also be polished, but the cementite is attacked preferentially
Irons and steels	Distilled water Oxalic acid (100 gl^{-1}) Hydrogen peroxide (30%)	80 ml 28 ml 4 ml	15 min	35	The solution must be prepared freshly before use. Careful washing is necessary before treatment. A microstructure is obtained similar to that produced by mechanical polishing, followed by etching with nital

Table 10.5   REAGENTS FOR CHEMICAL POLISHING[1,2,8,19]—*continued*

Metal	Reagent*		Time	Temp. (°C)	Remarks
Lead	Hydrogen peroxide (30%)	80 ml	Periods of 5–10 s	20	Use Russell's reagent (Table 10.1) to check that any flowed layer has been removed before final polishing in this reagent
	Glacial acetic acid	80 ml			
Magnesium	Fuming nitric acid	75 ml	Periods of 3 s	20	The reaction reaches almost explosive violence after about a minute, but if allowed to continue it ceases after several minutes, leaving a polished surface ready for examination. Specimen should be washed immediately after removal from solution
	Water	25 ml			
Nickel	Nitric acid (1.40)	30 ml	½–1 min	85–95	This solution gives a very good polish
	Sulphuric acid (1.84)	10 ml			
	Orthophosphoric acid (1.70)	10 ml			
	Glacial acetic acid	50 ml			
Silicon	Nitric acid (1.40)	20 ml	5–10 s	20	1:1 mixture also used
	Hydrofluoric acid (40%)‡	5 ml			
Tantalum	Sulphuric acid (1.84)	50 ml	5–10 s	20	Solution is useful for preparing surfaces prior to anodising
	Nitric acid (1.40)	20 ml			
	Hydrofluoric acid (40%)‡	20 ml			
Titanium	Hydrofluoric acid (40%)‡	10 ml	30–60 s	—	Swab until satisfactory
	Hydrogen peroxide (30%)	60 ml			
	Water	30 ml			
	Hydrofluoric acid (40%)‡	10 ml			Few seconds to several minutes according to alloy
	Nitric acid (1.40)	10 ml			
	Lactic acid (90%)	30 ml			
Zinc	Fuming nitric acid	75 ml	5–10 s	20	As for cadmium
	Water	25 ml			
	Chromium trioxide	20 g	3–30 min	20	Solution must be replaced frequently
	Sodium sulphate	1.5 g			
	Nitric acid (1.40)	5 ml			
	Water to 100 ml				
Zirconium (also Hafnium)	Acid ammonium fluoride	10 g	½–1 min	30–40	Rate of dissolution varies markedly with temperature and is about 20–60 μm min^{-1} in the given range
	Nitric acid (1.40)	40 ml			
	Fluosilicic acid	20 ml			
	Water	100 ml			
	Nitric acid (1.40)	40–45 ml	5–10 s repeated	—	Reaction is vigorous at air/ solution interface, and specimen is therefore held near surface of liquid. Hydrogen peroxide (30%) can be used in place of water.
	Water	40–45 ml			
	Hydrofluoric acid (40%)‡	10–15 ml			

* Acids are concentrated, unless otherwise indicated.
‡ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

ETCHING

Specimens should first be examined after polishing and before etching. This reveals features that have a significant difference in reflectivity from the main structure, or differences in colour and relief due to phases of large difference in hardness from the matrix. Nonmetallic inclusions, nitrides,

graphite, cracks, pores, voids and various kinds of pits can be recognised clearly and should be recorded. These features can be quite difficult to see after etching.

In order to obtain the maximum resolution from the light optical microscope (LOM) with minimum reflections from stray light, the microscope must be set up using the 'Köhler' principle of illumination.[20] Most modern microscopes are constructed to achieve this principle and it is only necessary to adjust the two iris diaphragms. The first of these, usually called the field diaphragm, should project an image (of the aperture) sharply in focus on the specimen and should be adjusted so that the image just lies outside the field of view. The aperture diaphragm should be sharply in focus on the rear of the objective lens. It can be viewed by removing the eyepiece and should be adjusted (through an auxiliary lens on some microscopes) so that the image is centrally located on the rear of the objective and it illuminates 90% of the lens area. If after these adjustments the image is too bright, it should be dimmed by either reducing the light intensity or interposing a filter. Reduction of the aperture size reduces the resolution achieved by the lens, emphasises differences in level and can introduce artefacts. Bright field illumination is the most commonly used illumination mode in metallographic work.

To emphasise small differences in surface topography, or to take advantage of the optical anisotropy of certain metals with non-cubic crystal structures, several techniques exist that are usually available on good light optical microscopes. These include:

1. Dark field illumination[19,21]

By this technique a specimen is illuminated by an annulus of light which passes up the outside of the objective and is focused as a cone by a concave reflector. Thus, the normal beam of light is not used to form the image. Instead, the light scattered by angled surfaces is focused to make the image and thus the contrast is reversed. Cracks, inclusions and defects are seen as bright features on a black background. In some cases, the colour of particles may be quite different in dark field vs. bright field. Cuprous oxide in tough pitch copper is pale blue grey in bright field, as is the sulphide, but the oxide appears bright ruby red in dark field while the sulphide is invisible. Manganese sulphide, calcium sulphide and Mn,Ca sulphide all appear to be dove grey in colour in bright field. However, in dark field MnS is dark, although the interface with the matrix may be visible, but the Ca-containing sulphides are bright, with pure CaS the brightest. So, dark field can be quite useful for studying calcium-treated steels. Dark field is also quite useful for the examination of polymers and many minerals.

2. Interference microscopy[22–25]

Interference microscopes have been described by several authors but the most sensitive and useful techniques have been developed by Tolansky.[22] His multiple-beam interferometer can be used with conventional microscopes, at magnifications of up to about 250 times. Monochromatic light is essential and a parallel beam normal to the surface is used. An optical flat, silvered or aluminised to give about 95% reflectivity, is placed in contact with the specimen and is slightly tilted to produce a thin wedge between the two. The light is repeatedly reflected between the specimen and the optical flat, and interference takes place to produce very thin, sharp, dark fringes. The spacing can be varied by the tilt of the plate. Where a change in the surface of the specimen occurs, e.g., a step or depression, the interference fringe is displaced one way or the other. A total fringe displacement corresponds to a change in height of half the wavelength of light used; it is possible to measure surface displacements of about 5–250 nm. To obtain sharp fringes, the reflectivity of the metallic surface should be the same as the reference plate, i.e., approximately 95%, and it may be necessary to aluminise the specimen surface for the best results, or use a lower reflectivity reference mirror.

Normarski has designed a very sensitive microscope for detecting height variations on the surface of a specimen.[21,25] He used a conventional polarising microscope, into which a double quartz prism is inserted between the objective and the analyser. If a step is present, this produces two images slightly displaced to one another and interference between these produces light and dark fringes, the spacing of which can be varied by adjusting the prism. A modification of the technique produces interference contrast in images. This is often called DIC—differential interference contrast.[26] DIC can be a very effective tool for viewing microstructures that have slight height differences that may be invisible in bright field but show up clearly using this method.

3. Polarised light

Polarised light is an extremely powerful illumination method for studying inclusions and structures of unetched, electropolished or mechanically polished surfaces of metals and alloys with non-cubic crystal structures, for example, Be, Hf, α-Ti, U and Zr. In certain cases, metals with cubic crystal structures may be examined more effectively after etching using polarised light.

The equipment needed includes a strong source of illumination, a polariser (prism or polariod filter) that can be rotated to change the plane of polarisation, and an analyser of comparable material which can also be rotated. At least one of these, usually the polariser, must be adjustable and the other can be fixed. When the analyser is oriented so that its plane of polarisation is at 90° to that of the polariser, an isotropic specimen will appear black if the objectives and the microscope are well adjusted and no depolarisation occurs. The objectives should be strain free for the highest sensitivity. Then, if a properly prepared metal with a non-cubic crystal structure is examined, the structure will be revealed.

Bausch and Lomb developed the Foster prism[20] which used a special calcite crystal that gave excellent polarised light images. However, the original source for this material has been long exhausted. This system has a fixed crossed position and cannot be adjusted to move slightly off the crossed position. It is now available again on certain microscopes.

With isotropic metals and the polariser and analyser set in the 'crossed' position, no light reaches the eyepiece. However, with an optically anisotropic material, e.g., a hexagonal metal like beryllium, magnesium or zinc, the reflected beam becomes elliptically polarised and the intensity of the component normal to the plane of polarisation of the incident light depends on the orientation of the anisotropic structure. Thus, the intensity of light which passes through the analyser will be dependent on the orientation of the structure to the surface of the specimen and to the incident beam. The image will vary from dark to bright, according to orientation and the grain structure of an anisotropic material will be revealed. On rotating the specimen, the intensity of light passing through the analyser from any one grain will pass from minimum to maximum intensity every 45° to give four maxima per revolution at 90° to each other, with a minimum intensity at 45° to each maximum. If the analyser and polariser are not quite crossed and differ by a few degrees, only two maxima and minima occur. The difference in contrast between the maxima and minima is much greater under these conditions and improves the sensitivity of the method, especially for weakly anisotropic or pleochroic materials.

The method can be used for studying grain structures, twins and martensite. In uranium alloys, for instance, the isotropic gamma phase can be distinguished from weakly anisotropic retained beta phase and the strongly anisotropic variants of the alpha phase. Martensite can be produced in eutectoidal aluminium bronze (Cu—11.8% Al) when quenched from the beta field. This martensite is easily observed in as-polished specimens using polarised light. Martensite can be made in certain nonferrous shape-memory alloys and observed with polarised light after polishing. In other systems, such as aluminium, the grain structure can be revealed by anodising with Barker's reagent and is observed with polarised light. If a sensitive tint filter (sometimes called a full-wave plate, a first-order red plate, or a λ plate) is added to the light path, the grey-contrast image is converted into colour contrast. Some anodised alloys apparently produce an anisotropic oxide film which has orientations related to the underlying lattice orientations. But, anodising of aluminium with Barker's reagent[27] does not produce such a film, as often claimed, but disproved by Perryman and Lack.[28] If such a film is present, colour should be observed with bright field illumination due to interference effects, as with heat tinting or colour etching. However, colour is not observed. Instead, a roughened surface is produced that creates elliptical polarisation effects. The grains are coloured according to variations in crystal orientation but Barker's reagent does not reveal variations in composition within grains, even in as-cast specimens, as colour tint etches do.

The other useful application is in the identification of inclusions, although this is rarely used today due to the widespread availability of energy-dispersive or wavelength-dispersive spectroscopy systems with scanning electron microscopes and electron microprobes. Glassy inclusions such as silicates display the so called 'optical cross' in polarised light. Other inclusions are optically isotropic or anisotropic, e.g., MnO and MnS can be distinguished in steels. Both look similar in bright field but under polarised light, the oxide is bright and the sulphide is dark. Other inclusions are pleochroic and display characteristic colours under crossed polars. Examples are the grey-blue Cu_2O phase in tough-pitch copper which is ruby red under polarised light, and Cr_2O_3 which changes from blue grey to a beautiful, emerald green. References 21, 29–31should be consulted for more detail.

The anisotropic metals include:

Antimony	Tin
Beryllium	Titanium
Cadmium	Uranium
Hafnium	Zinc
Magnesium	Zirconium

If prepared correctly, these metals will reveal their structure under crossed polarised light, although the quality of the images, and the strength of any observed colours, does vary.

The following metals can be made to respond to polarised light by anodising to produce an anisotropic film (see the note above about Barker's reagent), or by deep etching to produce an uneven surface with etch pits.

Aluminium	Molybdenum
Chromium	Nickel
Copper	Tungsten
Iron	Vanadium
Manganese	

Any fine lamellar structure, when etched, will reveal colour under polarised light because the etched fine lamellar structure produces elliptical polarisation. In a similar manner, solution annealed and aged beryllium copper produces beautiful colours under polarised light when etched due to the roughness created on the etched surface due to the overlapped coherency strains associated with the strengthening precipitates.

4. Colour[2,30,31]

Only two metals demonstrate natural colour: gold and copper. A few intermetallic phases exhibit natural colour, for example, $AuAl_2$, known as the 'purple plague' in the electronics industry. Others can be rendered in colour by:

(a) Optical methods of examination, such as polarised light, especially of etched structures with a sensitive tint plate inserted between polariser and analyser. This is available on most microscopes today and converts shades of grey into shades of colour. Unaffected regions that are white appear as magenta with a fixed sensitive tint filter. The colour pattern can be altered if the sensitive tint filter is adjustable (available on certain microscopes). Brighter colours are obtained in etched structures. Nomarski DIC also produces coloured surfaces where the colours correspond to height differences and can be adjusted by altering the Wollaston prism setting. These methods change shades of grey to colour contrast because of the use of the sensitive tint filter.

(b) By producing interference films by heat tinting or by chemical processes ('tint etching'). They can colour phases according to their reactivity or grains according to their crystal orientation. Most frequently, the reagents used deposit thin films of oxide, sulphide, chromate, phosphate or molybdate which cause colouration by interference of light. The colour depends on the thickness of films. Films that form on the less noble phase, usually the matrix, are produced by an anodic tint etch. Films that are preferentially deposited on the more noble phase, usually the second-phase particles, are produced by cathodic tint etches. A few tint etches, complex tint etches, colour both matrix and second phases. The anodic tint etches are most common. Heat tinting usually colours the matrix phase. The films grow according to the crystal orientation of the matrix phase, and growth is influenced by chemical segregation and residual deformation. A few tint etchants will colour MnS inclusions in steels white. Several etchants are known to preferentially attack or colour intermetallic compounds in Al and Mg alloys, but these are not tint etchants. They are usually called selective etchants. Some useful etchants are given in Tables 10.6 to 10.8. More details and examples are given in references 2, 30, 32–37.

Interference films can also be produced by vapour deposition of a compound to produce a thin dielectric film with a high refractive index. This increases the minor reflectivity differences between matrix and second-phase particles rendering them visible in colour contrast. Materials such as ZnTe, ZnSe, TiO_2, and ZnS have been commonly used for this purpose. The method was develop by Pepperhoff (1960) and is described in great detail by Bühler and Hougardy.[38] Gas contrast and reactive sputtering can also produce interference films.

5. Physical methods

(a) Cathodic vacuum etching (ion etching). The specimen is made a cathode in a high voltage gas discharge. High energy ions such as argon are accelerated at voltages of 1–10 kV and gas pressures of 10^{-2} Pa . This bombardment removes atoms at a rate dependent on orientation, presence of grain boundaries and intermetallic compounds.

(b) Thermal etching. On heating specimens, e.g., in vacuum or inert atmosphere, atoms are lost from weakly bound regions, e.g., grain boundaries. Surface tension forces lead to changes in surface topography at grain boundaries, leaving a structure characteristic of the high temperature. Thermal etching is used commonly with ceramics.

6. Chemical and electrochemical etching

Etching is usually an oxidation process. In general, elements with electrode potentials more negative than hydrogen will dissolve in many solutions, the rate depending on the local environment,

Table 10.6   COLOUR ETCHES FOR STEEL

See general safety note at the start of this Chapter.

Reagent			Procedure	Comments
1	Saturated sodium thiosulphate	50 ml	Immerse up to 2 min.	Klemm's I for carbon and alloys steels (also colours Cu alloys)
	Potassium metabisulphite	1 g		Colours ferrite, bainite and martensite, but not cementite
2	Saturated sodium thiosulphate	50 ml	Immersion up to 90 s	Klemm's II for austenitic Mn steels (also colours Cu alloys)
	Potassium metabisulphate	5 g		α martensite—brown, ε martensite—white Austenite—yellow to brown or shades of blue
3	0.6–10% HCl in water	100 ml	Immersion up to 60 s	Carbon, alloy and tool steels
	Ammonium bifluoride	0–1 g		Colours ferrite, bainite and martensite
	Potassium metabisulphite	0.5–1 g		Carbides unaffected
4	10–20% HCl in water	100 ml	Immerse up to 120 s	Stainless and maraging steels
	Ammonium bifluoride	0–2.4 g		Use lower HCl, no NH_4FHF for martensitic grades
	Potassium metabisulphite	0.5–1 g		Colours martensite and austenite but not carbides or nitrides

Table 10.7   COLOUR ETCHES FOR CAST IRON

See general safety note at the start of this Chapter.

Reagent			Procedure	Comments
1	HCl (35%)	2 ml	5–6 min immersion	Fe_3C—red/violet
	Selenic acid	0.5 ml	2–3 min if pre-etched	Ferrite—white
	Ethanol	100 ml	in 2% Nital	Phosphides—blue/green
2*	Water	100 ml	Pre-etch in 2% nital	Phosphides—yellow/brown
	Sodium thiosulphate	24 g	Immerse until surface	Sulphides—white
	Citric acid	3 g	blue/violet	Ferrites and carbides—blue/violet
	Lead acetate	2.4 g		
3*	Water	100 ml	Pre-etch in 2% Nital	Ferrite—red/violet
	Sodium thiosulphate	24 g	(a) Immerse 20–40 s	Phosphides—orange/brown
	Citric acid	3 g	(b) Immerse 50–90 s	Carbides—blue/violet
	Cadmium chloride	2 g		Ferrite—yellow

* Mix in order tested. Age etchant for 24 h in a dark bottle before use. Large quantities can be made as a stock solution.

Table 10.8   COLOUR ETCHES FOR ALUMINIUM ALLOYS

See general safety note at the start of this Chapter.

Reagent			Procedure	Comments
1	Sodium molybdate	3 g	Immersion (time	AlCuFeMn script—blue
	Ammonium bifluoride	2 g	selected by trial	FeSiAl—brown/blue
	HCl (35%)	5 ml	and error)	Ni_3Al, FeNiAl—brown
	Water	100 ml		$CuAl_2$—pale blue
2	Chromic trioxide	20 g	Immerse 5–30 s	If alloy susceptible to intergranular
	Sulphuric acid (1.84)	20 ml		corrosion, grain boundaries
	Ammonium bifluoride	5 g		coloured black
	Water	100 ml		
3	Sulphuric acid (95–97%)	20 ml	Immerse 30 s at 70°C	AlCuFeMn—brown
	Water	80 ml		Mg_2Si—brown to black
				Outlines other phases
4	Sodium hydroxide	10 ml	Immerse 5 s at 70°C	$CuAl_2$, Mg_2Si—brown
	Water	90 ml		
5	Potassium permanganate	4 g	Immerse for up to 20 s	Weck's reagent
	NaOH	1 g		Colours alpha matrix
	Water	100 ml		

resulting in grain boundary attack or outlining of phases or other structures. For elements with electrode potentials more positive than hydrogen, or for elements which polarise, solutions containing oxidising agents are needed. Making the specimen the anode in a low voltage cell has the same effect. Indeed, most electropolishing solutions will cause etching if the voltage is reduced, usually by a factor of 10.

Detailed etching procedures for individual metals are given below but, as a general principle, iron alloys are usually etched in dilute oxidising agents, e.g., nitric acid or picric acid in ethanol (see safety note regarding picric acid later in this chapter). Stainless steels are usually etched in weak oxidising reagents in alkaline solution, e.g., alkaline ferricyanides. Virtually the same result is achieved electrolytically in a 1% potassium hydroxide solution.

In the case of copper alloys, most etchants require an ammoniacal atmosphere plus an oxidising reagent such as air (by swabbing), hydrogen peroxide or dichromates, permanganates, persulphates, etc. Electrolytic etching in an oxidising acid, e.g., 1% chromium trioxide often suffices, the control of etching being achieved by varying the voltage.

Nearly all pure metals are notoriously difficult to etch, e.g., aluminium. Reduction reactions can also be used and these cause staining or colouration of phases, especially intermetallic compounds.

A wide variety of etching reagents have been devised by empirical methods. Some of these are reproduced here but the perceptive reader will see that these can be modified easily to cope with new compositions. Small amounts of some components are needed to control pH or potential. Some solutions are not stable and their effectiveness will change with time. Others containing mixtures of oxidising agents and organic chemicals can become very dangerous with time and should only be retained for short times and discarded in an appropriate fashion, immediately after use.

Reference is given to simple electrolytic etches. They can be used with simple direct current power supplies. This gives more control over etching than provided by simple immersion or swabbing. For further control of the etch process it is recommended that these etchants be used with a potentiostat[39,40] to control the potential at a known and reproducible value. This will yield selective, reliable and consistent etching.[41–43]

Although most etching work is conducted to reveal the phases and constituents in metals and alloys, there are etchants that will reveal dislocations. Etching to reveal dislocations in minerals goes back to at least 1817 with a publication by Daniels. In 1927, Honess listed etchants used to reveal dislocations in minerals. However, it was not until the work of Shockley and Read in 1949 that dislocations were studied scientifically in metals. The first deliberate use of etch pitting reagents to reveal dislocations was published in 1952 by Horn and Gevers. This was the first direct proof that dislocations (the concept of dislocations was proposed in the 1930s to explain the apparent low strength of metals compared to their theoretical strength) could be revealed by etching. A wide range of etching techniques exist for revealing dislocations and many are listed in Table 10.9 [see also 2].

7. Washing and drying

On completion of etching (with most etches) the specimen should at once be flooded with water, washed free from water with ethanol (avoid using ether or methanol) and dried in a blast of hot air from a hand dryer, hair dryer or equivalent. With non-aqueous etches, it may be preferable to do the initial washing with alcohol or acetone rather than water.

Porous specimens are often easily stained by residual etching solution seeping out of the pores. This trouble can usually be avoided by prolonging the washing and drying stages and in severe cases by prolonged soaking of the specimen in alcohol or acetone before final drying, or by ultrasonic cleaning. When working with porous specimens, it is best to infiltrate the pores, if interconnected to the surface, with a low viscosity epoxy resin using a vacuum impregnation system. If the pores are not interconnected, place the polished surface in a vacuum impregnation chamber, face up, apply a thin layer of a low viscosity epoxy to the surface and drive the epoxy into the surface pores under vacuum, or by applying pressure (this requires a special pressurisation chamber). After it hardens, carefully remove the excess epoxy from the top surface and final polish the specimen. But, very little metal can be removed or the impregnated layer will be removed. Some metallographers have used molten wax to fill surface pores, then scrapped off the hardened wax on the surface and completed polishing. As the pores and voids are filled, bleed out does not occur. Gifkins demonstrated that EDTA (ethylene-diaminetetra-acetic acid) could be used to remove tarnish from the surface of polished lead specimens. He also found that cracked specimens of steel and brass could be etched stain-free by adding a few drops of EDTA to the etchant. An aqueous 2% EDTA solution can be used ultrasonically to remove stains. This solution can etch certain metals, so the time in the ultrasonic cleaner must be minimised [see 2 for more details].

Table 10.9   ETCHING REAGENTS FOR DISLOCATIONS

Taken largely from Lovell, Vogel and Wernick[44]. See general safety note at the start of this Chapter.

Metal or alloy	Reagent*		Remarks
Aluminium (99.99%) (*see* ref. 62)	Hydrochloric acid Nitric acid Hydrofluoric acid$^\otimes$	50% 4% 3%	–
	Hydrochloric acid Nitric acid Hydrofluoric acid$^\otimes$	50 ml 47 ml 3 ml	Lacombe and Beaujard's reagent[45,46]
	Hydrofluoric acid$^\otimes$ Hydrochloric acid Nitric acid Hydrogen peroxide (29% w/v)	37 ml 18 ml 9 ml 36 ml	Make A, 49 : 51 HF : H_2O_2 Make B, 65 : 35 HCl : HNO_3 Mix in ratio A:B = 5:2, care required Keep at 0–15°C in use (ref. 47)
Antimony	Hydrofluoric acid$^\otimes$ Nitric acid Acetic acid Bromine	3 pts 5 pts 3 pts 3 drops	Electrolytic etch on cleaved surface 2–3 s
	Hydrofluoric acid$^\otimes$ Superoxol	1 pt 1 pt	Electrolytic etch. 1 s
Bismuth	1% Iodine in methanol		Cleaved surface. 15 s
Brass (65% Cu–35% Zn)	0.2% Sodium thiosulphate		Electrolytic etch. 10 A dm^{-2} 18–20°C. Remove film with hydrochloric acid
Brass (Alpha)[48]	Saturated aqueous ferric chloride Hydrochloric acid	50 ml 2 drops	—
Brass (Beta)[48]	Saturated aqueous ammonium molybdate Hydrochloric acid	30 ml 6–7 drops	Immerse the electrolytically polished surface for 30 min
Columbium (Niobium)	Sulphuric acid Hydrofluoric acid$^\otimes$ Water Superoxol$^{\ddagger\otimes}$	10 ml 10 ml 10 ml a few drops	Agitate specimen in solution
Copper (pure)	Saturated ferric chloride solution	4 pts	Rinse in ammonia solution
	Hydrochloric acid Acetic acid Bromine	4 pts 1 pt a few drops	*See* Ruff[49] for further solutions and references
Germanium (also 0.2 at. % boron, 6.0 at. % silicon, 0.2 at. % tin)	Hydrofluoric acid$^\otimes$ Nitric acid Acetic acid Bromine	3 pts 5 pts 3 pts 3 drops	3–5 s. Polish etch. 600 grit (P1200) carborundum ground surface
Germanium	Potassium ferricyanide Potassium hydroxide Water	8 g 12 g 100 ml	600 grit (P1200) carborundum ground surface. 2–5 min. Boiling solution
Iron (99.96%)	4% metanitrobenzosulphonic acid in ethanol		Long etch. Rinse in alcohol. Result questionable
Iron	(a) 1% nitric acid in ethanol (b) 0.5% picric acid in methanol†		1 min in (a) followed by rinse in methanol and 5 min in (b). Pits appear only in specimen cooled slowly from 750° to 800°C‡
	Fry's reagent Table 10.1, C(f)		10 s etch of chemically polished surface
Iron (99.99%)	Disa Electropol solution A–Z		Electrolytic etch. Observation by electron microscopy
Iron	2% Nital containing 2% of saturated picral		15 min
	Saturated picral		4 min. Anneal to decorate dislocations‡

(*continued*)

Table 10.9   ETCHING REAGENTS FOR DISLOCATIONS—*continued*

Metal or alloy	*Reagent**		*Remarks*
Iron–silicon (3.25 Si)	Acetic acid	133 ml	Electrolytic etch. 3 A dm^{-2}. 17–19°C.
	Chromium trioxide	25 g	Decorate with 0.004% carbon at 770°C
	Water	7 ml	or above in low-pressure acetylene atmosphere[‡]
Nickel–manganese	Orthophosphoric acid	100 ml	Electrolytic etch. 2 min. 200 A dm^{-2}
	Ethanol	100 ml	Copper cathode 40°C
Silicon	Hydrofluoric acid$^{\otimes}$	1 pt	15 min or longer. Chemically polished
	Nitric acid	3 pts	surface
	Acetic acid	12 pts	
	Hydrofluoric acid$^{\otimes}$	4 pts	600 grit (P1200) carborundum ground
	Nitric acid	2 pts	surface
	3% aqueous mercuric nitrate	4 pts	
	Hydrofluoric acid$^{\otimes}$	3 pts	600 grit (P1200) carborundum ground surface.
	Nitric acid	5 pts	Use de-ionised water
	Acetic acid	3 pts	Utensils and specimen must be dry
	3% aqueous mercuric nitrate	1.5–2 pts	2 min
	Hydrofluoric acid$^{\otimes}$	160 ml	600 grit (P1200) carborundum
	Nitric acid	80 ml	ground surface
	Water	160 ml	
	Silver nitrate	8 g	
	Hydrofluoric acid$^{\otimes}$		Use in ratio:
	Chromium trioxide	50 g	2:1 by vol. for large etch pits
	Water	per 100 g	1:1 for medium etch pits
			2:3 for small etch pits
			Time 15 s[50]
Tellurium	Hydrofluoric acid$^{\otimes}$	3 pts	1 min etch. Cleaved surface
	Nitric acid	5 pts	
	Acetic acid	6 pts	
Zinc	Chromium trioxide	160 g	Immerse with mild agitation for 1 min
	Hydrated sodium sulphate	50 g	Chemically polish before etching. Dip
	Water	500 ml	in solution of 320 g chromium trioxide per litre after etching, to remove stain Decorate with 0.1 atomic % cadmium Anneal at 300–400°C.[§] Age 1 week at room temperature
Zinc with 0.002% tin[51]	Saturated aqueous ammonium tungstate	35 ml	Etch by immersing for about 5 min Agitate to remove adherent layer
	Saturated aqueous ammonium molybdate	5 drops	Quench from 400°C and anneal 100–400°C[‡]
	Hydrochloric acid	5 drops	

* Acids are concentrated, unless otherwise indicated.
[‡] Superoxol contains hydrogrn peroxide (30%) 1 pt, hydrofluoric acid (40%) 1 pt, water 4 pts.
[§] Note that this heat treatment must alter the dislocation structure.
[†] Special handling is required for picric acid to avoid the risk of fire and/or explosion and local regulations must be consulted before use of this reagent.
$^{\otimes}$ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

TAPER SECTIONING

Taper sectioning[20,21] is used to give an apparent magnification of as much as 10 times by using a plane of section to cut the surface at a shallow angle, typically 6° (i.e., $\sin^{-1} 1/10$) so that the vertical features of the surface are given an apparent relative magnification of about 10 times. This magnification is only in the direction perpendicular to the coated surface when the taper angle is made as indicated in Figure 10.3.

(a) Taper section

(b) Method of mounting for taper section
Figure 10.3   *Taper sectioning* (*from Vickers Projection Microscope Handbook*)

Taper sectioning requires plating of the surface to be examined, followed by mounting in plastic at a suitable angle. The plating may be done with nickel or copper from conventional plating baths. Assuming that the surface is ready to be examined, it must not be altered during the plating procedure; cleaning before plating must be confined to methods such as solvent washing and cathodic alkaline degreasing, which have no appreciable effect on the particular surface under examination. The mounting procedure is evident from Figure 10.3.

This method may also be used for examining thin intermediate layers, for example in electroplating, or in the study of diffusion couples.

10.3   Metallographic methods for specific metals

10.3.1   Aluminium

PREPARATION

Aluminium and its alloys are soft and easily scratched or distorted during preparation. For cutting specimens, a laboratory abrasive cut-off saw should be used, with the correct wheel, and with light pressure and proper cooling, to avoid excessive heating and minimise deformation. Specimens are ground with waterproof SiC papers by the usual methods, but with slightly lower loads than in the contemporary method. Use 20 N (5 lbf) per specimen. Fine silicon carbide papers (600 grit (P1200) and finer) may cause embedding, particularly in the softer alloys. For high-purity aluminium, it may be advisable to coat the finer papers (if used) with paraffin wax. After the first grinding step (see the contemporary method described above) polishing is carried out in three or four steps, depending upon the alloy. Rigid grinding discs specially made for softer metals can be used for the second step, if substantial material must be removed. If heavy stock removal is not required, cloths can be used for step 2. Natural silk (with a psa backing or a magnetic platen set up) will yield the best surface finish, with excellent relief control and a reasonable removal rate. For steps 3 and 4 (if step 4 is chosen), use a woven polyester cloth rather than the chemotextile pad. For final polishing, either the napless polyurethane pad or a synthetic suede (rayon), medium nap cloth, can be used. The preferred final abrasive is colloidal silica. The sol-gel alumina suspension works nearly as well, and certainly far better than standard calcined aluminas. MgO is used rarely today as the final abrasive due to the many problems associated with its use, as discussed previously. The contemporary preparation

Table 10.10   MICROCONSTITUENTS WHICH MAY BE ENCOUNTERED IN ALUMINIUM ALLOYS

Microconstituent	*Appearance in unetched polished sections*
Al_3Mg_2	Faint, white. Difficult to distinguish from the matrix
Mg_2Si	Slate grey to blue. Readily tarnishes on exposure to air and may show iridescent colour effects. Often brown if poorly prepared. Forms Chinese script eutectic
$CaSi_2$	Grey. Easily tarnished
$CuAl_2$	Whitish, with pink tinge. A little in relief, usually rounded
$NiAl_3$	Light grey, with a purplish pink tinge
Co_2Al_9	Light grey
$FeAl_3$ (see note 1)	Lavender to purplish grey; parallel-sided blades with longitudinal markings
$MnAl_6$	Flat grey. The other constituents of binary aluminium–manganese alloys ($MnAl_4$, $MnAl_3$ and 'δ') are also grey and appear progressively darker. May form hollow parallelograms
$CrAl_7$	Whitish grey; polygonal. Rarely attacked by etches
Silicon	Slate grey. Hard, and in relief. Often primary with polygonal shape—use etch to outline
α(Al–Mn–Si) (see note 2)	Light grey, darker and more buff than $MnAl_6$
β(Al–Mn–Si) (see note 2)	Darker than α(Al–Mn–Si), with a more bluish grey tint. Usually occurs in long needles
Al_2CuMg	Like $CuAl_2$ but with bluish tinge
Al_6Mg_4Cu	Flat, faint and similar to matrix
(Al–Cu–Mn) (see note 3)	Grey
α(Al–Fe–Si) (see note 4)	Purplish grey. Often occurs in Chinese-script formation. Isomorphous with α(Al–Mn–Si)
β(Al–Fe–Si) (see note 4)	Light grey. Usually has a needle-like formation
(Al–Cu–Fe) (see note 5)	Grey α phase lighter than phase (*see* Note 5)
(Al–Fe–Mn) (see note 6)	Flat grey, like $MnAl_6$
(Al–Cu–Ni)	Purplish grey
(Al–Fe–Si–Mg) (see note 7)	Pearly grey
$FeNiAl_9$	Very similar to and difficult to distinguish from $NiAl_3$
(Al–Cu–Fe–Mn)	Light grey
$Ni_4Mn_{11}Al_{60}$	Purplish grey
$MgZn_2$	Faint white; no relief

The constituents are designated either by formulae denoting the compositions upon which they appear to be based, or by the elements, in parentheses, of which they are composed. The latter nomenclature is adopted where the composition is unknown, not fully established, or markedly variable.

(1) On very slow cooling under some conditions, $FeAl_3$ decomposes into Fe_2Al_7 and Fe_2Al_5. The former is micrographically indistinguishable from $FeAl_3$. The simpler formula is retained for consistency with most of the original literature.

(2) α(Al–Mn–Si) is present in all slowly solidified aluminium–manganese–silicon alloys containing more than 0.3% of manganese and 0.2% of silicon, while β(Al–Mn–Si), a different ternary compound, occurs above approximately 3% of manganese for alloys containing more than approximately 1.5% of silicon. α(Al–Mn–Si) has a variable composition in the region of 30% of manganese and 10–15% of silicon. The composition of β(Al–Mn–Si) is around 35% of manganese and 5–10% of silicon.

(3) (Al–Cu–Mn) is a ternary compound with a relatively large range of homogeneity based on the composition $Cu_2Mn_3Al_{20}$.

(4) α(Al–Fe–Si) may contain approximately 30% of iron and 8% of silicon, while β(Al–Fe–Si) may contain approximately 27% of iron and 15% of silicon. Both constituents may occur at low percentages of iron and silicon.

(5) The composition of this phase is uncertain. Two ternary phases exist. α(Al–Cu–Fe) resembles $FeAl_3$; β(Al–Cu–Fe) forms long needles.

(6) The phase denoted as (Al–Fe–Mn) is a solid solution of iron in $MnAl_6$.

(7) This constituent is only likely to be observed at high silicon contents.

method, with these minor changes, yields excellent surfaces with no relief, good edge retention, and freedom from artefacts, so that the true structure can be revealed. Many different second-phase particles, or intermetallic phases, can be encountered in aluminium and its alloys, see Table 10.10, and their polishing characteristics can vary somewhat.

Avoid using slurry or suspensions of fine diamond abrasives when polishing aluminium and its alloys as they are likely to become embedded in the surface. This is chiefly a problem with 1 μm diamond and finer sizes. When these fine sized diamond abrasives are added as a slurry, the particles roll between the specimen and the woven cloth or pad and can become embedded in the specimen as easily as in the cloth. This problem is not observed with coarser diamond added as slurries or suspensions. Fine diamond is best added as a paste where it is embedded in the cloth even before the wheel is turned on. See the previously described practice for charging a cloth with diamond paste.

Many aluminium alloys contain the reactive compound Mg_2Si. If this constituent is suspected, non-aqueous solvents, such as mineral spirits, purified kerosene or ethanol may be substituted for water during the final polishing step to avoid loss of the reactive particles by corrosion.

It should be noted that some aluminium alloys are liable to undergo precipitation reactions at the temperatures used to cure thermosetting mounting resins; this applies particularly to aluminium-magnesium alloys, in which grain boundary precipitates may be induced. A 'cold' setting resin should be used, but care must be taken with the set up to minimise the heat generated in polymerisation (see previous discussion under Mounting).

Electropolishing is often rapid and convenient (*see* Tables 10.4(a) and 10.4(b) but there may be nonuniform polishing or attack of the intermetallic phases.

ETCHING

Aluminium alloys now in use cover many complex alloying systems. A relatively large number of etching reagents have been developed; only those whose use has become more or less standard practice are given in Table 10.11. Many etches are designed to render the distinction between the many possible microconstituents easier, and the type of etching often depends on the magnification to be used. The identification of constituents, which is best accomplished by using cast specimens where possible, depends to a large extent on distinguishing between the colours of particles, so that the illumination should be as near as possible to daylight quality. It is recommended that a set of specially prepared standard specimens, containing various known metallographic constituents, be used for comparison. Because of these problems, and with the development of EDS and WDS techniques available on scanning electron microscopes and electron microprobes, the use of etchants to identify precipitates is infrequent today. However, as an aid to selecting constituents for image analysis measurements, these etchants have value as they can enhance the detectability of the desired particles.

Some etching reagents for aluminium require the use of a high temperature; in such cases the specimen should be preheated to this temperature by immersion in hot water before etching. For washing purposes, a liberal stream of running water is advisable.

Electrolytic etching of aluminium alloys

In addition to the reagents given for aluminium in Table 10.11, the following solutions have been found useful for a restricted range of aluminium-rich alloys:

1. The following solution has been used for grain orientation studies:

Orthophosphoric acid (density 1.65)	53 ml
Distilled water	26 ml
Diethylene glycol monoethyl ether	20 ml
Hydrofluoric acid (48%)	1 ml

   The specimen should be at room temperature and electrolysis is carried out at 40 V and less than $0.1\,A\,dm^{-2}$ An etching time of 1.5–2 min is sufficient for producing grain contrast in polarised light after electropolishing.

2. The solution below is also used for the same purpose and is more reliable for some alloys:

Ethanol	49 ml
Water	49 ml
Hydrofluoric acid	2 ml (quantity not critical)

   The specimen is anodised in this solution at 30 V for 2 min at room temperature. A glass dish must be used. Not suitable for high-copper alloys.

3. For aluminium alloys containing up to 7% of magnesium:

Nitric acid (density 1.42)	2 ml
40% hydrofluoric acid	0.1 ml
Water	98 ml

   Electrolysis is carried out at a current density of $0.3\,A\,dm^{-2}$ and a potential of 2 V. The specimen is placed 7.6 cm from a carbon cathode.

4. For cast duralumin:

Citric acid	100 g
Hydrochloric acid	3 ml
Ethanol	20 ml
Water	977 ml

   Electrolysis is carried out at $0.2\,A\,dm^{-2}$ and a potential of 12 V.

Table 10.11 ETCHING REAGENTS FOR ALUMINIUM AND ITS ALLOYS

See general safety note at the start of this Chapter.

No.	Reagent		Remarks
1	Hydrofluoric acid (40%)[§] Hydrochloric acid (1.19) Nitric acid (1.40) Water (Keller's etch)[‡]	0.5 ml 1.5 ml 2.5 ml 95.5 ml	15 s immersion is recommended. Particles of all common micro-constituents are outlined. Colour indications: Mg_2Si and CaSi: — blue to brown α(Al–Fe–Si) and (Al–Fe–Mn): — darkened β(Al–Cu–Fe): — light brown $MgZn_2$, $NiAl_3$, (Al–Cu–Fe–Mn), Al_2CuMg and Al_6CuMg: — brown to black α(Al–Cu–Fe) and (Al–Cu–Mn): — blackened Al_3Mg_2: — heavily outlined and pitted The colours of other constituents are little altered. Not good for high Si alloys
2	Hydrofluoric acid (40%)[§] Water	0.5 ml 99.5 ml	15 s swabbing is recommended. This reagent removes surface flowed layers, and reveals small particles of constituents, which are usually fairly heavily outlined. There is little grain contrast in the matrix. Colour indications: Mg_2Si and $CaSi_2$: — blue $FeAl_3$ and $MnAl_6$: — slightly darkened $NiAl_3$: — brown (irregular) α(Al–Fe–Si): — dull brown (Al–Cr–Fe): — light brown Co_2Al_9: — dark brown (Al–Fe–Mn): — brownish tinge α(Al–Cu–Fe), (Al–Cu–Mg) and (Al–Cu–Mn): — blackened α(Al–Mn–Si), β(Al–Mn–Si) and (Al–Cu–Fe–Mn) may appear light brown to black β(Al–Fe–Si) is coloured red brown to black The remaining possible constituents are little affected
3	Sulphuric acid (1.84) Water	20 ml 80 ml	30 s immersion at 70°C; the specimen is quenched in cold water. Colour indications: Mg_2Si, Al_3Mg_2 and $FeAl_3$: — violently attacked, blackened and may be dissolved out $CaSi_2$: — blue α(Al–Mn–Si) and β(Al–Mn–Si): — rough and attacked $NiAl_3$ and (Al–Cu–Ni): — slightly darkened β(Al–Fe–Si): — slightly darkened and α(Al–Fe–Si), (Al–Cu–Mg) — pitted and (Al–Cu–Fe–Mn): — outlined and blackened Other constituents are not markedly affected
4	Nitric acid (1.40) Water	25 ml 75 ml	Specimens are immersed for 40 s at 70°C and quenched in cold water. Most constituents (not $MnAl_6$) are outlined. Colour indications: β(Al–Cu–Fe) is slightly darkened Al_3Mg_2 and AlMnSi: attacked and darkened slightly Mg_2Si, $CuAl_2$, (Al–Cu–Ni) and (Al–Cu–Mg) are coloured brown to black
5	Sodium hydroxide Water	1 g 99 ml	Specimens are etched by swabbing for 10 s. All usual constituents are heavily outlined, except for Al_3Mg_2 (which may be lightly outlined) and (Al–Cr–Fe) which is both unattacked and uncoloured. Colour indications: $FeAl_3$ and $NiAl_3$: — slightly darkened (Al–Cu–Mg): — light brown α(Al–Fe–Si): — dull brown* α(Al–Mn–Si): — rough and attacked; slightly darkened* $MnAl_6$ and (Al–Fe–Mn): — coloured brown to blue (uneven attack) $MnAl_4$: — tends to be darkened The colours of other constituents are only slightly altered

(continued)

Table 10.11 ETCHING REAGENTS FOR ALUMINIUM AND ITS ALLOYS—*continued*

No.	Reagent		Remarks
6	Sodium hydroxide Water	10 g 90 ml	Specimens immersed for 5 s at 70°C, and quenched in cold water. Colour indications:
			β(Al–Fe–Si): slightly darkened $Mn_{11}Ni_4Al_{60}$: light brown β(Al–Cu–Fe): light brown and pitted $CuAl_2$: light to dark brown $FeAl_3$: dark brown
			($FeAl_3$ is more rapidly attacked in the presence of $CuAl_2$ than when alone)
			$MnAl_6$, $NiAl_3$, (Al–Fe–Mn), $CrAl_7$ and AlCrFe: blue to brown α(Al–Fe–Si), α(Al–Cu–Fe), $CaSi_2$ and (Al–Cu–Mn): blackened
7	Sodium hydroxide Sodium carbonate (in water)	3%–5% 3%–5%	Useful for sensitive etching where reproducibility is essential. In general, the effects are similar to those of Reagent 5, but the tendency towards colour variations for a given constituent is diminished. Particularly useful for distinguishing $FeNiAl_9$ (dark blue) from $NiAl_3$ (brown). Potassium salts can be used.
8	Nitric acid Hydrofluoric acid[§] Glycerol	20 ml 20 ml 60 ml	A reliable reagent for grain boundary etching, especially if the alternate polish and etch technique is adopted. The colours of particles are somewhat accentuated
9	Nitric acid, 1% to 10% by vol. in alcohol		Recommended for aluminium–magnesium alloys. Al_3Mg_2 is coloured brown. 5–20% chromium trioxide can be used
10	Picric acid[†] Water	4 g 96 ml	Etching for 10 min darkens $CuAl_2$, leaving other constituents unaffected. Like Reagent 4
11	Orthophosphoric acid Water	9 ml 91 ml	The reagent is used cold. Recommended for aluminium–magnesium alloys in which it darkens any grain boundaries containing thin β-precipitates. Specimen is immersed for a long period (up to 30 min). Mg_2Si is coloured black, Al_3Mg_2 a light grey, and the ternary (Al–Mn–Fe) phase a dark grey
12	Nitric acid		10 s immersion colours Al_6CuMg_4 greenish brown and distinguishes it from Al_2CuMg, which is slightly outlined but not otherwise affected
13	Nitric acid (density 1.2) Water Ammonium molybdate, $(NH_4)_6Mo_7O_{21},4H_2O$	20 ml 20 ml 3 g	20 ml of reagent are mixed with 80 ml alcohol. Specimens are immersed and well washed with alcohol after etching. Brilliant and characteristic colours are developed on particles of intermetallic compounds. The effects depend on the duration of etching, and for differentiation purposes standardisation against known specimens is advised
14	Sodium hydroxide (various strengths, with 1 ml of zinc chloride per 100 ml of solution)		Generally useful for revealing the grain structure of commercial aluminium alloy sheet[27]
15	Hydrochloric acid (37%) Hydrofluoric acid (38%)[§] Water	15.3 ml 7.7 ml 77.0 ml	Recommended (30 s immersion at room temperature) for testing the diffusion of copper through claddings of aluminium, aluminium–manganese–silicon, or aluminium–manganese on aluminium–copper–magnesium sheet. Zinc contents up to 2% in the clad material do not influence the result[52]
16	Ammonium oxalate Ammonium hydroxide, 15% in water	1 g 100 ml	Develops grain boundaries in aluminium–magnesium–silicon alloys. Specimens are etched for 5 min at 80°C in a solution freshly prepared for each experiment

* These are isomorphous and the colour depends on the proportion of Mn and Fe.

‡ Sodium fluoride can be used in place of HF in mixed acid etches.

§ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

† Special handling is required for picric acid to avoid the risk of fire and/or explosion and local regulations must be consulted before use of this reagent.

5. For commercial aluminium:

Hydrofluoric acid (40%)	10 ml
Glycerol	55 ml
Water	35 ml

This reagent, used for 5 min at room temperature, with a current density of $1.5\,A\,dm^{-2}$ and a voltage of 7–8 V, is suitable for revealing the grain structure after electropolishing.[53]

6. For distinguishing between the phases present in aluminium-rich, aluminium–copper–magnesium alloys, electrolytic etching in either ammonium molybdate solution or 0.880 ammonia has been recommended. In both cases, Al_2CuMg is hardly affected, $CuAl_2$ is blackened, Al_6Mg_4Cu is coloured brown, while Mg_2Al_3 is thrown into relief without change of colour.[54]

Note: Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

Anodising

Etching to reveal the grain structure of aluminium alloys is not always easy. In cases where standard etchants do not reveal the grain structure, anodising solutions are utilised. Of these, Barker's reagent[27] is the most widely used. This is an electrolytic etching method where an aluminium cathode is used; its area should be substantially greater than the polished surface to be etched. The specimen is the anode and is parallel to the cathode with about a 10 mm spacing. A dc current of 20–45 V is placed across the anode and cathode while they are immersed in the electrolyte, a 1.8% solution of fluoroboric acid in water. Voltage is not too critical. Good results have been obtained with 2 min of etching at 20 or 30 V dc. This roughens the specimen surface and no colour is observed in bright field. Contrary to many publications, Barker's reagent does not create a film at the polished face. High magnification examination of the anodised surface with the SEM reveals a fine roughening. When viewed with polarised light, the grain structure is revealed with grains in different shades from white to black. If a sensitive tint plate is insert in the light path, then the grains exhibit colours. Anodising does not reveal chemical segregation ('coring') within the grain structure, only grain orientation differences. There are other anodising solutions for aluminium, and for other metals [see 2 for a complete listing]. Some of these may produce an interference layer but Barker's does not.

GRAIN COLOUR ETCHING[55]

For many aluminium alloys containing copper, and especially for binary aluminium-copper alloys, it is found that Reagent No. 1 of Table 10.11 gives copper films on cubic faces which are subject to preferential attack and greater roughening of the surface. Subsequent etching with 1% caustic soda solution converts the copper into bronze-coloured cuprous oxide, and a brilliant and contrasting representation of the underlying surfaces is obtained. The technique is of use in orientation studies in so far as the films are dark and unbroken on {100} surfaces, but shrink on drying on other surfaces. In particular {111} faces have a bright yellow colour with a fine network on drying, which has no preferred orientation, while {110} faces develop lines (cracks in film) which are parallel to a cube edge.

ETCHING TO PRODUCE ETCH PITS[45]

The orientation of crystal grains may be determined by developed etch pits on specimens previously electropolished (see Table 10.4). The following reagents develop pits with facets parallel to the {100} cube planes:

	a	*b*	*c*
Fuming nitric acid	15 ml	15 ml	47 ml
Pure hydrochloric acid	45 ml	46 ml	50 ml
Hydrofluoric acid	15 ml	10 ml	3 ml
Distilled water	25 ml	29 ml	—

Note: Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

Mixture *c* is recommended where only a few large well-formed etch figures are preferred. Etching with dry gaseous hydrochloric acid gives pits with facets parallel to {111} planes.

10.3.2   Antimony and bismuth

PREPARATION

Antimony, as usually obtained, is hard and brittle, and easily breaks up into fragments. Mounting in a press may cause fracturing. It is safer to mount specimens in a castable resin. Preparation can be conducted using either the traditional or contemporary methods. Pure antimony is not a commonly encountered metallographic subject but alloys containing Sb are. These are easier subjects than the pure metal. Sb is often present in alloys made up of the low-melting point metals, e.g., Pb, Bi or Cd. These alloys do not respond well to diamond abrasives and are better prepared with the traditional method using candle wax on the SiC papers, especially the fine papers. Embedded SiC particles can be easily removed when polishing with aqueous alumina slurries. Copper alloys may contain antimony as a minor element.

   Bismuth is a soft metal, but also brittle, although not very difficult to prepare. The pure metal is encountered less than alloys containing bismuth. The preparation follows the same guidelines as for antimony and for low-melting point alloys containing Bi.

ETCHING

1. (a)	Water	22 ml	Mix equal	Sb and Sb-Bi alloys
	HNO_3 (1.40)	8 ml	quantities of (a) and (b)	
(b)	Water	30 ml	immediately before use	
	Ammonium molybdate	4.5 g	~1 min	
2.	Water	100 ml	~1 min	Grain structure of Sb
	Citric acid	25 g		and Bi alloys
	Ammonium molybdate	10 g		

10.3.3   Beryllium

PREPARATION

Due to its toxicity, preparation of Be and its alloys is restricted usually to laboratories designed to handle Be and suitably inspected and licensed. Be is not easy to prepare as it is easily deformed (mechanical twinning) by handling. Conventional methods must be modified. All operations which produce Be dust must be done in a glove box. Wet cutting and grinding are absolutely necessary to reduce damage to the specimens and to prevent dust formation. However, the sludge created must be properly disposed of. All metallic dusts, regardless of the chemical element, are dangerous if inhaled but Be dust is among the most dangerous dusts. The metal deforms easily by mechanical twinning, so light loads must be used during grinding and polishing. Some authors claim that water must be avoided, even when grinding Be, while others state that no difficulties were encountered using water as the coolant or lubricant. A four-step procedure can be used to prepare beryllium and its alloys. Start with 320 grit (P400) SiC paper, at 15–20 N (4 lbf) load, 240–300 rpm, with water cooling, until cutting damage has been removed. Next, use a natural silk cloth with a psa backing (or a magnetic platen setup) set up and 6 μm diamond paste, 120–150 rpm, same load, for 5 minutes. Follow with 3 μm diamond paste on a woven polyester cloth, used as in the second step, but for 4 minutes. Final polish with colloidal silica or with the sol-gel alumina suspension, using 10–15 N (3 lbf) per specimen, 80–120 rpm, for 2 minutes. An attack-polish agent is often added to the final polishing suspension to facilitate damage removal and enhance polarised light response. Aqueous 5% oxalic acid and 30% concentration hydrogen peroxide have been used as the attack polishing agents. Be is difficult to etch. However, due to its hcp crystal structure, excellent results are obtained with as-polished surfaces viewed with cross-polarised light.

   Other methods of preparation have been discussed[56,57] including *electropolishing* (see Table 10.4).

ETCHING

1. Hydrofluoric acid (40%)   10 ml
   Ethanol   90 ml

   On immersion for 10–30 s microconstituents are in general outlined, and some colour differentiations are observed. The identifications of constituents commonly met with in commercial beryllium, both in the etched and unetched condition, are as shown in Table 10.12.

2. Water   95 ml   1–15 s   Be alloys
   Sulphuric acid (1.84)   5 ml

Table 10.12 MICROCONSTITUENTS IN COMMERCIAL BERYLLIUM

Constituent	Appearance unetched	Effect of etching
Carbide	Hard angular grey particles, staining in air to many colours, finally brown	No effect on colour
Silicon-rich phase	Light blue grey	Not stained, but outlined
Nitride	Needle-like particles, darker grey than carbide	Unaffected
$TiBe_{12}$	Angular particles, slightly pink	Unaffected
$CaBe_{13}$	Light yellow, usually angular	Unaffected
$FeBe_{12}$	Almost invisible unetched	Coloured reddish brown
$MnBe_{12}$	Similar to iron, but slightly pink	Outlined
Boride	Reddish particles in grain boundaries	Coloured blue or purple
$MoBe_{22}$	Almost invisible unetched	Coloured chocolate brown
UBe_{13}	Invisible unetched	Phase revealed as a yellow or green dendritic structure
Aluminium	Bright yellow, often appearing speckled. Soft and difficult to polish	Outlined
Magnesium	Very soft, and white in appearance	Removed
$ZrBe_{13}$	Barely distinguishable dendritic phase	Outlined and coloured light blue

3. Water	100 ml	2–16 min	Outlines precipitates first, then grain
Oxalic acid	10 g		boundaries. Better used electrolytically

Note: Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

10.3.4 Cadmium

PREPARATION

The preparation of cadmium for metallographic examination should be carried out in the same manner as for zinc. Cd and its alloys are soft and easily deformed by mechanical twinning if cutting and grinding are too aggressive. When possible, use a precision saw to cut the specimens or a good quality laboratory abrasive cut-off saw. Pure Cd and high-Cd alloys do not respond well to diamond abrasive and it is better to use the 'traditional' method of preparation (see mechanical polishing), but substitute aqueous alumina slurries for diamond. Grinding with SiC can be continued to grit sizes finer than 600 (P1200) and then polish with 3 and 1 µm aqueous alumina slurries, before finishing polishing with colloidal silica (works very well with cadmium). Cd plated steels and other metals can be challenging to prepare as water must be avoided, at least in the final polishing step. Consequently, colloidal silica cannot be used. Final polishing is performed usually with alumina powders mixed in mineral spirits, purified kerosene or ethanol. These are less satisfactory but there is no attack of the coating, as with an aqueous suspension.

Electrolytic polishing is satisfactory[20,58] for pure Cd (*see* Table 10.4).

ETCHING

	Reagent		Conditions	Remarks
1.	Ethanol	2 ml	Few seconds	Most alloys
	Nitric acid (1.40)	98 ml	to a minute	Thallium also
2.	Water	100 ml	Up to a minute	Eutectics of Cd
	Hydrochloric acid (1.19)	25 ml		
	Ferric chloride	8 g		
3.	Water	40 ml		
	Hydrofluoric acid (40%)	10 ml	5–10 s	Most Cd alloys, also
	Hydrogen peroxide (30%)	10 ml		thallium and indium

Note: Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

10.3.5 Chromium

PREPARATION

Pure Cr is soft but brittle; however, plated Cr is hard and brittle and is characterised by an internal crack pattern. Chromium and its alloys are not too difficult to prepare but they are very difficult to etch. Mechanical polishing using the contemporary approach can be followed by a brief electrolytic polish or an attack polish can be used in the last step (*see* Tables 10.3 and 10.4). Hard or decorative chromium plate may be mounted in a thermosetting epoxy resin to enhance edge retention and prepared using the contemporary method. Water is not a problem.

ETCHING

Table 10.13 ETCHING REAGENTS FOR CHROMIUM

See general safety note at start of this Chapter.

No.	Reagent*		Remarks
1	Dilute hydrofluoric acid‡		After electropolishing with the reagent listed in Table 10.4, the specimen is agitated for a few seconds in dilute hydrofluoric acid‡
2	Hydrochloric acid (concentrated)		Shows striations in electrodeposits
3	Nitric acid	10 ml	Suitable for alloys. Also used electrolytically; specimen is made anode at 4 V, 45 s. Proportions 1:3:2 also used. This decomposes on standing, especially in contact with stainless steel. *Beware!*
	Hydrochloric acid	20 ml	
	Glycerol	30 ml	
4	Sulphuric acid (10%)		Used hot with swabbing

* Acids are concentrated unless otherwise indicated.
‡ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

10.3.6 Cobalt

PREPARATION

Cobalt and its alloys are more difficult to prepare than stainless steels or nickel-based superalloys and much more difficult to etch. Cobalt is a tough metal with an hcp crystal structure. However, it does not respond well under polarised light. While it is sensitive to deformation by mechanical twinning, this is not as big a problem as with Be or Mg. Preparation of cobalt and its alloys can be done by the contemporary method. Always cut specimens with a high quality laboratory abrasive cutter using a softly bonded wheel, such as used to section Ti. Co cuts slowly, like refractory metals, and can be damaged by aggressive cutting. Two steps of SiC may be needed, but start with as fine a grit as possible, 220 or 240 grit or 320 grit SiC (P240–P400). Three diamond steps are advised with 9, 3 and 1 μm diamond. Final polishing is best conducted using an attack polishing agent added to colloidal silica for up to 3 minutes. An etch-repolish-etch cycle may be needed to remove the last bit of disturbed metal. Some metallographers follow mechanical polishing with a brief chemical polish.

ETCHING

Cobalt may be etched with some of the reagents used for nickel and iron alloys, but some alloys are strongly resistant to attack. *See* Table 10.14.

10.3.7 Copper

PREPARATION

Pure copper is low in hardness, extremely ductile and highly malleable. There are a number of relatively pure Cu grades made, with minor differences in deoxidation, for electrical applications. Preparation of these grades can be rather challenging, particularly for scratch removal and obtaining a high degree of grain boundary delineation. Cu–Zn alloys (brasses) are also challenging to prepare

Table 10.14   ETCHING REAGENTS FOR COBALT AND ITS ALLOYS

See general safety note at the start of this Chapter.

No.	Reagent*		Remarks
1	Hydrochloric acid	60 ml	The solution should be aged for 1 hour. Grain boundaries and
	Nitric acid	15 ml	the general structure of alloys are revealed. May also be used
	Acetic acid	15 ml	electrolytically. Of wide application, including hard metals
	Water	15 ml	
2	Nitric acid	10 ml	Reveals general structure. May be used electrolytically (*see*
	Hydrochloric acid	20 ml	Table 10.13, Reagent 3. Same precautions)
	Glycerol	30 ml	
3	Potassium ferricyanide	10 g	For hard cobalt–chromium alloys containing carbon. Used at
	Potassium hydroxide	10 g	approx. 70°C, 10–20 s. Can be replaced by electrolytic 3%
	Water	100 ml	KOH. Suitable for carbides
4	Chromium trioxide	2–10 g	Used electrolytically, the specimen being made the anode at 6 V
	Sulphuric acid	10 ml	
	Water	90 ml	

* Acids are concentrated unless otherwise indicated.

scratch-free and difficult to bring out all the grain boundaries. This is a common problem with all face-centred cubic metals and alloys, such as α-brass that exhibit annealing twins. Sectioning is a critical step as damage from sectioning can be extensive. The least damaging cutting methods are needed. Damage from band sawing can extend to nearly a mm in depth. Always cut Cu and its alloys with a high quality abrasive cut-off saw with the proper wheel, good coolant and low pressure. Use the contemporary preparation method described above, and in Ref. [33]. After careful sectioning, start grinding with the finest possible SiC grit, e.g., 240 (P280) or 320 (P400) grit, to remove the cutting damage. Do not grind with worn paper. With an automated machine using six specimens at a time, a sheet of SiC paper is worn out (i.e., its removal rate is reduced to a very low value) in about 60 s. For good scratch control, use of a psa-backed (or a magnetic platen setup) selected silk cloth (an Ultra-Pol™ cloth specifically) in step 2 is critical. Final polishing can be effectively performed using a medium nap synthetic suede cloth (e.g., a Microcloth® pad), without need for an attack polish. Attack polishing agents have been used, and can be helpful, but they are unnecessary if sectioning is done with minimal damage and the contemporary practice is used. To study inclusions, examine the specimens before etching. Tough-pitch copper (Cu—0.4 wt. % O) contains numerous Cu_2O particles but can also contain copper sulphides. Both types of particles look similar in bright field illumination. Under dark field illumination, the cuprous oxide particles are bright ruby red while the sulphides are invisible. There are several alloys, cast and wrought, with lead additions. These can be easily observed with bright field and are well retained using the contemporary method.

ETCHING

Cast copper alloys are easy to etch due to their chemical inhomogenity, although grain boundaries may be difficult to reveal. Dendrites are usually easily revealed, particularly using colour tint etches.[2,32–37] Most homogeneous copper alloys have much the same etching characteristics as copper, and the same etching reagents as are used for copper may be tried. Reagents 1 and 2, and several other variations, are used widely to reveal the structure of most coppers and copper alloys. Alloys containing more than one phase usually etch easily, but careful attention must be paid to the time of etching. Most etchants reveal one phase, but not the other. Etchants can be used to selectively colour or darken specific phases in metals and alloys,[59] and Cu alloys are no exception. For example, when alpha-beta alloys, such as naval brass are etched, there are a few etchants that will colour or darken the alpha phase only, many that will darken only the beta phase, and a few that will colour both alpha and beta. For example, equal parts of NH_4OH and H_2O_2 (3% conc.) will darken the alpha phase; Klemm's I (see Table 10.6) will colour beta phase; and, Beraha's selenic acid reagent for copper (similar to etch 1 in Table 10.7, but 300 ml ethanol) will colour both phases. There are a number of excellent colour 'tint' etchants for copper and its alloys[2,33] and these are very useful for Cu alloys.

LEADED COPPER ALLOYS

Difficulties can arise in the preparation and examination of leaded alloys, owing to the different hardnesses of the constituents, and also because specimens are particularly susceptible to smearing of the lead over the copper matrix. The contemporary method of preparation, as described above and in the section on Mechanical Polishing, works well on leaded brasses and bronzes. It may be helpful, if there is any flowed metal after polishing, to lightly etch the specimen, then repeat the final polishing step before examination. Colloidal silica is quite good for minimising smeared surface metal and works well with leaded bronzes. If it is necessary to etch, Reagents 31 and 32 of Table 10.15 may be used to etch the lead, or ferric chloride or chromic acid reagents to attack the copper-rich matrix.

The dithizone process described under *Iron and steel* (p. **10**–45–**10**–50) is also applicable to brasses. (*See also electrolytic etching*, below.)

Table 10.15 ETCHING REAGENTS FOR COPPER AND ITS ALLOYS

See general safety note at the start of this Chapter.

Principal use	No.	Reagent		Remarks
Copper, copper alloys in general. Brass, bronze and nickel–silver	1	Ammonium hydroxide Water Hydrogen peroxide (3% conc.)	50 ml 50 ml 20 ml	Used for copper, and many copper-rich alloys. Gives a grain boundary etch, and also tends to darken the α solid solution, leaving the β solid solution lighter. The hydrogen peroxide content may be varied. Less is required the lower the copper content (*see* Reagent 2)
	2	Ammonium hydroxide Water Hydrogen peroxide (3% conc.)	50 ml 50 ml 10 ml	Used for bronze, 70:30 and 60:40 brasses; this etch may with advantage be followed by a ferric chloride etch (Reagent 6) to darken the β areas in duplex alloys
	3	Ammonium hydroxide Water Ammonium persulphate, 2½% solution	10 ml 10 ml 10 ml	Recommended for polish attack on copper and copper alloys
	4	Ammonium persulphate Water	10 g 100 ml	Used cold or boiling for copper, brass, bronze, nickel–silver and aluminium–bronze. Tends to produce relief effects. Good for aluminium bronzes followed by Reagent 23 to darken β martensite (retained β is pink) and then Reagent 24 to etch $\gamma_2(\delta)$ brown
	5	Dilute ammonium hydroxide solution (10–50%)		May be used for polish or swab attack on brass and bronze. The oxidising action of atmospheric oxygen is necessary for the process
	6	Ferric chloride, various strengths and compositions. To 100 parts of water are added: Hydrochloric acid (1.19) / Ferric chloride (g) 20 / 1 10 / 5 50 / 5 25 / 8 6 / 19 25 / 25 1 / 10* 10 / 3‡		Used as a general reagent for copper, brass, bronze, nickel–silver, aluminium–bronze and other copper-rich alloys. It darkens the β constituent in brasses and gives grain contrast following ammoniacal or chromic acid etches. The most suitable composition should be found by trial and error in specific cases. This reagent generally emphasises scratches in imperfectly prepared specimens, and tends to roughen the surface. For sensitive work it is frequently a great advantage to replace the water in the reagent by a 50:50 water–alcohol mixture or by pure alcohol
	7	Ethanol (commercial) Ferric chloride (anhydrous) Hydrochloric acid	96 ml 59 g 2 ml	Dilute 5:1 with alcohol. Wash with alcohol or acetone. More delicate and controllable than aqueous solutions

Table 10.15   ETCHING REAGENTS FOR COPPER AND ITS ALLOYS—*continued*

Principal use	No.	Reagent		Remarks
Copper, copper alloys in general. Brass, bronze and nickel–silver (*continued*)	8	Chromic acid CrO_3 saturated in water		Used for copper, brass, bronze and nickel–silver. The etching time is 1 to 1½ min. Grain boundaries are attacked and β constituents are coloured pale yellow, while the primary solid solution is coloured dark yellow
	9	Chromic acid, 100–150 g l^{-1} of water, 1–2 drops of hydrochloric acid are added immediately before use to a 50 ml portion		Used for copper, brass, bronze, nickel–silver, and recommended for revealing the silicides of Ni, Co, Cr and Fe in certain alloys. Alternate polishing and etching is recommended when a grain contrast is obtained. The primary solid solution is not attacked. The β copper–zinc phase is coloured light yellow while the δ copper–tin phase is coloured brown to black. The reagent may be followed by a ferric chloride etch
	10	Chromic acid Nitric acid (1.40) Water	25 g 40 ml 35 ml	This reagent is useful for distinguishing the general constituents of many copper alloys. The γ and δ phases are particularly well shown up as shining blue crystals
	11	Sulphuric acid (1.84) Potassium dichromate saturated in water	5 ml 100 ml	Etching time ½ to 1 min. Suitable for copper, but attacks oxide inclusions strongly
	12	Nitric acid, various strengths		Used for any purpose requiring deep etching and the removal of a thick layer of surface material. The times of etching are short and difficult to control
	13	Sulphuric acid (1.84) Hydrogen peroxide (10 vol.)	5 ml 100 ml	Etching time is to 1–1½ min. Used for pure copper, but attacks oxide
	14	Silver nitrate, 100 g l^{-1} of water, following exposure to hydrogen sulphide		This technique has been used for 70:30 and 60:40 brasses, and produces satisfactory contrast
	15	Silver nitrate, 20 g l^{-1} of water		Immerse for 30 s, and wash off silver stain under water. Useful in certain cases for pure copper
	16	Ammonium hydroxide Ammonium oxalate saturated in water	10 ml 30 ml	Used for high-zinc brasses
	17	Ammonium hydroxide Potassium arsenate saturated in water	10 ml 30 ml	Used for high-zinc brasses
	18	Copper ammonium chloride. 100 g l^{-1} of water, plus ammonium hydroxide to slight alkalinity		Copper, brass and nickel–silver. Specially recommended for darkening in large β areas duplex brasses
	19	Ammonia Potassium permanganate (0.4%) in water	20 ml 30 ml	Used for pure copper. Etching time 2 to 3 min. Liable to produce staining
	20	Bromine water, saturated		Etching time 30 to 60 s. May be used, satisfactorily with pure copper if the coating which forms is removed by washing in strong ammonia

(*continued*)

Table 10.15   ETCHING REAGENTS FOR COPPER AND ITS ALLOYS—*continued*

Principal use	No.	Reagent		Remarks
Aluminium–bronze Copper alloys with beryllium, silicon, manganese and chromium	*4*	See above		As for Reagent 4
	6	See above		As for Reagent 6. Darkens β
	10	See above		As for Reagent 10. Also generally useful for aluminium-bronzes
	21	Chromic acid Nitric acid (1.40) Water	20 g 50 ml 30 ml	Recommended for aluminium–bronze after pretreatment with 10% hydrofluoric acid solution in order to remove surface oxide films[§]
	22	Chromic acid Nitric acid (1.40) Water	20 g 5 ml 75 ml	As for Reagent 21
	23	Nitric acid (1.40) Hydrogen peroxide (100 Vol.)	0.5 ml 99 ml	Darkens martensite
	24	Sod. hydroxide Water	10 g 100 ml	$\gamma_2 (\delta)$ etched brown
	25	Ferric nitrate Ammonium nitrate Nitric acid Water	20 g 20 g 2 ml 500 ml	Good for complex aluminium bronzes
	26	Ammonium hydroxide Water Hydrogen peroxide, 3% solution	25 ml 25 ml 20 ml	Age 1 week in loosely stoppered bottle before use. To distinguish eutectoid $(\alpha + \gamma_2)$ from acicular β. γ_2 attacked
Copper alloys with beryllium, silicon, manganese and chromium	*8*	—		As for Reagent 8. Is also useful for manganese bronze
	27	Potassium dichromate Water Sodium chloride (saturated) Sulphuric acid (s.g. 1.84)	2 g 100 ml 4 ml 8 ml	Used for copper, and copper alloys with beryllium, manganese and silicon. Also suitable for nickel–silver, bronzes and chromium–copper alloys. This reagent should be followed by a ferric chloride etch to give added contrast
High-nickel alloys	*28*	Nitric acid (s.g. 1.42) Glacial acetic acid Water	50 ml 25 ml 25 ml	Recommended for high-nickel alloys which might prove resistant to attack by the more usual reagents, and for bright copper electro-deposits. 1:1 nitric acid : acetic acid is also used
Copper–nickel–aluminium	*29*	Acetic acid, 75% Nitric acid Acetone	30 ml 20 ml 30 ml	Recommended for copper-rich copper–nickel–aluminium alloys. NiAl shows as dove-grey rectangular needles; Ni$_3$Al is globular and darker grey. The γ_2 phase of the aluminium–copper system is a pale grey; (*see also* Reagent 24)
Copper-silicon alloys	*30*	Hydrogen peroxide (30 vol.) Water Potassium hydroxide (20%) Ammonium hydroxide (s.g. 0.90)	20 ml 25 ml 5 ml 50 ml	Used specifically to distinguish the κ phase in copper-silicon alloys, and in ternary and more complex alloys based on this system.
Leaded copper and bearing metals of this material	*31*	Nitric acid Glacial acetic acid Glycerol	20 ml 20 ml 80 ml	General reagent for leaded copper, bronzes, etc. *See* below for further notes on leaded coppers. Darkens lead
	32	Trichloroacetic acid Water Ammonium hydroxide to make 100 ml	20 g 20 ml	As for Reagent 31. Etches and outlines lead constituent, bringing it into prominence. Monochloroacetic acid may be substituted

(*continued*)

Table 10.15   ETCHING REAGENTS FOR COPPER AND ITS ALLOYS—*continued*

Principal use	No.	Reagent	Remarks
Macro-etching	33	Heat tinting	This technique occasionally gives useful results. Phosphor bronzes react the most favourably
	34	No-etching	Several constituents which may be present may be observed in unetched sections. Thus the selenide and telluride, appear blue grey, while the oxide appears blue. Metallic bismuth appears a very pale blue grey. Cuprous oxide, unless the particles are very small, appears ruby-red in polarised light or with dark-field illumination; selenide and telluride remain dark. Zinc oxide (in brass) appears transparent and anisotropic in polarised light, blue-grey with ordinary illumination

* Usually used with 1 part of chromic acid CrO_3.

‡ Used with one part of cupric chloride and 0.05 parts of stannous chloride.

§ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

ELECTROLYTIC ETCHING OF COPPER ALLOYS

Copper alloys are particularly suitable for electrolytic etching, and this technique frequently gives good results with alloys (e.g., high-nickel alloys) which are otherwise difficult to etch. Solutions which have been found effective are given in Table 10.16; potential differences and current densities must be adjusted to suit specific materials. Reagents listed for electrolytic polishing of copper (Table 10.4) may also be tried (at about one-tenth the voltage).

A very sensitive etching of homogeneous copper alloys may be obtained by electrolytically polishing in phosphoric acid solution ($1 \, kg \, l^{-1}$), and short-circuiting the electrodes when polishing is complete. The polarisation current set up gives anodic action at the crystal boundaries only.

10.3.8   Gold

PREPARATION

Gold and its alloys, as well as the other precious metals, are very soft, easily deformed (they are exceptionally malleable), and are quite difficult to prepare for metallographic examination. Control of deformation, smeared metal and scratch removal is a challenge. As one might expect, they are among the most difficult metals to etch due to their great corrosion resistance. Embedding of abrasive can be a problem with precious metals. Nevertheless, they can be prepared using a variation of the contemporary practice.

Sectioning must be done with a good metallographic laboratory cut-off saw, with a precision saw, or a low-speed saw, with the proper blade and low pressure to minimise the depth of damage. Gold and its alloys can be mounted in a thermosetting resin or in cast epoxy. Start by grinding with 220, 240 or 320 grit SiC (P240 to P400) waterproof paper, 10–15 N (3 lbf) load per specimen, 150–250 rpm with water cooling, until the cutting damage has been removed. Polishing is done only with diamond paste using chemotextile pads (known variously as Texmet® 1000, Pellon® or Pan W), with only a minor amount of water as the lubricant. The waxiness of the carrier in the paste will be the main lubricant. Loads in all steps are low, as in the SiC step, at 3 lbf per specimen. The rotational speed is in the range 150–250 rpm. Use three diamond steps in this way with 9, 3 and 1 μm diamond paste for 5, 3 and 2 minutes, respectively.

Final polishing is conducted using a polyurethane pad, such as a Chemomet® pad with a 0.05 μm, sol-gel alumina suspension (Masterprep™ alumina) at 10 N (2 lbf) per specimen, 100–150 rpm, for 2 minutes. Colloidal silica is useless with precious metals. Its amorphous silica particles are spherical in shape and produce little, if any, cutting action, while its pH of 9.5–10 is inadequate to yield a chemical attack-polish action. Ordinary calcined alumina abrasives do not yield as good

Table 10.16   ELECTROLYTIC ETCHING OF COPPER ALLOYS

See general safety note at the start of this Chapter.

Principal use	No.	Reagent		Remarks
General	1	Ferrous sulphate Sodium hydroxide Sulphuric acid (1.84) Water	30 g 4 g 100 ml 1900 ml	May be used to develop contrast after the use of ammoniacal hydrogen peroxide reagents. β in brasses is darkened. A current density of 0.1 A dm^{-2} at 8–10 V is suitable
Cupro–nickel and Nickel–silvers	2	Citric acid	100 g/l	Also useful for brasses
	3	Ammonium molybdate in excess of ammonia		Also useful for brasses
	4	Glacial acetic acid Nitric acid (1.40) Water	5 ml 10 ml 85 ml	This reagent tends to minimise the effect on the microstructure of the coring which usually occurs with these alloys
Brasses	5	Ammonium acetate 100 g l^{-1} of water		Current density 0.3 A dm^{-2}
	6	Ammonium sulphate 10 g l^{-1} of water		Current density 0.3 A dm^{-2}
	7	0.10 M ammonium acetate 0.50 M sodium thiosulphate 14 M ammonium hydroxide Distilled water	10 ml 30 ml 30 ml 30 ml	Carried out at 31 A dm^{-2}. The etching time is approximately inversely proportional to the copper content of the material
	8	Chromic acid CrO$_3$ 170 g l^{-1} of water		Useful for distinguishing the γ and ε phases of the copper-zinc system. At current densities above 23 A dm^{-2} the γ phase is attacked, but not the ε phase. At low current densities the order of the attack is reversed. The zinc-rich solid solution is attacked under both conditions.
Aluminium–bronze and copper–beryllium alloys	9	Chromic acid Water	10 g 900 ml	This reagent is satisfactory for all stages of heat treatment, and is useful for following the stages of precipitation in the age-hardening of copper-beryllium alloys. Distilled water must be used as tap water leads to staining. A potential of 6 V, with an aluminium cathode, is satisfactory
Leaded copper and brass	10	Dilute sulphuric acid (up to 10% by vol.)		Electrolytic etching at 6 V, with a carbon cathode, has been recommended for lead-bearing copper and brass, in order to avoid, misinterpretation of the structure due to surface flow

a surface finish as the sol-gel alumina. For high Au content specimens, such as 18-karat gold and higher ($\geq 75\%$ Au), it is necessary to add an attack polish agent to the suspension for scratch removal. Several attack polishing agents can be used. CrO$_3$ in water is excellent and has been used in several concentrations from 5 to 20 g per 100 ml of water. This solution does contain undesirable Cr^{+6} ions which may pose a problem with its disposal (users must consult their local regulations on how to properly dispose the residue). Hydrogen peroxide (30% conc.) presents few environmental disposal problems and also works well. Generally, the attack polishing agent is added to the sol-gel alumina slurry in a 1:5 ratio by volume. If the slurry thickens too much, add some distilled water. When an attack polishing agent is used, the metallographer must avoid any physical contact with the abrasive and must properly clean up the equipment after use so that residues of it do not affect the next user of the equipment. It is advisable to wear proper personal protective equipment. When an attack polishing agent must be used, due to the higher purity of the alloy, polishing may be conducted for 3–6 minutes.

Table 10.17   ETCHING REAGENTS FOR GOLD AND ITS ALLOYS

See general safety note at the start of this Chapter.

No.	Reagent		Remarks
1	Potassium cyanide, 10% in water Ammonium persulphate, 10% in water	10 ml 10 ml	Used for gold and its alloys. A fresh solution, warmed if necessary, must be used for each experiment. The etching time varies from ½ to 3 min. The attack may be speeded up by the addition of 2% of potassium iodide, but this is liable to give staining effects (see text below for details of its use)
2	Tincture of iodine, 50% solution in aqueous potassium iodide		Used for gold alloys. With silver–gold alloys a silver iodide film may form. This may be removed by immersion in potassium cyanide solution
3	Aqua regia (20 ml conc. nitric acid + 80 ml conc. hydrochloric acid)		The hot solution is used. If too much silver is present a silver chloride film may form; this may be removed by ammonium hydroxide or potassium cyanide solutions. Use fresh only; liable to decompose with evolution of chlorine and NO_2
4	Potassium sulphide solution		Solution used hot; particularly useful for gold-nickel alloys
5	Chromic acid (chromium trioxide) Hydrochloric acid (1.19)	3 g 100 ml	Gold-rich alloys (up to 1 min)

ETCHING

Etching of gold and its alloys, and all precious metals, is challenging due to their great corrosion resistance. Etch 1 works well with gold, but its use is unusual. The two solutions must not be pre-mixed. One person holds the specimen with tongs and a tuff of cotton with a second pair of tongs. Another person takes two eyedroppers and fills each with one of the solutions. That person then drips equal amounts of the two etchants onto the specimen surface while the first person swabs the surface. Dripping and swabbing is continued until the correct degree of etching has been obtained. This must be done over something that will collect anything that drips from the specimen, so it requires careful pre-planning and execution. NaCN can be used in place of KCN and hydrogen peroxide (30% conc.) can be substituted for the ammonium persulphate solution with equivalent results. But, this etch becomes less effective for gold contents above 18 karat.

ETCHING

The five solutions given in Table 10.17 are of general suitability.

ELECTROLYTIC ETCHING OF GOLD

The microstructure of gold may be developed by anodic treatment in concentrated hydrochloric acid to which a little ferric chloride has been added. Dilute solutions of hydrochloric acid, potassium cyanide or potassium cyanide plus potassium iodide may also be used.

10.3.9   Indium

PREPARATION

The pure metal and many of its alloys are very soft and should be prepared by the methods recommended for lead or cadmium. It is frequently sufficient to cut suitable specimens with a sharp razor blade; however, the damage introduced must be removed. Pure In and its alloys can be more difficult to prepare than lead and its alloys, although some In-based intermetallic compounds are relatively easy to prepare. See the discussions on preparing Cd or Pb.

ETCHING

Etching reagents containing hydrofluoric acid, nitric acid, or mixtures of the two acids, are in general satisfactory, and the following are recommended for indium-rich alloys.[60,61] Vilella's reagent for steels, etch 2 (below), has been used successfully.

1. Potassium dichromate — 1.3 g
   Sulphuric acid conc. (1.84) — 4.5 ml
   Saturated sodium chloride solution — 2.7 ml
   Hydrofluoric acid (40%) — 17.7 ml
   Nitric acid conc. (1.40) — 8.8 ml
   Water — 66.3 ml — Use up to 1 min
2. Hydrochloric acid (1.19) — 20 ml — For alloys containing bismuth it is
   Picric acid — 4 g — necessary to increase the proportions
   Ethanol — 400 ml — of alcohol and hydrochloric acid.

Note: Special handling is required for picric acid to avoid the risk of fire and/or explosion and local regulations must be consulted before use of this reagent.

Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

10.3.10   Iron and steel

PREPARATION

Iron and low-carbon steels are more susceptible to surface deformation during preparation than higher alloyed steels and tool steels so sectioning and grinding must be performed carefully. The development of excessive heat at the surface must be avoided. Pure iron, and sheet steels, are soft and ductile. Removing all deformation and scratches is difficult because the structure is mainly ferrite. Higher hardness steels are easier to deal with and are more forgiving. However, some of the highly alloyed stainless steels can be rather challenging. It is not uncommon to see deformation-induced martensite in an austenitic stainless steel due to overly aggressive preparation. Preparing tool steels is usually easy, but there are situations where they can be quite difficult; for example, preparing as-quenched specimens or over-austenitised specimens. An as-quenched tool steel frequently exhibits hardnesses in the 60–70 HRC range. Sectioning must be done with the greatest care, low pressure and a very softly bonded wheel, to avoid introducing heat, or worse yet, burning. Some metallographers prefer to break the specimen in three-point bending to avoid the heat introduced during cutting an as-quenched tool steel. Over-austenitised tool steels generally contain excessive amounts of retained austenite because more carbon than desired was put into solution, which depresses the martensite start and finish temperatures. Excessive heat generated in section and grinding, and even polishing, can alter the retained austenite content. Austenitic stainless steels must be cut with low applied pressure as they can be work hardened dramatically. Hadfield manganese steels, also austenitic, have an even greater ability to be work hardened. Austenitic Fe–Ni magnetic alloys can be very difficult to prepare scratch free. Graphite retention is a problem with certain cast iron grades (grey iron, compacted graphite iron, ductile iron, malleable iron). Metallographers used to advocate grinding specimens with SiC paper up to 600 grit (P1200) with water as the coolant, and then repeat the 600 grit (P1200) step without water, claiming this enhanced graphite retention. That approach is unnecessary. A 4 or 5 step contemporary practice (see Mechanical Polishing), gives perfect surfaces with excellent graphite retention. White cast iron is easier to prepare but one must avoid any procedure that would create relief, that is, height differences between different phases. The use of the hard, woven napless cloths or synthetic napless pads in polishing ensure that relief is absent, when the correct load is used.

Galvanised steel (Zn coated) is a frequent metallographic subject. Final polishing steps must be performed without water, or the Zn coating will be heavily attacked. A similar technique may be employed for tin-plate, although Sn-coated layers are thinner and more difficult to study by light microscopy, and for Cd-coated steels (see section on cadmium).

The contemporary preparation practice works very well for irons and steels (see mechanical polishing). This practice can be altered depending upon needs and materials being prepared. Rigid grinding discs can be used for steps 1 or 2. For example, high hardness tool steels and alloy steels can be prepared perfectly in as little as 3 steps. Step 1 uses SiC paper for grinding to remove the cutting damage. Grits from 120–320 (P120–P400) can be used. Step 2 uses the Buehler Hercules H disc, or equivalent, with a 3 μm polycrystalline diamond suspension at 120–150 rpm, 25–30 N (6 lbf) load per specimen, for 5 minutes. Step 3 uses either a 0.05 μm sol-gel alumina suspension or a 0.05 μm colloidal silica at 120–150 rpm, with a similar load, for 5 minutes, on either a medium nap synthetic suede cloth (for e.g., a Microcloth® pad) or a polyurethane pad. If the specimens are mounted in the thermosetting epoxy resin, with a modern mounting press that cools the specimen under pressure after polymerisation so that there are no shrinkage gaps, then edge retention will be superb despite the 5 minute time, even if the medium napped cloth is used.

MICROGRAPHIC CONSTITUENTS OBSERVED

The metallography of iron and steel is complex, and the various constituents likely to be observed
may be very briefly summarised as follows:

1. *Ingot iron and wrought iron*. These consist mainly of *ferrite* (α-iron; body centred cubic crystal
   structure), the etching characteristics of which may be affected by phosphorus, manganese or
   silicon in solid solution, or by the presence of slag inclusions (wrought iron is no longer made
   commercially). Carbon is usually present in low amounts and carbon present above the very
   low solid solubility in ferrite is in the form of *cementite* (iron carbide, Fe_3C). Sulphur may be
   present as *iron sulphide* if Mn is not present, but otherwise as *manganese sulphide.* Several
   forms of relatively pure iron are made, such as: *electrical iron*, *interstitial-free steel*, and sheets
   steels of various compositions. These are all essentially ferritic in content with minor amounts
   of non metallic inclusions and cementite. Dual-phase sheet steels have a more complicated
   structure, as they contain small grains consisting of martensite and retained austenite.

2. *Normalised and annealed carbon steels*.* The microconstituents present vary according to
   the carbon content. Below 0.8% of carbon, specimens consist of *ferrite* and an interlamellar
   eutectoidal mixture of *ferrite* and *cementite* which is known as *pearlite*. At 0.8% of carbon,
   specimens are entirely *pearlitic*. Above 0.8% carbon, the constituents are a network of massive
   cementite surrounding *pearlitic* areas. Normalised and annealed steels ($<0.8\%$ C) differ in the
   character and extent of the pearlitic areas, which are usually coarser in the latter case. Very
   rapid cooling gives very fine, unresolvable (by LOM) pearlite. Very slow cooling gives a coarse,
   easily resolved interlamellar spacing in the pearlite. Special annealing cycles can 'spheroidise'
   the cementite leading to the formation *of globular cementite*, producing a softer, more ductile
   condition than offered by fine pearlite. Prolonged heating of high carbon steels at 600–800°C
   decomposes cementite into *ferrite* and free *graphite*, which must be considered as a possible
   constituent.

3. *Hardened and tempered carbon and alloy steels*. At a high temperature (above that at which
   the transformation of α-iron into face centred cubic, γ-iron takes place), carbon steels consist
   of *austenite*, a solid solution of carbon in γ-iron. Some austenite can be retained in highly
   alloyed steels, such as tool steels, depending upon the austenitising temperature used in heat
   treatment. In most steels a variety of decomposition products may arise depending on the
   severity of quenching locally, the alloy content ('hardenability'), and the section size. The
   structures obtained are:

   (a) Martensite, which requires rapid quenching (the rate required is a function of the steel's
       hardenability and the section size). In high-carbon steels, particularly when too much
       carbon is put in solution, this structure appears as an intersecting system of parallel or
       lenticular 'needles' (often called, erroneously, 'acicular' martensite). In high-carbon steels,
       particularly when over-austenitised, some residual austenite may be retained in between
       the 'needles'. The three-dimensional shape, however, is not acicular but looks like two
       dinner plates facing each other, hence, the more correct name, 'plate' martensite. Electron
       microscopy is needed for a detailed study of martensite. Plate martensite exhibits a mid-rib
       twin. In low-carbon alloy steels and maraging steels, *lath martensite* is formed that has a
       parallel-banded structure containing high densities of dislocations. Medium-carbon steels
       have mixtures of lath and plate martensite. When the prior-austenite grain size is fine, as
       it should be, the structure of martensite is difficult to reveal with the light microscope.

   (b) Bainite is formed at lower rates of quenching. It is a non-lamellar aggregate of ferrite and
       cementite.

       Upper bainite comprises bundles of parallel laths of ferrite between which carbide
       precipitates. It can form by continuous cooling, or during isothermal decomposition of
       austenite at 400–500°C (it is usually easier to discern bainite types that are formed isother-
       mally). It etches up more darkly, the lower the temperature at which it forms, but the
       structure is only seen in clear detail by electron microscopy.

       Lower bainite is more usually found in alloy steels with high Cr, Ni and/or Mo contents
       that were quenched too slowly to form fully martensitic structures or were isothermally
       transformed to deliberately form lower bainite. Like upper bainite, it is diffusion controlled
       (although in both cases, the actual γ to α transformation may be diffusionless with diffu-
       sion occurring behind the transformation front), but forms at lower temperatures, usually

---

* By 'normalising' is meant the reheating of a steel to a temperature at which it consists of a solid solution of carbon in γ-iron,
followed by free cooling in air. By 'annealing' is meant the reheating of a steel to a similar temperature for an appreciable time,
followed by slow cooling, usually in a furnace. See Chapter 29 for a more detailed discussion of steel heat treatment.

below 350°C. It is difficult to distinguish from a tempered martensite by optical examination and needs electron microscopy for full identification. It is acicular or plate-like with subsidiary plates or needles nucleated from existing plates (unlike upper bainite, which is nucleated from austenitic boundaries). Lower bainite comprises ferrite plates or needles with carbides precipitated internally on one orientation. (In tempered martensite, two or more orientations of carbides are found.) Lower bainite is also free from twins.

(c) *Pearlite*. This is a lamellar eutectoid of α-iron and cementite, the spacing of which is dependent on the temperature at which it forms. It nucleates as nodules which grow from prior-austenitic grain boundaries or in low-carbon steels from ferrite/austenite interfaces.

(d) In alloy steels and commercial plain carbon steels, manganese sulphides are present, not iron sulphide, which would melt at ordinary hot working temperatures and cause 'hot shortness'.

(e) In cast irons, similar structures are found, but the higher carbon content results in either primary cementite or flakes of graphite depending on alloy content and/or cooling rate. Graphite can also be present as a eutectic or as nodules. By careful preparation, the internal structure of graphite can be revealed by polarised light. Phosphorus introduces a characteristic eutectic of ferrite and Fe_3P or a ternary eutectic with Fe_3C called Steadite.

ETCHING OF IRON, STEEL AND CAST IRONS

Etching reagents are used for many purposes, such as:

1. To reveal the general structure of the steel for which a few reagents can be used for most steels.
2. To differentiate between various carbides or to differentiate carbides from nitrides (the latter remain unetched). For these, an enormous variety of quite complex reagents has been developed. It may be difficult to reproduce the effects claimed by those skilled in the use of these reagents, particularly the colours produced. Some of these reagents are used hot. In general, most reagents are based on an alkaline solution containing a mild, oxidising reagent and a chemical likely to cause selective staining of the minor phases. Phenolic mounts do not hold up well in boiling reagents, but the thermosetting epoxy resins are not degraded. In Table 10.18 a few tried and reliable etches are given which should be used before considering the more complex etches in the literature.
3. To reveal the prior-austenite grain boundaries in heat treated steels. The most successful etch is water saturated with picric acid (Note that special handling is required for picric acid to avoid the risk of fire and/or explosion and local regulations, must be consulted before use of this reagent) plus a wetting agent. Sodium dodecylbenzene sulphonate is very effective. A small

Table 10.18   ETCHING OF IRON STEEL AND CAST IRONS

See also refs. 1 and 19 for extended list of etchants. See general safety note at the start of this Chapter.

No.	Etchant		Conditions	Remarks
1	Nitric acid (1.40) Ethanol (Nital)	1.5–5 ml to 100 ml	5–30 s depending on steel	Ferrite grain boundaries in low carbon steels. Darkens pearlite and gives contrast with ferrite or cementite network. Etches martensite and its decomposition products in many steels. Better than picral for ferritic grain boundaries
2	Picric acid* Ethanol (Picral)	4 g 100 ml	5–30 s depending on steel	Similar to Reagent 1 but gives more uniform etch of pearlite. Better for detail of pearlite and bainite. Reveals undissolved carbides in martensite and gives better distinction of carbides in spheroidised steels. Differentiates pearlite and bainite. Does not etch ferrite grain boundaries or as-quenched martensite

(*continued*)

Table 10.18   ETCHING OF IRON STEEL AND CAST IRONS—*continued*

No.	Etchant		Conditions	Remarks
3	50/50 mixture of Reagents 1 and 2*		5–30 s depending on steel	Used for low alloy steels. Gives lower contrast but more even etching than Reagent 1
4	HCl (1.19) Picric acid* Ethanol (5 ml HCl and 1 g picric acid* usually referred to as Vilella's reagent)	1–5 ml 1–4 g to 100 ml	5–10 s	May attack prior-austenite boundaries; increased contrast between grains. (Attack of boundaries in martensite alloys increased if tempered for 30 min at 310°C). Good for tool steels and martensitic stainless steels
5	Chromium trioxide Water Sodium hydroxide (add carefully)	16 g 145 ml 80 g	10–30 min in boiling solution	Reveals intergranular oxidation of medium carbon alloy (nickel) steels as a white layer
6	Sodium metabisulphite Water	1–20 g to 100 ml	5–60 s	Increases contrast in martensitic steels; distinguishes pearlite, bainite and martensite in high carbon alloy steels
7	Picric acid* Sodium hydroxide Water	2 g 25 g to 100 ml	Either 10 s to 2 m. boiling soln. or electrolytically cold at 5–22 Am^{-2} for 2 min (stainless steel cathode)	Blackens cementite. No effect on M_7C_3, $M_{23}C_6$, M_6C or MC
8	Potassium ferricyanide Potassium or sodium hydroxide Distilled water to 100 ml (Murakami's reagent)	10 g 10 g	2–20 min at 20–50°C (or electrolytically as Reagent 7)	M_7C_3, $M_{23}C_6$ and iron phosphide stained. In cast irons, immerse 10 s at 80°C to darken iron phosphide, then 30 s, at 80°C to darken cementite unaffected by 10 s immersion. In stainless steels, carbides darken, sigma phase blue, ferrite yellow
9	Nitric acid (1.40) Hydrochloric acid (1.19) Glycerol (also known as Vilella's reagent but do not confuse with Reagent 4)	10 ml 20 ml 30 ml	Immerse up to 30 s or use electrolytically with stainless steel cathode *Do not keep, discard safely when yellow; gives off chlorine and NO$_x$ do not leave in contact with stainless steel*	Etches high chromium cast irons, stainless steel and high chromium steels. A mixture of 15 ml HCl, 10 ml glycerol and 5 ml HNO_3, known as glyceregia, is used to reveal the structure of stainless steels by swabbing.
10	Sodium hydroxide Water	20–45 g to 100 ml	5–60 s Electrolytic with 1–3 V d.c. stainless steel or Pt cathode	In stainless steels, sigma and chi phases yellow to reddish brown (chi etches before sigma), ferrite blue grey or tar, carbides outlined after longer etch
11	Potassium permanganate Sodium hydroxide Water	4 g 4 g to 100 ml	1–10 min in boiling soln. Electrolytic for 5–30 s as Reagent 10	In tool steels, blackens MO_2C, M_6C and $Cr_{23}C_6$
12	Ferric chloride Hydrochloric acid (1.19) Water	2 g 5 ml 30 ml	Immerse 1–5 min	In tool steels attacks ferrite and martensite, outlines carbides, leaves austenite unattacked

* Special handling is required for picric acid to avoid the risk of fire and/or explosion and local regulations must be consulted before use of this reagent.

teaspoon full is added to about 200 ml of the solution. The tridecyl version is also very effective as the wetting agent, but is harder to obtain. If the steel contains some Cr, it may be necessary to add a few drops of HCl per 100 ml of the etch. This etch works only when there is P in the steel, usually >0.005 wt. % is needed. The phosphorus segregates to the austenite grain boundaries during austenitisation. Good results are obtained with as-quenched steels and with

steels tempered up to about 550°C. Tempering in the range of about 350–550°C will also drive P to the prior-austenite grain boundaries, with the maximum rate at about 454–482°C. This etch is less effective or ineffective for steels with less than about 0.2 wt. % C. Reference 2 describes the use of etchants for revealing prior-austenite grain boundaries in great detail and lists many etchants for this purpose.

4. To reveal a phase selectively or to reveal segregation or dendrites in castings. These are specialised tasks that can often be done effectively with colour etchants. In stainless steels, one might want to preferentially colour or darken delta ferrite so that it can be measured. Other such phases include sigma and chi. In quality studies, a longitudinal section might be prepared to evaluate the degree of chemical segregation. In carbon and alloy steels, segregation might promote a banded, or layered pattern of alternating ferrite and pearlite, and in the pearlitic band other constituents, such as bainite and martensite, might be observed. In heat treated steels, the structure may be fully martensitic, nevertheless, chemical variations can be detected. In austenitic stainless steels, chemical variations can be detected in fully austenitic structures. To achieve these goals, colour tint etches are used. Dendritic structures in cast steels and cast irons are well revealed using colour etchants.

5. To reveal austenite grain boundaries in austenitic stainless steels, Fe–Ni magnetic alloys or austenitic Hadfield manganese steels. This requires special etchants. When annealing twins are present, it would facilitate grain size measurement if the twins were not revealed while bringing up the grain boundaries. This is possible in basic austenitic stainless steels using 60% HNO_3 in water, 20°C, 1.4 V dc, Pt cathode, 60–120 s. Other less noble materials work for the cathode, but voltage control may be different. If the voltage increases, twins will be revealed. This etch also has the advantage of revealing virtually all of the grain boundaries, while 'standard' stainless steel etchants used by immersion or swabbing, do not reveal a high percentage of the grain boundaries, and also bring up twin boundaries (this makes grain size measurements more difficult).

LEAD IN STEELS

Lead particles in free-cutting steels can be revealed by three reagents:

1.	10% ammonium acetate in water,	Brown stains on lead particles after 30 s immersion.
2.	30 g potassium dichromate 225 ml water (hot to aid solution) 30 ml acetic acid added to cold solution	10–20 s etch reveals lead as yellow to gold particles under cross-polars with polarised light. (Steel not etched)
3.	1 g potassium cyanide 100 ml water, mixed with 0.25 g diphenyl diacarbazone in 10 ml chloroform	Etch first in picrate. Rinse and dry. Then swab with this solution. Lead coloured red, especially under polarised light. Note: this is a very dangerous etch and some of the ingredients may be illegal to use.

The general distribution of lead can be displayed by the following:

1. Etched ground surface in nitric acid, wash and dry.
2. Cover for 5 min with absorbent paper soaked in mixture of 50% glacial acetic acid and 50% of 10% chromium trioxide in water.
3. Strip paper and wash with 10% acetic acid leaving yellow lead chromatic colouration. Wash with water.
4. Develop paper in either the third etchant above or in 1% potassium cyanide in 100 ml water plus 10 ml of 0.1% solution of dithizone in chloroform. After washing and drying, the distribution of lead is indicated by red spots. (This is generally applicable to distribution of lead in metals, e.g., in brasses.)

Today, most metallographers examine leaded steels by means of SEM using a backscattered electron image, as the strong atomic number contrast produces excellent images.

INCLUSIONS AND PRECIPITATES IN STEEL

Many of these can be recognised by shape and colour without etching and can be identified positively by X-ray analysis with scanning electron microscopes. The following notes are a useful guide to a quick optical assessment.

Iron phosphide	Brilliant white, especially in cast irons. Distinguished from cementite (Fe_3C) by alkaline potassium ferricyanide (Murakami's reagent) which darkens phosphide before cementite at 20°C or by alkaline sodium picrate which only darkens cementite.
Iron nitride	Bluish grey. Not attacked by alkaline potassium ferricyanide. Coloured yellow in 4% picric acid in ethanol. See earlier comments regarding the hazards of using picric acid.
Iron sulphide	Brownish yellow (only present in steels made before the 20th C).
Manganese sulphide	Dove grey. Ferrous sulphide is attacked by 1% oxalic acid in water; manganese sulphide is attacked by 10% chromic acid in water. Both deformed by hot rolling.
Chromium oxide	Dark bluish grey; brilliant green under polarised light (crossed polars).
Silicates	Iron silicate dark grey; manganese silicate somewhat lighter, greenish tint. Often glassy as spheres (as-cast condition) which show 'optical cross' under polarised light.
Titanium nitride	Sections of golden yellow cubes. If large amounts, dendritic growth from corners of cube but this is rare.
Zirconium nitride	As TiN but more lemon yellow.
Alumina	Angular particles in groups not elongated by rolling, usually bluish grey.
Silica	Dark angular particles, often not elongated by rolling (only sand entrapped in a casting will contain silica).

FERROMAGNETIC ANALYSIS

To distinguish between magnetic and non-magnetic phases, e.g., ferrite from austenite in iron–chromium–nickel alloys, a thin film of a colloidal suspension of magnetic particles is applied to the surface of a specimen subject to a magnetic field. The particles concentrate on the magnetic constituent, usually in a characteristic banded or mosaic pattern. The following suspension has been recommended.[62]

A coarse flaky precipitate of magnetite is prepared by dissolving 2 g of $FeCl_2 \cdot 4H_2O$ and 5.4 g of $FeCl_3 \cdot 6H_2O$ in 300 ml of hot water, and adding, with constant stirring, 5 g of caustic soda in 50 ml of water. The precipitate is filtered, washed with water and with 0.1 N hydrochloric acid.

Table 10.19   ELECTROLYTE ETCHING OF STEELS

See general safety note at the start of this Chapter. Some etches in Table 10.18 can be used electrolytically. The following are used exclusively electrolytically

No.	Etchant		Conditions	Remarks
1	Lead acetate Water	10 g to 100 ml	2 V d.c. Stainless steel cathode 5–20 s	In Fe–Cr–Ni cast alloys Sigma phase: blue red Ferrite: Dark blue Austenite: Pale blue Carbides: Yellow
2	Ammonium hydroxide (0.88)		2–6 V d.c. Pt cathode 30–60 s	Stainless and high alloy steels. Etches carbides; sigma phase unattacked
3	Chromium trioxide Water	10 g to 100 ml	3–6 V d.c. Pt cathode 5–60 s	Stainless steels. Carbides outlined and attacked. Austenite, ferrite, phosphide attacked in that order
4	Oxalic acid Water	10 g to 100 ml	6 V d.c. Stainless steel cathode 5–60 s	Outlines carbides first then grains in stainless steels
5	Potassium or sodium hydroxide Water	1 g to 100 ml	1–6 V d.c. Stainless steel cathode 5–30 s	By control of voltage, can be made to etch various phases sequentially. High voltages outline carbides and grains. Low voltages selectively stain phases in sequence. Establish behaviour on a given composition (which applies to most electrolytic etches)

On transferring the precipitate to 1 l of 0.5% soap solution and boiling, a colloidal suspension is obtained, which should be filtered from the unsuspended residue. The suspension may now be applied to the surface of the specimen, which is placed in the field of an electromagnet. The magnetic properties of the particles deteriorate gradually owing to oxidation. The addition of small amounts of photographic reducing agents has been found an advantage in this connection.[62] Commercially prepared ferromagnetic solutions ('Ferrofluid') can be obtained.

10.3.11   Lead

PREPARATION

The preparation of lead and its alloys for micrographical examination is difficult, owing to the softness of the metal. Lead preparation is similar in many aspects to preparing the other soft, low-melting point metals and alloys, such as Bi, Sn, In and Cd. All require careful sectioning with a metallographic laboratory abrasive cut-off saw or a low-speed or precision saw. In past practices, cutting with a hack saw was recommended, but this produces substantial deformation and a rough surface. Old preparation methods never removed the deformed metal and created new deformation so that the etchants used were more akin to deep etches or chemical polishes that removed a great deal of matrix. Examination by light microscopy revealed a black matrix with white second phase particles, but the etch depth was so extensive that only low magnifications could be used. Those practices should be avoided. Lead and its alloys can be prepared properly. Because diamond abrasives are largely ineffective with lead and its alloys, it is better to use the traditional method, perhaps employing SiC grits finer than 600 (P1200), followed by aqueous alumina slurries on a medium napped synthetic suede cloth, such as a Microcloth® pad. After proper cutting, to minimise surface deformation and roughness, the specimen can be mounted (cast resins may be preferred if the press temperature can cause phase changes, recrystallisation, grain growth, or even melting; but use a moulding practice and resin that gives the lowest possible heat of polymerisation).

Start grinding with the finest possible SiC paper, e.g., 320 or 400 grit (P400 or P800) with low loads 20 N (4 lbf) per specimen, 150–250 rpm, for about 30 s per sheet of paper (when doing 6 specimens at the same time). The SiC paper loads up faster when grinding these soft metals and alloys and has a shorter effective life. For grits of 600 (P1200) and finer, embedding is a problem. There are several things that can be done. First, waterproof alumina paper, if available, embeds less as the alumina is tougher. Secondly, one can coat the surface with candle wax which helps reduce embedding. It has been scientifically shown that candle wax is much more effective than natural bee's wax. If embedding occurs, whether or not the metallographer coats the paper, it can be removed by polishing with aqueous alumina slurries on the medium napped synthetic suede cloth. Diamond polishing will not remove embedded SiC particles. Grinding with 400, 600 and 800 grit (P800, P1200 and P1500) SiC paper, with water cooling, low loads, 150–250 rpm, for 30 s each, is adequate.

For rough polishing, one or two steps of aqueous calcined deagglomerated alumina slurries, using 3 and 1 or only a 1 μm particle size, on a synthetic suede medium napped cloth, at 20–25 N (5 lbf) per specimen, 120–50 rpm, for 4–5 minutes is adequate. If the metallographer grinds only to a 600 grit (P1200) SiC paper, use both steps. Final polishing can be performed with the same type cloth using either the 0.05 μm sol-gel alumina slurry (Masterprep™ alumina), or colloidal silica, at 15–20 N (4 lbf) per specimen, 80–150 rpm, for 4 minutes. If the automated polishing head speed is <100 rpm, use contrarotation. Examine the specimen and then etch with a mild etchant, such as Pollack's reagent (100 ml water, 10 g citric acid and 10 g ammonium molybdate). Remove the etch by repeating the final polish, then re-etch. Even better results can be obtained by following this procedure with a brief vibratory polish using colloidal silica on a synthetic suede medium napped cloth. Perfect surfaces can be obtained and fine detail of the structure, revealed using Pollack's reagent, can be examined at 1000X.

ETCHING

Rapid tarnishing (oxidation) of polished and etched samples may be avoided by the use of EDTA in the etchant, or as a rinse after etching with a 2% solution (see: washing and drying under Etching). Table 10.20 lists many etchants that have been used for lead and its alloys. Bear in mind that nearly all were developed for use on specimens that were poorly prepared and the etchant was designed for heavy attack. This makes examination of the matrix phase almost impossible and permits examination of second phases only at low magnification. Pollack's reagent (100 ml water, 10 g citric acid, 10 g ammonium molybdate) is a leaner version of etch 15 and produces superb results. 2% nital is also acceptable.

Table 10.20   ETCHING REAGENTS FOR LEAD AND ITS ALLOYS

See general safety note at the start of this Chapter.

No.	Etchant*		Remarks
1	Nitric acid		Recommended for pure lead. Specimen is alternately etched and washed until the desired result is obtained. Macro etch mainly
2	Acetic acid 5% in alcohol		Slow-acting grain contrast etch for lead
3	Acetic acid Hydrogen peroxide (30 vol.)	30 ml 10 ml	This is recommended as a general-purpose reagent for lead, and its alloys with tin, antimony, calcium, sulphur, selenium and tellurium, as well as many other metals. The proportions may have to be adjusted slightly to suit individual cases. The reagent may be made somewhat less vigorous by dissolving a little lead in it before use. The usual etching time is 3–5 s. The action is exothermic and may give rise to recrystallisation and grain growth if continued for too long a time. The reagent should not be kept for more than 1 h. It is recommended that the surface of the specimen be cleaned after etching with nitric acid. (*See also* Table 10.5)
4	Acetic acid Nitric acid Water	30 ml 40 ml 160 ml	Used at 40–42°C for lead, and lead–tin alloys rich in lead
5	Acetic acid Nitric acid Glycerol	10 ml 10 ml 40 ml	This reagent is recommended when the alternate etching and polishing technique is employed. Used for lead, lead–calcium, lead–antimony and lead–cadmium alloys. Also used for ternary lead–cadmium–antimony. The lead-rich matrix is grey, the compound SbCd blue, the antimony-rich solid solution whitish yellow, and the cadmium-rich solid solution brownish yellow. This reagent may be used hot (up to 80°C). (Beware of recrystallisation!)
6	Hydrochloric acid Nitric acid Alcohol	10 ml 5 ml 85 ml	Used for eutectic lead–tin alloys
7	Hydrochloric acid Ferric chloride Water	30 ml 10 g to 150 ml	Used mostly for lead–antimony alloys
8	Hydrochloric acid (1.19)		General reagent for grain boundary etching. Usually good for alloys containing antimony
9	Hydrochloric acid, 1–5% in alcohol		Used for lead–tin alloys. For higher tin contents the 5% reagent is preferable
10	Nitric acid, 5% in alcohol		Produces grain contrast in lead-rich alloys
11	Nitric acid, 10% in water		Used for lead-rich alloys. May be improved by the addition of a little chromic acid
12	Sodium hydroxide saturated in water		Used for lead–tin alloys
13	Silver nitrate, 5–10% in water		Swab etch used for lead–tin and lead–antimony alloys. Useful for anti-friction alloys in general
14	Molybdic acid Ammonium hydroxide Water Filter solution and add to nitric acid	100 g 140 ml 240 ml 60 ml	This reagent, applied by the alternate swab and wash technique, gives a rapid etching which is very effective for removing thick layers of cold worked metal. It may be followed by Reagent 5 An alternative is Russell's reagent (*see* Table 10.1)
15	Citric acid Ammonium molybdate Water	25 g 10 g 100 ml	A useful grain boundary etch for lead and dilute lead alloys. Often used after chemical polish

* Acids are concentrated, unless otherwise indicated.

10.3.12 Magnesium

PREPARATION

Magnesium and its alloys are among the most difficult metals to prepare that are routinely encountered by metallographers. Magnesium and its alloys are low in hardness, although precipitates can be present that are substantially harder and relief control can be difficult. Mg is an hcp metal and deformation twinning occurs readily during handling, even in compression mounting. Sectioning must be done with a proper laboratory cut-off saw, or with a low speed or precision saw, using the correct wheel and ample coolant to minimise damage. There is considerable debate in the literature over avoiding or not avoiding water during preparation. Some say that water must be avoided in the last step, others say water must be avoided in all steps, still others say water need not be avoided. Pure Mg is attacked rather slowly by water, while Mg alloys exhibit a greater attack rate. Experiments by the present author have showed that careful, restricted use of water in cleaning after the final step (and all preceding steps), was not harmful. Some metallographers use a 3:1 mixture of glycerol to ethanol as the coolant in all steps, including grinding. Always use a coolant when grinding as all metal dusts, including Mg dust, is harmful if inhaled.

The contemporary preparation practice can be used, but with certain modifications. After obtaining a proper cut, mount the specimen. If precipitation reactions are possible, use a castable resin and a practice that minimises the heat of polymerisation (see Mounting). Grind the specimens with water cooled SiC paper starting with the finest grit size possible, 220–320 grit (P240–P400), 20 N (5 lbf) per specimen, 250 rpm, until the cutting damage is removed and the samples in the holder are on the same plane. Oil-based diamond slurries can be used in place of aqueous slurries, for example. Oil is a better lubricant, so the surface finish is better after each step, with less drag, but cleaning is more difficult than with water-based diamond suspensions. Use three steps of oil-based diamond slurries with 9, 3 and 1 μm particles sizes, 120–150 rpm, contrarotation (if the head speed is <100 rpm) if possible, for 6, 5 and 4 minutes, respectively, on a synthetic chemotextile pad (known variously as Texmet[®], 1000, Pan W or Pellon[®]). Cleaning after each step was done by holding the specimen holder under running tap water (use lukewarm water) for about a second, just enough to remove much of the residue. Then, scrub the samples and the holder with ethanol using cotton, rinse with ethanol and blow dry under warm air.

The final step can be performed with several abrasives. Colloidal silica, although aqueous, works well with pure Mg, but it etches the alloys. The sol-gel alumina suspension, Masterprep[™] alumina, is an aqueous suspension, but does not seem to attack constituents in Mg alloys. A proprietary suspension called Masterpolish[®], which is nearly water free, has also been used and the results were excellent. All were utilising 0.05 μm particle size abrasives. They were used on a polyurethane synthetic pad with light load, 10–15 N (3 lbf) per specimen, 120–150 rpm (slower speeds are fine), for 90–180 s. The same washing procedure was used; brief rinse with lukewarm tap water, scrubbing with ethanol, rinse with fresh ethanol, and blow dry with hot air. Examine the specimen as-polished to see if the surface scratch control and relief control were adequate. Etch with one of the common reagents. If the structure is not crisp enough, repeat the last polishing step and re-etch. It is best to use surgical grade cotton as imperfections in cosmetic cotton puffs have been known to scratch polished Mg surfaces. Pure Mg, with its hcp crystal structure, will respond to polarised light. The response may be improved by using a polish-etch-polish cycle, or by using the vibratory polisher.

ETCHING

The general grain structure of alpha-Mg is revealed by examination under crossed polarised light. This will also reveal mechanical twins formed before or during preparation. A selection of etching reagents suitable for magnesium and its alloys is given in Table 10.21. Of these, 4 and 1 are the most generally useful reagents for cast alloys, while 16 is a useful macro-etchant and, followed by 4, is invaluable for showing up the grain structure in wrought alloys. The acetic-picral solutions are quite useful.

The appearance of constituents after etching. The micrographic appearances of the commonly occurring microconstituents in cast alloys are as given in Table 10.22.

ELECTROLYTIC ETCHING OF MAGNESIUM ALLOYS

The following has been recommended for forged alloys. The specimen is anodically treated in 10% aqueous sodium hydroxide containing 0.06 g l^{-1} of copper. A copper cathode is used and a current

Table 10.21   ETCHING REAGENTS FOR MAGNESIUM AND ITS ALLOYS

See general safety note at the start of this Chapter.

No.	Etchant*		Remarks
1	Nitric acid Diethylene glycol Distilled water	1 ml 75 ml 24 ml	This reagent is recommended for general use, particularly with cast, die-cast and aged alloys. Specimens are immersed for 10–15 s, and washed with hot distilled water. The appearance of common constituents following this treatment is outlined in Table 10.22. Mg-RE (rare earth) alloys also
2	Nitric acid Glacial acetic acid Water Diethylene glycol	1 ml 20 ml 19 ml 60 ml	Recommended for solution-heat-treated castings, and wrought alloys. Grain boundaries are revealed. The proportions are somewhat critical. Use 1–10 s
3	Citric Acid Water	5 g 95 ml	This reagent reveals grain boundaries, and should be applied by swabbing. Polarised light is an alternative
4	Nitric acid, 2% in alcohol		A generally useful reagent
5	Nitric acid, 8% in alcohol		Etching time 4–6 s. Recommended for cast, extruded and rolled magnesium–manganese alloys
6	Nitric acid, 4% in alcohol		Used for magnesium-rich alloys containing other phases, which are coloured light to dark brown
7	Nitric acid, 5% in water		Etching time 1–3 s. Recommended for cast and forged alloys containing approximately 9% of aluminium
8	Oxalic acid, $20\,\mathrm{g\,l^{-1}}$ in water		Etching time 6–10 s. Used also for extruded magnesium–manganese alloys
9	Acetic acid, 10% in water		Etching time 3–4 s. Used for magnesium–aluminium, alloys with 3% of aluminium
10	Tartaric acid, $20\,\mathrm{g\,l^{-1}}$ of water		Etching time 6 s ⎫ ⎬ These reagents are recommended for magnesium alloys with 3 to 6% of Etching time 12 s ⎭ aluminium
11	Orthophosphoric acid, 13% in glycerol		
12	Tartaric acid, $100\,\mathrm{g\,l^{-1}}$ of water		Used for wrought alloys. Mg_2Si is roughened and pitted. 10 s to 2 min for Mg–Mn–Al–Zn
13	Citric acid and nitric acid in glycerol		Used for magnesium-zirconium alloys. The magnesium-rich matrix is darkened and other phases left white
14	Orthophosphoric acid Picric acid[‡] Ethanol	0.7 ml 4 g 100 ml	Recommended for solution-heat-treated-castings. The specimen is lightly swabbed, or immersed with agitation for 10–20 s. The magnesium-rich matrix is darkened, and other phases (except Mg_2Sn) are little affected. The maximum contrast between the matrix and $Mg_{17}Al_{12}$ is developed. The darkening of the matrix is due to the development of a film, which must not be harmed by careless drying
15	Picric acid saturated in 95% alcohol[‡] Glacial acetic acid	10 ml 1 ml	A grain boundary etching reagent; especially for Dow metal (Al 3% Zn 1%, Mn 0.3%). Reveals cold work and twins
16	Picric acid, 5% in ethanol[‡] Glacial acetic acid Distilled water	50 ml 20 ml 20 ml	Useful for magnesium–aluminium–zinc alloys. On etching for 15 s, an amorphous film is produced on the polished surface. When dry, the film cracks parallel to the trace of the basal plane in each grain. The reagent may be used to reveal changes of composition within grains, and other special purposes
17	Picric acid, 5% in ethanol[‡] Glacial acetic acid Distilled water	50 ml 16 ml 20 ml	As for reagent 16, but suitable for a more restricted range of alloy composition[63]
18	Picric acid, 5% in ethanol[‡] Glacial acetic acid Nitric acid (1.40)	100 ml 5 ml 3 ml	General reagent[64]
19	Picric acid, 5% in ethanol[‡] Distilled water	10 ml 10 ml	Mg_2Si is coloured dark blue and manganese-bearing constituents are left unaffected[63]

(continued)

Table 10.21   ETCHING REAGENTS FOR MAGNESIUM AND ITS ALLOYS—*continued*

No.	Etchant*		Remarks
20	Hydrofluoric acid (40%)[§] Distilled water	10 ml 90 ml	Useful for magnesium–aluminium–zinc alloys. $Mg_{17}Al_{12}$ is darkened, and $Mg_3Al_2Zn_3$ is left unetched. If the specimen is now immersed in dilute picric acid solution (1 vol. of 5% picric acid in alcohol and 9 vol. of water) the matrix turns yellow, and the ternary compound remains white[63‡]
21	Picric acid[‡], 5% in ethanol Distilled water Glacial acetic acid	100 ml 10 ml 5 ml	Reveals grain-boundaries in both cast and wrought alloys. This reagent is useful for differentiating between grains of different orientations, and for revealing internally stressed regions[63]
22	Nitric acid conc.		Recommended for pure metal only. Specimen is immersed in the cold acid. After 1 min a copious evolution of NO_2 occurs, and then almost ceases. At the end of the violent stage, the specimen is removed, washed and dried. Surfaces of very high reflectivity result, and grain boundaries are revealed

* Acids are concentrated, unless otherwise indicated, e.g., with specific gravity.
‡ Special handling is required for picric acid to avoid the risk of fire and/or explosion and local regulations must be consulted before use of this reagent.
§ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

Table 10.22   THE MICROGRAPHIC APPEARANCE OF CONSTITUENTS OF MAGNESIUM ALLOYS

Microconstituent	*Appearance in polished sections, etched with Reagent 1 (zirconium-free alloys)*
$Mg_{17}Al_{12}$ (see note 1)	White, sharply outlined and brought into definite relief
$MgZn_2$ (see note 2)	Appearance very similar to that of $Mg_{17}Al_{12}$
$MgAl_2Zn_3$ (see note 3)	Appearance similar to those of $Mg_{17}Al_{12}$ and $MgZn_2$
Mg_2Si (see note 4)	Watery blue green; the phase usually has a characteristic, Chinese-script formation, but may appear in massive particles. Relief less than for manganese
Mg_2Sn (see note 4)	Tan to brown or dark blue, depending on duration of etching. Individual particles may differ in colour
Manganese (see note 5)	Grey particles, usually rounded and in relief. Little affected by etching
(MgMnAl) (see note 5)	Grey particles, angular in shape and in relief. Little affected by etching

Microconstituent	*Appearance in polished sections, etched with Reagent 4 (zirconium-bearing alloys)*
Primary Zr (undissolved in molten alloy)	Hard, coarse, pinkish grey rounded particles, readily visible before etching
Zinc-rich particles (see note 6)	Fine, dark particles, loosely clustered and comparatively inconspicuous before etching
Mg_9Ce	Compound or divorced eutectic in grain boundaries. Appearance hardly changed by few percent of zinc or silver
Mg_5Th	Compound or divorced eutectic in grain boundaries (bluish). Appearance hardly changed by few percent of zinc if Zn exceeds Th
Mg–Th–Zn	Brown acicular phase. Appears in Mg–Th–Zn–Zr alloys when Th ≥ Zn
$MgZn_2$	Compound or divorced eutectic in grain boundaries. Absent from alloys containing rare earths or Th

(1) This is the γ-phase of the magnesium–aluminium system; it is also frequently called Mg_4Al_3 or Mg_3Al_2.
(2) Although the phase MgZn may be observed in equilibrium conditions, $MgZn_2$ is frequently encountered in cast alloys.
(3) This ternary compound occurs in alloys based on the ternary system magnesium–aluminium–zinc and may be associated with $Mg_{17}Al_{12}$.
(4) Blue unetched.
(5) These constituents are best observed in the unetched condition.
(6) Alloys of zirconium with interfering elements such Al, Fe, Si, N and H, separating as a Zr-rich precipitate in the liquid alloy. Co-precipitation of various impurities makes the particles of indefinite composition.
Note: The microstructure of all zirconium—bearing cast alloys with satisfactory dissolved zirconium content is characterised by Zr-rich coring in the centre of most grains. In the wrought alloys zirconium is precipitated from the cored areas during preheating or working, resulting in longitudinal striations of fine precipitate which become visible on etching.
For descriptions of the metallography of magnesium alloys references 66 and 67 should be consulted.

density of $0.53\,A\,dm^{-2}$ is applied at 4 V. After etching, the specimen is successively washed with 5% sodium hydroxide, distilled water and alcohol, and is finally dried.

NON METALLIC INCLUSIONS IN MAGNESIUM-BASED ALLOYS[64,65]

The detection and identification of accidental flux and other inclusions in magnesium alloys involves the exposure of a prepared surface to controlled conditions of humidity, when corrosion occurs at the site of certain inclusions, others being comparatively unaffected. The corrosion product or the inclusion may then be examined by microchemical techniques.

MAGNESIUM ALLOYS

The surface to be examined should be carefully ground and polished as described above. Alcohol or other solvents capable of dissolving the flux must be avoided. As soon as possible the prepared specimens are placed in a humidity chamber, having been protected in transit by wrapping in paper. A suitable degree of humidity is provided by the air above a saturated solution of sodium thiosulphate. The presence of corrosive inclusions is indicated by the development of corrosion spots. At this stage the corroded area may be lightly ground away to expose the underlying structure for microexamination so that the micrographic features which are holding the flux become visible. With other specimens, or with the same specimens re-exposed to the humid conditions, identification of the inclusions may be proceeded with, as follows:

1. Detection of chloride
The corrosion product is scraped off, and dissolved on a microscope slide in 5% aqueous nitric acid. A 1% silver nitrate solution is then added, and a turbidity of silver chloride indicates the presence of the chloride ion. The solution of the corrosion product should preferably be heated before adding the silver nitrate to remove any sulphide ions, which also gives rise to turbidity. Alternatively, a 10% solution of chromium trioxide may be added directly to the corrosion spot, when chloride is indicated by an evolution of gas bubbles from the metal surface, and the development of a brown stain. This method is less specific than the silver nitrate method, and may give positive reactions in the presence of relatively large amounts of sulphates and nitrates.

2. Detection of calcium
Scrapings of corrosion product are dissolved in a small watch glass on a hot plate in 2 ml water and one drop of glacial acetic acid. A few drops of saturated ammonium oxalate solution are added to the hot solution. The presence of calcium is indicated by turbidity or precipitation. Spectroscopic identification of calcium in the solution is also possible.

3. Detection of boric acid in inclusions
Scrapings of corrosion product and metal are placed in a test tube with 1 ml of water. The inclusion dissolves, and complete solution of the sample is effected by adding a small portion of sulphuric acid (density 1.84) from 9 ml carefully measured and contained in a graduated cylinder. When solution is complete, the remainder of the acid is added and the mixture is well shaken; 0.5 ml of a 0.1% solution of quinalisarin in 93% (by weight) of sulphuric acid is now added, mixed in, and allowed to stand for 5 min. A blue colour indicates the presence of boric acid. The colour in the absence of boric acid varies from bluish violet to red according to the dilution of the acid, which must thus be carefully controlled as described.

4. Detection of nitride
A drop of Nessler's solution applied directly to the metal surface in the presence of nitride, gives an orange brown precipitate, which may take about 1 min to develop. This test should be made on freshly prepared surfaces on which no water has been used, since decomposition of nitride to oxide occurs in damp air.

5. Detection of sulphide
The corrosion product is added to a few drops of water slightly acidified with nitric acid. A drop of the solution placed on a silver surface gives rise to a dark stain if sulphide was present in the corrosion product. Sulphur printing may also be applied.

6. Detection of iron
The corrosion product is dissolved in hydrochloric acid. A drop of nitric acid is added with several drops of distilled water. In the presence of iron, the addition of a crystal of ammonium thiocyanate develops a blood-red colouration.

In all the above tests, a simultaneous *blank* test should be carried out.

Iron-printing, analogous to sulphur-printing, can be applied using cleaned photographic paper impregnated with a freshly prepared solution of potassium ferricyanide and potassium ferrocyanide acidified with nitric or hydrochloric acid.

10.3.13 Molybdenum

PREPARATION

Refractory metals and alloys are difficult to prepare as they exhibit low grinding and polishing rates and are easily deformed or smeared during preparation. Regardless of their actual indentation hardness, which is not high, cutting of refractory metals, such as Mo and its alloys, is slow and tedious. Avoid production cutting devices, such as power hack saws. Use a good laboratory abrasive cut-off saw with a very softly bonded wheel, designed for cutting refractory metals (such as Ti, Zr, Hf, etc.). Mo and its alloys can be tough or brittle, depending upon composition. They are susceptible to damage production during cutting and grinding. The contemporary method (see Mechanical Polishing) can be used, but requires modification. After sectioning, start with the finest possible grit size SiC paper, e.g., 320 grit (P400) SiC. Use moderate loads, 25–30 N (6 lbf) per specimen, 150–250 rpm, and grind until the cutting damage is removed and all surfaces are at the same plane. Next, use 9 μm diamond on a psa-backed selected silk cloth, such as an Ultra-Pol™ cloth, at the same load, 150–200 rpm, for 10 minutes. Charge the cloth with diamond paste and add the proper lubricant. During the 10 minute cycle, periodically add the same size diamond in slurry or suspension form. Keep the cloth properly lubricated during diamond polishing to minimise flowed metal. Next, use 3 μm diamond, in like manner, with a woven polyester pad, such as a Trident™ cloth, with the same load, 150–200 rpm, for 8 minutes. If the sample holder's head speed is <100 rpm, run these steps in contrarotation mode. A 1 μm diamond step, similar to the 3 μm step, can be used for the more difficult grades. Final polishing uses either the medium-nap, synthetic suede cloth, or a polyurethane pad, with colloidal silica at the same load, 120–150 rpm, for 5 minutes. For best results, an attack polish agent must be added to the colloidal silica. Many solutions have been recommended.[2] A 1:5 mixture of hydrogen peroxide (30% conc.) to colloidal silica is effective. A similar mix of 5–20% CrO_3 in water to colloidal silica also works well (see comments regarding this attack polish reagent under preparation of gold). Diluted Murakami's reagent has also been used.

ETCHING

Molybdenum is not easy to etch, but there are good etchants available. An excellent etchant for Mo consists of water, hydrogen peroxide (30% conc.) and sulphuric acid in a 7:2:1 ratio. If the specimen is immersed for 2 minutes, the grain structure is revealed in colour. If the etch is used by swabbing, a grain boundary etch results. Listed below are two additional useful etchants.

Etchant		*Conditions*	*Remarks*
1. (a) Potassium hydroxide	10 g	Mix equal amounts of	Grain boundary etch
Water	to 100 ml	(a) and (b) as needed	
(b) Potassium ferricyanide	10 g		
Water	to 100 ml		
2. Ammonia (0.88)	50 ml	Boil for up to 10 min	General etch
Hydrogen peroxide (3%)	50 ml		
Water	50 ml		

10.3.14 Nickel

PREPARATION

Nickel is a face-centred cubic metal and shares many of the preparation problems of other fcc metals. Damage is easily introduced during cutting and grinding. Pure Ni is more difficult to prepare than its alloys. Ni–Fe and Ni–Cu alloys can be rather challenging subjects while the Ni-based superalloys are simpler. The latter are prepared much like austenitic stainless steels and share common etchants. The contemporary method works well for Ni and its alloys (see Mechanical Polishing), although it must be modified somewhat. For pure Ni, Ni–Cu and Ni–Fe alloys, start with the best possible

cut surface, i.e., least amount of induced deformation and smoothest surface. Always cut with a laboratory abrasive cut-off saw using the correct wheel, low pressure and ample coolant. Grind with 220, 240 or 320 grit (P240–P400) SiC paper, or alternative surfaces with similar abrasive sizes. Use 20–25 N (5 lbf) load per specimen, 200–300 rpm, until the cutting damage is removed and all the specimens are on the same plane.

Polish with three steps of diamond abrasive, 9, 3 and 1 μm diamond. Charge the cloth with diamond paste (see mechanical polishing) and add the recommended lubricant. Add the same diamond size as a slurry or suspension during the cycle. Use napless, woven cloths that yield the best possible surface finish, e.g., a psa-backed selected silk with the 9 μm diamond and a psa-backed (or a magnetic platen setup) polyester cloth with both 3 and 1 μm diamond sizes. Use 25–30 N (6 lbf) load per specimen, 100–150 rpm, and 5, 3 and 2 minutes for the 9, 3 and 1 μm steps, respectively. Final polishing is conducted with 0.05 μm colloidal silica or sol-gel alumina suspensions using the medium napped, synthetic suede cloth or a polyurethane cloth, both psa-backed (or a magnetic platen setup), at the same load, 80–150 rpm, for up to 2 minutes. Contrarotation is preferred if the head speed is <100 rpm. Examine the specimen, then etch it. If the surface quality is inadequate, remove the etch by repeating the last step, and re-etch. Alternatively, particularly with these alloys, remove the etch with the last step, then place the specimens on the vibratory polisher using a psa-backed synthetic suede cloth and colloidal silica for 20–30 minutes. This will facilitate removal of the last remnants of damage. The Ni-based superalloys are prepared in a similar manner, although the 1 μm step can usually be dropped, especially for solution annealed and aged specimens. If the 1 μm step is dropped, increase the 3 μm step time to 5 minutes.

ETCHING

Since nickel is generally resistant to corrosive media, etching involves the use of rather aggressive reagents, which tend to form etch pits and may attack inclusions. The difficulty of etching increases with the purity of the metal. Some etchants for pure Ni, such as No. 10, are rather dangerous to use. They must be used under a properly working chemical fume hood by personnel well-versed in such etchants' potential danger. In general, etching reagents (Table 10.23) either reveal the grain boundaries ('flat etch') or produce grain contrast (less common). Low-nickel copper–nickel alloys may be etched by the reagents recommended for the purpose under *Copper*. Heat-resisting nickel-base alloys are etched with the solutions used for stainless steels (Table 10.18).

ELECTROLYTIC ETCHING OF NICKEL AND ITS ALLOYS

This technique frequently gives better results than ordinary immersion or swab etching. Suitable solutions are summarised in Table 10.24.

Table 10.23   ETCHING REAGENTS FOR NICKEL AND ITS ALLOYS

See general safety note at the start of this Chapter.

No.	Etchant*		Remarks
1	Nitric acid (1.40)	10 ml	Pure nickel, and nickel–chromium alloys. Grain boundaries etched
	Hydrochloric acid (1.19)	20 ml	
	Glycerol	30 ml	
2	Nitric acid (1.40)	10 ml	Used for pure nickel, cupro–nickel, Monel metal and nickel–silver
	Acetic acid	10 ml	
	Acetone	10 ml	
3	Nitric acid (1.40)	50 ml	Useful for nickel and most nickel-rich alloys
	Glacial acetic acid	25 ml	
	Water	25 ml	
4	Nitric acid, 2% in alcohol, mixed in various proportions with hydrochloric acid, 2% in alcohol		Used for pure nickel

(continued)

Table 10.23   ETCHING REAGENTS FOR NICKEL AND ITS ALLOYS—*continued*

No.	Etchant*		Remarks
5	Hydrochloric acid Ferric chloride Water	30 ml 10 g 120 ml	Pure nickel
6	Hydrochloric acid (1.19) Ferric chloride Water	20 ml 10 g 30 ml	Pure nickel
7	Sulphuric acid (1.84) Hydrogen peroxide (10%)	1 ml 10 ml	Pure nickel
8	Sulphuric acid (1.84) Potassium dichromate (saturated in water)	10 ml 50 ml	Pure nickel
9	Ammonium persulphate, $100 \, g \, l^{-1}$ of water		Cast nickel
10	Ammonium persulphate, 10% in water Potassium cyanide, 10% in water	10 ml 10 ml	Pure nickel. Also recommended for cross-sections of nickel plated steels. The steel is not affected but may be etched by Reagent 2 for *Iron and steel*
11	Ammonium hydroxide		Used as a polish attack for nickel plate
12	Ammonium hydroxide Hydrogen peroxide (30%)	85 ml 15 ml	Used for nickel–silvers

* Acids are concentrated, unless otherwise indicated, e.g., with specific gravity.

Table 10.24   ELECTROLYTIC ETCHING OF NICKEL ALLOYS

See general safety note at the start of this Chapter.

No.	Etchant*		Conditions	Remarks
1	Sulphuric acid (1.84) Hydrogen peroxide (30%) Water	22 ml 12 ml to 100 ml	6 V d.c. Pt cathode 5–30 s	General etch
2	Sulphuric acid (1.84) Water	5 ml to 100 ml	6 V d.c. Pt cathode 5–15 s	All Ni-base alloys, especially Ni–Cu and Ni–Cr. Delineates carbides
3	Ammon. Persulphate Water	10 g to 100 ml	6 V d.c. Nickel cathode	Most alloys, especially Ni–Fe, Ni–Cr cast alloys
4	Chromium trioxide Water	6 g to 100 ml	As etchant 3	As etchant 3
5	Nitric acid (1.40) Glacial acetic acid Water	10 ml 5 ml 85 ml	1.5 V d.c. Pt cathode 20–60 s *(do not keep)*	Grain contrast for all nickel alloys
6	Oxalic acid Water	10 g 100 ml	6 V d.c. Stainless steel cathode 10–15 s	Superalloys, Ni–Au, Ni–Cr, Ni–Mo alloys
7	Phosphoric acid (1.71) Water (if necessary, sulphuric acid (1.84))	70 ml 30 ml 15 ml	2–10 V d.c. Ni cathode 5–60 s	Superalloys, Ni–Cr, Ni–Fe
8	Phosphoric acid (1.71) Sulphuric acid (1.84) Chromium trioxide	85 ml 5 ml 8 g	10 V d.c. Pt cathode 5–30 s	Ni-base superalloys. Gamma prime. Ti and Nb segregation

* Acids are concentrated, unless otherwise indicated, e.g., with specific gravity.

10.3.15   Niobium

PREPARATION

Niobium is soft and tough while its alloys are harder and simpler to prepare. Use the method described for molybdenum. Final polishing is performed using an attack-polishing agent, such as 30% conc. hydrogen peroxide. The following attack polishing solution can be added (exercising great care with respect to both operation and subsequent clean up in view of the hazards of hydrofluoric acid) to aqueous alumina slurries:

Hydrofluoric acid	2 ml
Nitric acid	5 ml
Lactic acid	30 ml

Note: Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

Attack polishing using manual methods is quite tedious and increases the risk that the metallographer will have physical contact with the chemicals, even when using the correct personal protective equipment. An automated polisher should be used to reduce the risk of accidents.

Chemical polishing solutions are often used after mechanical polishing refractory metals and alloys to further improve the surface quality. A good solution consists of 30 ml water, 30 ml nitric acid, 30 ml HCl and 15 ml HF. Use at room temperature by swabbing or by immersion. Another solution contains 120 ml water, 6 g ferric chloride, 30 ml HCl and 16 ml HF. Immerse the specimen 2 minutes. This chemical polish is also recommended for V (immerse 1 minute) and for Ta (immerse for 3 minutes).

Table 10.25   ETCHING REAGENTS FOR NIOBIUM ALLOYS

See general safety note at the start of this Chapter.

No.	Etchant*		Conditions	Remarks
1	Hydrochloric acid (1.19)	15 ml	Immerse 10–60 s	The only general-purpose etch free from HF
	Sulphuric acid (1.84)	15 ml		
	Nitric acid (1.40)	8 ml		
	Water	62 ml		
2	Hydrofluoric acid (40%)‡	10 ml	Immerse 15–20 s	General etch
	Nitric acid (1.40)	10 ml		
	Lactic acid	30 ml		
3	Hydrofluoric acid (40%)‡	10 ml	Immerse up to 3 min *or*	Grain boundary etch, especially at low voltages, electrolytically
	Nitric acid (1.40)	20 ml	Use electrolytically	
	Water	70 ml	12–30 V d.c. Pt cathode up to 1 min	

* Acids are concentrated, unless otherwise indicated, e.g., with specific gravity.
‡ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

10.3.16   Platinum group metals

PREPARATION

The preparation of these metals is similar to that of gold (see section on Gold). The method described to prepare gold and high gold alloys works well for the other precious metals and will produce surfaces free of damage.

ETCHING

The reagents given in Table 10.25 will produce satisfactory microstructures if the preparation and polishing have been done carefully. These reagents are very strong and great care must be exercised in their use. They should only be used by people well trained in the use of dangerous chemicals.

Table 10.26   ETCHING REAGENTS FOR PLATINUM GROUP

See general safety note at the start of this Chapter.

No.	Etchant*		Conditions	Remarks
1	Aqua Regia Nitric acid (1.4) Hydrochloric acid (1.19)	 34 ml 66 ml	Up to 1 min. May need to be warmed	Pt, Pd, Rh alloys
2	Potassium ferricyanide Sodium hydroxide Water	3.5 g 1 g 150 ml	Several minutes	Most alloys, including Os alloys
3	Hydrochloric acid (1.19) Hydrogen peroxide (3%) Water	20 ml 1 ml 80 ml	Several minutes	Ru alloys
4	Potassium cyanide Water	5 g 100 ml	Electrolytic 1–5 V a.c. Pt cathode 1–2 min	Pt alloys
5	Hydrochloric acid (1.19) Sodium chloride Water	20 ml 25 g 65 ml	Electrolytic with Pt or graphite electrode. 25 s 10 V a.c. 1 min 1.5 V a.c. 1–2 min 20 V a.c. 1 min 6 V a.c. 1 min 5–20 V a.c.	 Rh alloys Pt-Rh alloys Ir alloys Pt alloys Ru-base alloys
6	Hydrochloric acid (1.19) Ethanol	10 ml 90 ml	Electrolytic 30 s, 10 V a.c. Graphite cathode	Os, Pd, Pt, Ir
7	Hydrochloric acid (1.19)		1–2 min electrolytic 5 V a.c. Pt or graphite electrode	Rh, Pt. Grain contrast

* Acids are concentrated, unless otherwise indicated, e.g., with specific gravity.

10.3.17   Silicon

PREPARATION

Silicon, which is very hard and brittle, is not often prepared for metallographic examination except in the area of electronic devices. Grinding Si with coarse grit SiC paper produces extensive damage to both the leading and trailing edges and should be avoided. Cut the specimen as close as possible to the desired plane-of-polish. Mounting in cast epoxy is preferred due to the brittleness of silicon. Si can be prepared in three steps, assuming that it has been sectioned using a low-speed saw or a precision saw. The first step uses a type A diamond lapping film, (e.g., an Ultra-Prep type A film) with 15 μm diamond abrasive and water cooling, with firm pressure, 100–150 rpm, until the cutting damage is removed, the surface is flat and has reached the desired location. Step 2 uses a synthetic chemotextile pad, such as Texmet® 1000, Pan W or Pellon®, with 3 μm diamond paste, 30 N (7 lbf) load, 240–300 rpm, for 2 minutes. A unique aspect of this step is the use of the 0.05 μm sol-gel alumina suspension as the lubricant with the diamond, rather than the traditional lubricant. This produces a dual polishing action that is very beneficial. The third, and final, step is with colloidal silica on a synthetic polyurethane pad, 20–25 N (5 lbf) load per specimen, 100–150 rpm for 90 s. Silicon responds well to colloidal silica. Specific details about preparing integrated circuits and other devices containing Si can be found in ref. [18].

ETCHING

Polished surfaces of silicon may be etched with 5% aqueous hydrofluoric acid, to which various amounts of concentrated nitric acid may be added. Microstructures developed in this way show angular grains, with twin markings, together with the particles of other constituents due to the presence of impurities (e.g., iron, aluminium and calcium).

Commercial silicon may contain inclusions of slag and unreduced quartz. Silicate inclusions may be detected by etching a polished section for 3 h in a stream of chlorine. The specimen is then immersed in concentrated hydrofluoric acid for 10 min in order to etch and attack the quartz

Table 10.27 ETCHING REAGENTS FOR SILVER AND ITS ALLOYS

See general safety note at the start of this Chapter.

No.	Etchant*		Remarks
1	Ammonium hydroxide and hydrogen peroxide—various proportions		The silver-rich matrix is in general unaffected. Other phases (e.g., the β silver–antimony phase) are often coloured blue to brown
2	Ammonium hydroxide Hydrogen peroxide (3%)	50 ml 10–30 ml	Recommended for silver, silver–nickel and silver–palladium alloys. Also useful for the examination of silver-soldered joints
3	Sulphuric acid (10% in water) to which a few crystals of chromic acid CrO_3 have been added (2 g)		This reagent reveals the grain structure of silver and silver-rich alloys
4	Solution containing $7.6\,g\,l^{-1}$ of chromic acid (CrO_3) and $8\,g\,l^{-1}$ of sulphuric acid		Useful general etching reagent. Used as a sensitive etching reagent for silver–copper alloys
5	Ferric chloride $20\,g\,l^{-1}$ of water		Recommended for silver solders
6	Potassium cyanide, 10% in water Ammonium persulphate, 10% in water	10 ml 10 ml	Etch for pure silver and dilute alloys. Duration 1–2 min
7	Solution A: 50:50 nitric acid in water Potassium dichromate Solution B: Chromic acid CrO_3 Sodium sulphate Water	100 ml 2 g 20 g 1.5 g 100 ml	Used for silver alloys in general. Solution A is diluted to 20 vol. and an equal amount of solution B added. The reagent is applied by gentle swabbing or with a camel hair brush. A loose film of silver chromate should form if the reagent is working correctly. If the film is adherent, more of solution A should be added. If no film forms, more of solution B is required
8	Chromic acid, CrO_3, 0.2% and sulphuric acid, 0.2% in water		Used (1 min immersion) for silver and silver-rich alloys
9	Potassium dichromate saturated in water Sodium chloride saturated in water Sulphuric acid	100 ml 2 ml 10 ml	Silver and silver-rich alloys. Silver solders
10	Chromic acid and hydrogen peroxide in water. Various proportions		General reagent. Composition adjustments must be made to suit specific cases
11	Sodium hydroxide (10%) Potassium ferricyanide (30%)	10 ml 10 ml	5–15 s. Ag alloys with W, Mo and WC (dilute with equal vol. of water if too fast)

* Acids are concentrated, unless otherwise indicated, e.g., with specific gravity.

inclusions (*see also* Table 10.9). This is a very dangerous etching procedure that requires properly designed equipment, correct ventilation, and well trained personnel.

10.3.18   Silver

PREPARATION

Silver is very soft and ductile, and is prepared in the same manner as gold and its alloys. The method is described in the section for gold. Embedding of abrasives can be a problem, as for gold.

Pure silver and dilute silver alloys are difficult to etch, but several solutions will give good results on duplex or more complex alloys. The strengths of the reagents, unless otherwise noted in Table 10.27, should be adjusted to the specific alloys to be examined.

ELECTROLYTIC ETCHING OF SILVER

In many cases excellent grain boundary and grain contrast etching is obtained by electrolysis (specimen as anode) in one of the solutions given in Table 10.28.

See also reagents listed for electrolytic polishing of silver, Table 10.4b. The silver cyanide–potassium carbonate reagent in Table 10.4b is particularly convenient, because, on reduction of the polishing potential from 1.5 to 0.5 V for 90 s, etching occurs.

Table 10.28 ELECTROLYTIC ETCHING OF SILVER ALLOYS

See general safety note at the start of this Chapter.

No.	Etchant*	Remarks
1	Citric acid 100 g l^{-1} of water	15 s to 1 min. 6 V d.c. Ag cathode. Most alloys
2	Ammoniacal ammonium molybdate	Molybdic acid is dissolved in an excess of strong ammonia. The composition is not critical provided ammonia is in excess. The optimum potential and current density should be experimentally established for each case
3	Potassium cyanide 50 g l^{-1} of water	This reagent is used particularly for silver when it is in contact with other metals, as in plated articles. Optimum conditions should again be established experimentally
4	Hydrofluoric acid + a little stannous chloride‡	Used for silver–tin alloys containing more than 73% of silver

* Acids are concentrated, unless otherwise indicated, e.g., with specific gravity.

‡ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

10.3.19 Tantalum

PREPARATION

The preparation of tantalum (pure and commercial) follows the same procedures as described for Mo and Nb (see these sections). Attack polishing agents are often used (see previous comments on safety issues). The following mixture has been used as the polishing medium:

Alumina, carefully levigated	35 g
Hydrofluoric acid (60%)	20 ml
Ammonium fluoride	20 g
Distilled water	1000 ml

Note: Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

Chemical polishing is often used after mechanical polishing to further improve the surface quality. Kelly recommends the following mixture: 25 ml lactic acid, 15 ml nitric acid and 5 ml HF. Swab vigorously for 2 minutes.

ETCHING

The reagents given in Table 10.29 have been found useful.

10.3.20 Tin

PREPARATION

Tin is allotropic with a body-centred tetragonal crystal structure at room temperature. It will respond to polarised light when properly polished. Because of its relative softness, the same precautions should be observed as for lead and its alloys. The method described for lead, works well for tin.

For further details of methods for tin and tin alloys, refs.[1, 19, 69–71] may be consulted.

ETCHING

Tin is anisotropic and the grain structure can be revealed under crossed polarised light. The reagents of Table 10.30 have been recommended for tin-rich alloys. In general, etching times are not critical and the progress of the treatment should be judged visually.

Table 10.29   ETCHING REAGENTS FOR TANTALUM

See general safety note at the start of this Chapter.

No.	Etchant*		Remarks
1	Ammonium fluoride, 20% in water Hydrofluoric acid (43%), 60% in water‡	10 ml 10 ml	Used at 50–60°C (ineffective when cold). Immersion for 1 min etches up the structure of tantalum without colouring inclusions of tantalum sulphide, Ta_2S_5
2	Ammonium fluoride, 20% in water Sulphuric acid (1.84)	10 ml 20 ml	Used at 60°C for 1–2 min. Etching effects are similar to those for Reagent 1
3	Ammonium fluoride, 20% in water Nitric acid	10 ml 10 ml	Used at 60°C; the matrix is usually not adequately etched but Ta_2S_5 is blackened. This reagent may be used after Reagent 1 or 2 to identify Ta_2S_5
4	Ammonium fluoride, 20% in water		Used for 5–6 min at 80°C. The grain structure of the matrix is developed, and Ta_2S_5 is not affected
5	Ammonium fluoride, 20% in water Hydrogen peroxide	20 ml 10 ml	This reagent is used boiling, and colours Ta_2S_5 brown. The matrix is not affected
6	Sulphuric acid Nitric acid Hydrofluoric acid‡	25 ml 10 ml 10 ml	For general structure[68]

* Acids are concentrated, unless otherwise indicated, e.g., with specific gravity.

‡ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

ELECTROLYTIC ETCHING OF TIN ALLOYS

A 10% aqueous solution of hydrochloric acid or 20% sulphuric acid may be used at a very low current density; this is especially useful for tin-iron alloys. Satisfactory results are also obtained from:

Glacial acetic acid   130 ml
Perchloric acid   50 ml†

used at a current density of 3–6 A dm^{-2} (use with care; see Section 10.2, p. **10**–14, *Electrolytic Polishing*).

Note: A specially designed, dedicated fume hood, with a vertical stack and a wash down system is required for perchloric acid. Note that some solutions containing perchloric acid present grave explosion hazards and there are restrictions on the use of these solutions in some locations.

10.3.21   Titanium

PREPARATION

Pure titanium is soft and ductile. Because of its hcp crystal structure, it deforms by mechanical twinning, and this can be caused by rough handling. If improperly sectioned, the depth of damage can be extensive. Sectioning is very difficult, as cutting rates are low. While their indentation hardness values are low compared to tool steels and high speed steels, Ti and its alloys are much more difficult to cut and require a more softly bonded abrasive wheel than the hardest steels. Grinding and polishing rates are also lower than for steels, or most other metals. Some authors have stated that Ti and its alloys should not be mounted in phenolic resins as hydrogen can be absorbed from the resin to form TiH; or, if hydrides are present (as in a specimen in a H-rich service environment), the heat from compression moulding may dissolve some, or all, of the hydride. The author of the present section has never observed hydrides in specimens mounted with different thermosetting resins. However, in a field failure of commercial purity (CP) titanium that contained very large amounts of titanium hydrides, the mounting temperature was observed to dissolve some of the hydrides. A mount made using a low-viscosity, slow curing epoxy resin revealed the greatest amount of TiH. Mounts made with a fast curing epoxy (cures in about 45 min.), which generates a high heat of polymerisation, had a reduced amount of TiH, similar to the amount obtained using a thermosetting resin. So, in failure analysis work, if hydrides may be present, it is best to use a slow curing epoxy resin with a conductive mounting approach (see the section on *Mounting*), to minimise the exotherm produced during polymerisation and the chance of dissolving any TiH.

Table 10.30 ETCHING REAGENTS FOR TIN AND ITS ALLOYS

No.	Etchant*		Remarks
1	Nitric acid, 2% in alcohol		This reagent is a general one for tin-rich alloys, and particularly for tin–cadmium, tin–antimony and tin-iron alloys. The tin-rich matrix is darkened, and the intermetallic compounds usually little affected
2	Nitric acid, 5% in alcohol		Tin, tin–cadmium and tin–iron alloys
3	Nitric acid Acetic acid Glycerol	10 ml 30 ml 50 ml	Mainly used as a reagent for tin. Used at 38–40°C
4	Nitric acid Acetic acid Glycerol	10 ml 10 ml 80 ml	Used at 38–40°C for tin-lead alloys, especially tin-rich alloys Pb is blackened
5	Picric acid[‡] and nitric acid in alcohol—proportions variable		Useful for tin-iron alloys in contact with steel
6	Hydrochloric acid, 1–5% in alcohol		Useful for tin–lead, tin–cadmium, tin–iron, tin–antimony–copper alloys
7	Hydrochloric acid Ferric chloride Water	2 ml 10 g 95 ml	Useful for tin-rich alloys in general and for Babbitt metal. It is often an advantage to add alcohol to this reagent. Any cadmium-rich solid solution present is stained black, while the β-phase of the tin–cadmium system turns brown
8	Hydrochloric acid Ferric chloride Water Alcohol	5 ml 2 g 30 ml 60 ml	Reveals general structure of tin and alloys without lead. Tin–iron and tin–copper compounds unattacked
9	Stannous chloride in acid solution		Tin-rich alloys in general. The composition may be varied to suit individual alloy systems
10	Potassium dichromate, in dilute acidified aqueous solution (composition variable)		Recommended for tin–cadmium alloys
11	Potassium ferricyanide in caustic soda (composition variable)		Used for tin–cadmium–antimony alloys. It distinguishes SbSn (with tin and cadmium in solid solution), which is not affected, from CdSb in tin–cadmium–antimony alloys
12	Ammonium persulphate Water	5–10 g 100 ml	Used particularly for tinplate. The tin is heavily darkened, leaving the basis metal unattacked. Most intermetallic compounds of tin are also unattacked. More dilute solution gives grain boundary etch with tin and alloys
13	Nitric acid and hydrofluoric acid in glycerol[§]		Various strengths are recommended for tinplate. The contrast between plating and steel may be improved by the use of Reagent 2 (Table 10.17)
14	Sodium sulphide 20% in water, with a few drops of hydrochloric acid		Useful for tin-rich tin–antimony–copper alloys. The phase SbSn is not affected, but the phase Cu_6Sn_5 is coloured brown[72]
15	Silver nitrate Water	5 g 100 ml	Darkens primary and eutectic lead in lead-rich lead–tin alloys[69]

* Acids are concentrated, unless otherwise indicated.
‡ Special handling is required for picric acid to avoid the risk of fire and/or explosion and local regulations must be consulted before use of this reagent.
§ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

To prepare Ti and its alloys, a three step contemporary procedure is used that has been shown to be capable of producing perfect images of CP Ti in crossed polarised light, and a vast range of alpha, alpha-beta and beta alloys. Of course, we must start with a properly sectioned piece, and this is extremely important with Ti. Use only a laboratory abrasive cut-off saw, or a precision saw, with the proper wheel (extremely critical), with low pressure and copious cooling. Mount the specimens as discussed above. Step 1 uses psa-backed 320 grit (P400) SiC paper, water cooled, with 25–30 N (6 lbf) load per specimen, 240–300 rpm, until the cutting damage is removed and the specimens are at the same plane. This may require more than one sheet of paper.

Step 2 employs a psa-backed (can use a magnetic platen set up) selected silk cloth, such as an Ultra-Pol™ cloth, with 9 μm diamond, 25–30 N (6 lbf) load per specimen, 120–150 rpm, for 10 minutes. The cloth is critical to the success of this method. Selected silk yields a good removal rate and a better surface finish than any other cloth while minimising relief, and maximising edge retention. If other cloths or rigid grinding discs are used, the results will be inadequate for CP Ti examination by polarised light (unless an additional step is added). If the polishing head rotates at <100 rpm, use contrarotation mode. Start by charging the cloth with paste, then add the appropriate lubricant. During the 10 minute cycle, periodically add the same size diamond in slurry or suspension format to keep the cutting rate high.

Step 3 uses 0.05 μm colloidal silica on a medium napped synthetic suede cloth, same load, 120–150 rpm, for 10 minutes. This method works much better if contrarotation can be used. This requires a polisher with a low head speed, ideally 30–60 rpm. If the head speed exceeds 100 rpm, the abrasive will be thrown off the polishing cloth onto the metallographer and the walls. This is especially bad, as the colloidal silica must be mixed in a 5:1 ratio with hydrogen peroxide (30% conc.). If the addition of hydrogen peroxide causes the colloidal silica to stiffen, add distilled water. With 20 s left in the third step, stop adding any abrasive. With 10 s left in the cycle, turn the water jet onto the polishing cloth surface and wash off both the abrasive from the cloth and from the specimen. Then, rinse the specimen and holder with water, scrub with cotton soaked in ethanol or in a soap solution, as desired, rinse in water, displace the water with ethanol, and blow dry under a stream of hot air. CP Ti specimens will yield excellent grain structure images under crossed polarised light. The image quality can be further enhance by a brief (20–30 minutes) vibratory polish using colloidal silica on the medium napped synthetic suede cloth.

ETCHING

The presence of surface oxide films on titanium and its alloys necessitates the use of strongly acidic etchants, usually containing HF. Those given in Table 10.31 are useful. HF is a very dangerous acid and skin contact must be avoided as it produces very severe burns involving irreversible damage to the bone, even in dilute solutions and has other potential fatal hazards. Reagents should be kept in polyethylene beakers, as glass is attacked by HF.

10.3.22   Tungsten

PREPARATION

Tungsten, compared to the other refractory metals, is one of the easier to prepare. The methods described for Mo and Nb are adequate for W. See these sections. The use of an attack-polish agent is helpful when preparing tungsten.[73]

ETCHING

The etching of tungsten is not difficult as Murakami's Reagent is quite satisfactory. Inclusions (e.g., thorium, uranium or calcium oxides) may be seen in the polished, unetched surface, while the general structure of filaments which have been heated *in vacuo* or in a reducing atmosphere may often be observed owing to evaporation effects. A selection of suitable etching reagents is given in Table 10.32.

ELECTROLYTIC ETCHING OF TUNGSTEN

This may be carried out in a mixture of 25 ml of normal aqueous sodium hydroxide and 20 ml of hydrogen peroxide. The current density and potential are somewhat critical, and should be carefully controlled after investigation to find the optimum conditions for specific cases. A sodium hydroxide solution of 0.025 normal strength has also been used, at a current density of 5 A dm.$^{-2}$

Table 10.31   ETCHING REAGENTS FOR TITANIUM AND ITS ALLOYS

See general safety note at the start of this Chapter.

No.	Etchant*		Conditions	Remarks
1	Hydrofluoric acid (40%)§ Nitric acid (1.40) Lactic acid	1–3 ml 10 ml 30 ml	5–30 s	Mainly unalloyed titanium; reveals hydrides
2	Hydrofluoric acid (40%)§ Nitric acid (1.40) Lactic acid	1 ml 30 ml 30 ml	5–30 s	As Etchant 1
3	Hydrofluoric acid (40%)§ Nitric acid (1.40) Water (Kroll's reagent)	1–3 ml 2–6 ml to 100 ml	3–10 s	Most useful general etch
4	Hydrofluoric acid (40%)§ Nitric acid (1.40) Lactic acid	10 ml 10 ml 30 ml	5–30 s	Chemical polish and grain boundary etch
5	Potassium hydroxide (40%) Hydrogen peroxide (30%) Water (can be varied to suit alloy)	10 ml 5 ml 20 ml	3–20 s	Useful for α/β alloys. α is attacked or stained. β unattacked
6	Hydrofluoric acid (40%)§ Nitric acid Glycerol	20 ml 20 ml 40 ml	5–15 s	General purpose, TiAlSn alloys
7	Hydrofluoric acid§ Nitric acid (1.40) Glycerol Water	1 ml 25 ml 45 ml 20 ml	3–20 s	TiAlSn alloys

* Acids are concentrated, unless otherwise indicated.
§ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

Table 10.32   ETCHING REAGENTS FOR TUNGSTEN

See general safety note at the start of this Chapter.

No.	Etchant*		Remarks
1	Sodium hydroxide, 10% in water Potassium ferricyanide, 10% in water (Murakami's reagent)	10 ml 10 ml	This reagent is used cold and, on immersion of the specimen for approximately 10 s, develops grain boundaries
2	Hydrogen peroxide, 3% in water		This reagent develops grain boundaries, but only after some 30–90 s in the boiling reagent
3	Potassium ferricyanide Caustic soda Water	305 g 44.5 g 1000 ml	Recommended for deep etching of single crystal bars and wires in order to produce etch-pits for the investigation of orientation
4	Hydrofluoric acid§ Nitric acid (1.40) Lactic acid	5 ml 10 ml 30 ml	Swab 10–20 s, rinse and dry. Follow with Murakami's reagent (Etchant 1)

* Acids are concentrated, unless otherwise indicated, e.g., with specific gravity.
§ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

10.3.23   Uranium

PREPARATION

Conventional methods are used but as the metal is toxic, pyrophoric when finely divided, and an α-particle emitter, it is essential to keep the metal wet during cutting and to carry out the operation

Table 10.33   ETCHING REAGENTS FOR URANIUM ALLOYS

See general safety note at the start of this Chapter.

No.	Etchant		Conditions	Remarks
1	Nitric acid (1.40) Glacial acetic acid Glycerol	30 ml 30 ml 30 ml	5–60 s	Most U alloys; distinguishes precipitated phases, e.g., U_2Ti U_2Mo, UZr_2, eutectoid nucleation at grain boundaries (like pearlite in steel)
2	Orthophosphoric acid Diethylene glycol Ethanol	30 ml 30 ml 40 ml	Electrolytic 20 V stainless steel cathode 5–30 s	Will electropolish at high voltages (30–40V), stains phases differentially at 10–20 V
3	Hydrofluoric acid (40%)* Nitric acid (1.40) Glycerol	10 ml 40 ml 40 ml	5–10 s	U–Mo, U–Nb, U–Zr alloys (gamma phase)
4	Hydrofluoric acid (40%)* Nitric acid (1.40) Lactic acid (or distilled water)	1 ml 30 ml 30 ml	5–30 s	U–Be, U–Nb, U–Zr, U–Mo. Also U–Al alloys. UAl_2 UAl_3, UAl_4 Stained differentially according to time

* Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

behind a screen so that particles cannot be ingested. Preparation of any radioactive metal can only be done in specially designed facilities that have been licensed to work with such metals, and requires personnel properly trained to deal with the hazards involved.

Methods utilising attack-polish solutions are preferred and give structures which can be examined under polarised light with crossed polars, which is the most useful method of examination.[56]

Recommended attack-polish solutions are:

1. Dilute hydrofluoric acid and nitric acid (1 ml + 5 ml respectively in 100 ml water).
2. 50 g chromium trioxide, 10 ml nitric acid, 100 ml water is less aggressive but, like the other, needs careful handling to avoid contact with the skin. This gives the best results for polarised light examination.

Note: Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

ETCHING

Polarised light is the most useful technique.

α-uranium—high grain contrast under crossed polars about 1° off the extinction position. The various transformation products, granular α, martensite, etc., can be distinguished.
β-uranium—weakly anisotropic when retained but clearly distinguishable from α and γ.
γ-uranium—optically isotropic and therefore distinguished from α and β. In uranium alloys with molybdenum, niobium and rhenium, γ_0 is tetragonal with $c/a = 0.5$, is optically active, and the grain structure is visible under crossed polars.

On ageing, these alloys develop γ_0 with $c/a < 0.5$ and this is readily detected by polarised light metallography.

Note that chemical etching may give quite different structures, e.g., in U–Ti alloys. Chemical etching is responsive to the manner of decomposition of γ uranium and will reveal the sequence of decomposition, e.g., distribution of U_2Ti, UZr_2, etc., whereas polarised light reveals the final and true grain structure which may be quite different from the etched structure.[74]

10.3.24   Zinc

PREPARATION

Though somewhat harder than lead and tin, zinc and its alloys must be carefully prepared, as improper cutting and grinding produces mechanical twinning in a comparatively thick surface layer. The depth

Table 10.34   ETCHING REAGENTS FOR ZINC AND ITS ALLOYS

See general safety note at the start of this Chapter. These reagents are of general applicability to zinc and many zinc-rich alloys. Etchant 3 is suitable for examination of microconstituents at high magnifications.

No.	Etchant		Remarks
1	Hydrochloric acid, 1% in alcohol		For Zn and lead alloys; immerse for up to several minutes.
2	Sodium hydroxide, $100 \, g \, l^{-1}$ of water		For pure Zn, Zn–Co and Zn–Cu alloys; swab or immerse for up to 15 sec.
3	Nitric acid, 1–2% in alcohol		Rinse in 20% chromic acid in water to avoid stains. Good for Zn–Fe layers in galvanised samples
4	Nitric acid 94 ml ⎱ Stock Chromic acid 6 ml ⎰ solution		A few drops of this stock solution are added to 100 ml of water immediately before use. The resulting solution is generally useful, particularly for the recognition of small amounts of other microconstituents in zinc
5	Chromic acid, CrO_3 200 g Sodium sulphate, Na_2SO_4 15 g Water 1000 ml		Palmeton Reagent for commercial zinc and zinc alloys. If a film of stain results, this may be removed by immersion in a 20% solution of chromic acid in water
6	Chromic acid, CrO_3 50 g Sodium sulphate, Na_2SO_4 4 g Water 1000 ml		As for Etchant 5. This composition is recommended for die-castings. Modified Palmerton Reagent
7	Chromic acid, CrO_3 200 g Sodium sulphate, Na_2SO_4 7.5 ml Water 1000 ml		Recommended for zinc-rich alloys containing copper. Subsequent immersion in 20% chromic acid solution is again helpful
8	Chromic acid, CrO_3 200 g Sodium sulphate, Na_2SO_4 7 g Sodium fluoride 2 g Water 1000 ml		Recommended for die-casting alloys containing aluminium, as the aluminium-rich microconstituent is satisfactorily etched with this reagent. In the presence of copper, staining may result; to prevent this, immerse after etching, without washing, in a solution of 50 g chromic acid and 4 g sodium sulphate in 1000 ml, water (*see* Etchant 5).
9	Solution prepared thus: mix 51 ml of concentrated potassium hydroxide solution with 50 ml of water and 20 ml of concentrated copper nitrate solution. Stir in 25 g of powdered potassium cyanide. Filter, and add 2.5 ml of concentrated citric acid solution before use		Etch by immersion for 10–20 s. The zinc-rich phase is coloured dark brown to black. The iron-phase in commercial alloys usually appears as white rods, and the lead-phase as round white spots

of damage can approach at least 2 mm on a saw cut or filed surface. If such a surface layer experiences preparation-induced heating, it is likely to cause recrystallisation of the deformed surface layer.

Zinc, as with Pb, Sn, Sb, Bi and Cd, is not abraded well with diamond abrasives. It is better to use the traditional method with several stages of SiC paper. Follow the approach described for lead. Embedding can be a problem with Zn, although it is less of a problem than with Pb. Polish using aqueous alumina slurries, as described for Pb.

ETCHING

The reagents listed in Table 10.34 may be used for zinc and its alloys.

ELECTROLYTIC ETCHING OF ZINC ALLOYS

Comparatively little work has been done on electrolytic etching of zinc alloys because the microstructures are relatively simple and adequately brought out by the above listed reagents. For alloys containing copper, however, a 20% aqueous chromic acid solution has been recommended, the specimen being the anode.

Ternary alloys containing aluminium and copper may be conveniently etched electrolytically in a solution made by adding 20 drops of hydrochloric acid to 50 ml alcohol.

DEVELOPMENT OF MICROSTRUCTURES WITHOUT ETCHING

Zinc and many zinc-rich alloys develop satisfactory microstructures if the polished surface is allowed to remain exposed to the air for 1–3 days. Similar results may be obtained by heating at 100°C for a shorter time, but care must be taken to ensure that the use of the high temperature does not lead to any structural modification.

10.3.25   Zirconium (and Hafnium)

PREPARATION

Pure zirconium, and hafnium (which is quite similar to Zr), are soft, ductile hcp metals that can easily be deformed by mechanical twinning.[75] As with Ti, they must be sectioned with a laboratory abrasive cut-off machine using a very softly bonded wheel to minimise damage. As with all refractory metals, the grinding and polishing rates are low and scratch elimination can be difficult using standard methods. The contemporary preparation method is suitable for the alloys, but for the pure metals, a procedure similar to used with lead, with attack polishing additions followed by chemical polishing, works better. After proper cutting, the specimen is mounted and ground with 320 grit (P400) SiC paper with water cooling, 20–25 N (5 lbf) load, 200–250 rpm, until the surface damage is removed and the specimens are all ground to a common plane.

Step 2 uses 9 μm diamond on a psa-backed selected silk cloth, same load, 150–200 rpm, for 5 minutes. Step 3 uses 3 μm diamond on a woven polyester cloth, with the same load, same rpm, for 3 minutes. Step 4 uses 0.05 μm colloidal silica, with an attack polish agent, on a medium napped, synthetic suede cloth, at 25–30 N (6 lbf) load, 120–150 rpm, for 7 minutes. In these three polishing steps, contrarotation should be used, if the head speed is <100 rpm. See comments about this under Ti. A number of attack-polish agents[2] have been used, and those described for Ti are fine with Zr and Hf. Cain has developed several chemical polishing solutions that are used after polishing to improve polarised light response. Kelly's chemical polish solution also works quite well: 25 ml lactic acid, 15 ml nitric acid and 5 ml HF (swab vigorously for 2 minutes). For high-purity Zr or Hf, use the method for lead (coating the SiC with wax is not necessary) and add a 5 or 3 μm aqueous alumina step. Use an attack polish agent with each alumina step and follow with a chemical polish using Ann Kelly's solution. Vibratory polishing with colloidal silica on a medium napped synthetic suede cloth for 20–30 minutes also improves the polarised light response of Zr, Hf and their alloys.

ETCHING

When properly prepared, these metals and alloys can be examined in crossed polarised light. Hence, etching is often unnecessary. Etching reagents for zirconium, hafnium and their alloys are summarised in Table 10.35.

Table 10.35   ETCHING REAGENTS FOR ZIRCONIUM AND HAFNIUM

See general safety note at the start of this Chapter.

No.	Etchant		Remarks
1	Nitric acid (1.40)	20 ml	The reaction rate may be increased, by heating the sample in a
	Hydrofluoric acid (1.19)*	20 ml	stream of hot water before immersion in the reagent. Conversely
	Glycerol	60 ml	the reaction rate is decreased by chilling the specimen
2	Glycerol	60 ml	On etching for 3–5 s, microconstituents are outlined and
	Hydrofluoric acid (1.19)*	20 ml	differentiated, and carbides unattacked. In the presence of
	Nitric acid	10 ml	moisture the reagent tends to stain the specimen
3	Glycerol	16 ml	Etching times of 1–2 s are used. The reagent is useful for alloys
	Hydrofluoric acid (1.19)*	2 ml	which are not satisfactorily etched by Etchant 2
	Nitric acid (1.40)	1 ml	
	Water	2–4 ml	
4	Hydrofluoric acid (1.19)*	20 ml	Short etching times are necessary (1–2 s). The reagent is similar
	Water	80 ml	to Etchant 3 but is more drastic
	Nitric acid (1.40)	1 ml	

* Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

ELECTROLYTIC ETCHING

Solutions for electrolytic etching are given in Table 10.36.

10.3.26   Bearing metals (lead-tin-antimony), low-melting point solders, and type metals

PREPARATION

Bearing metals consist of hard particles of intermetallic compounds set in a matrix of soft lead-rich or tin-rich material. In general, bearing metals are easier to prepare than Pb, Sn, Bi, Cd and Zn. Many times, the metallographer encounters these as layers on metals, usually steels. These specimens must be mounted for edge retention and can be prepared with the contemporary method for steel. Printing metals and solders are easier to prepare than the pure metals, but the method described for lead should be used.

ETCHING

All the reagents listed for lead and tin alloys may be tried for revealing the structure of bearing metals, the choice depending on whether the alloy is lead-rich or tin-rich. Of the reagents used for lead, the most useful for the present purpose are: Nos. 4, 6, 8, 11 and 12; of the reagents for tin, Nos. 1, 6 and 7 are suitable.
    Further reagents are summarised in Table 10.37.

ELECTROLYTIC ETCHING

Bearing metals may be polished electrolytically in a solution containing 60% perchloric acid and acetic anhydride in the ratio of 1 part to 4 parts by volume (see the safety comments under Electrolytic

Table 10.36   ELECTROLYTIC ETCHING OF ZIRCONIUM

See general safety note at the start of this Chapter.

No.	Etchant		Remarks
1	Ethanol	70 ml	Suitable for cast zirconium
	Perchloric acid (density 1.2)*	20 ml	
	2-Butoxyethanol	10 ml	
2	Acetic acid	1000 ml	Suitable for worked and annealed material
	Perchloric acid (density 1.59)*	50 ml	
3	Ethanol	30 ml	Etching time 10–20 s at 1 A dm^{-2}
	Hydrochloric acid conc.	10 ml	
4	Ethanol	450 ml	As for Etchant 3
	Distilled water	70 ml	
	Perchloric acid*	25 ml	

* A specially designed, dedicated fume hood, with a vertical stack and a wash down system is required for perchloric acid. Note that some solutions containing perchloric acid present grave explosion hazards and there are restrictions on the use of these solutions in some locations.

Table 10.37   ETCHING REAGENTS FOR BEARING METALS

See general safety note at the start of this Chapter.

No.	Etchant	Remarks
1	Iodine in potassium iodide solution	Type metals containing small amounts of zinc
2	Iodine, 10% in alcohol	Type metals containing large amounts of zinc
3	Silver nitrate (2–5%) in water	Useful for bearing metals in general

Polishing and the discussion of Figure 10.2 as this mixture can be explosive). If the voltage is reduced after polishing, sensitive etches of most bearing metal materials may be obtained.

10.3.27   Cemented carbides and other hard alloys

PREPARATION

Cemented carbides are hard, usually >1200 HV. This alters the preparation procedure. Sectioning is usually performed with a low-speed saw or a higher speed, precision saw, some of which are called linear precision saws because the sample is fed into the blade at a controlled rate rather than being gravity-fed. These saws use a non-consumable diamond blade and yield excellent cuts with little damage and superb surface smoothness. Because of the high hardness of sintered carbides, SiC grinding paper (and alumina grinding paper), is not useful. Instead, diamond must be used for all steps. A wide variety of products can be employed. After sectioning, the specimens are embedded in a polymer and the thermosetting epoxy containing a silica filler (such as Epomet® Resin) is ideal.

Step 1 uses either a metal-bonded diamond disc with a coarse diamond size (there are several types available, e.g., an Ultra-Prep disc) with a coarse diamond, e.g., 45 μm size, which is water cooled, as with SiC paper, with a load of 25–30 N (6 lbf) per specimen, 240–300 rpm, for 5 minutes. Otherwise, a rigid grinding disc can be used. In this case, the diamond abrasive is added in suspension or slurry form. A particle size of 30 to 45 μm is used. The other parameters are the same. If the head speed is <100 rpm, use contrarotation.

Step 2 can also use the same two working surface options, but with a finer diamond size. For example, a 9 μm metal-bonded diamond disc can be used, with the same settings as for step 1, except for 4 minutes. Alternatives include another rigid grinding disc, or a psa-backed selected silk or nylon cloth. These are used with 9 μm diamond and the same settings. Step 3 uses 3 μm diamond on either of several cloths—selected silk, nylon, polyester or a chemotextile pad (all with psa backings or using a magnetic platen set up). As elsewhere, charge the cloth with paste, press the paste into the cloth surface with a finger tip, add some lubricant and begin polishing. During the cycle, add diamond of the same size in slurry or suspension form. For step 3, use the same load, 120–150 rpm, for 3 minutes. Again, use contrarotation if the head speed is <100 rpm. At this point the surfaces are more than adequate quality for routine examination.

If the sintered carbide is coated, and particularly when multiple CVD layers are applied, the resolution of these coatings will be enhanced if additional steps are used. A 1 μm diamond step, in the same manner as the 3 μm step can be added. That can be followed by final polishing with colloidal silica on a synthetic suede cloth or with the polyurethane pad, same load, 120–150 rpm, for 2 minutes. Again, use contrarotation if possible. Another option is to use a brief vibratory polish with colloidal silica, 20–30 minutes is adequate. These polishing steps enable complex coatings to be resolved clearly and give maximum detail of the cobalt binder phase. These features must be studied at the limits of the light microscope for resolution and magnification, so SEM examination is also widely used, particularly backscattered images as the different carbides and the binder phase can be revealed nicely in the range of 2000–5000X, where the limited resolution of backscattered electron image remains sufficient.

ETCHING

Graphite and eta phase are observed best before etching. A number of etching reagents have been developed for these materials, and a selection is given in Table 10.38.

ELECTROLYTIC ETCHING OF TUNGSTEN CARBIDE–COBALT AND TUNGSTEN
CARBIDE–TITANIUM CARBIDE–COBALT ALLOYS

Two solutions have been recommended:

1. For tungsten carbide in a matrix of cobalt:

   Sodium hydroxide   10%   in water
   Potassium ferricyanide   10%

   On electrolysis at 2 V, the carbide particles are attacked, and the cobalt binder phase is almost unaffected.

Table 10.38   ETCHING REAGENTS FOR CEMENTED CARBIDES, ETC.

See general safety note at the start of this Chapter.

No.	Etchant		Remarks
1	Potassium hydroxide, 20% in water Potassium ferricyanide, 20% in water		The cold solution is used as a general reagent (Murakami's reagent). Equal volumes are mixed NaOH can be substituted for KOH
2	Potassium hydroxide Potassium ferricyanide Water	10 g 10 g 10 ml	The boiling solution is used as a general reagent (Mod. Murakami's reagent) NaOH can be substituted for KOH
3	Aqua regia (20 ml nitric acid + 80 ml hydrochloric acid)		General reagent
4	Hydrofluoric acid§ Nitric acid conc.	70 ml 30 ml	Rapidly attacks eutectic material in iron–tungsten carbide alloys and iron–molybdenum carbide alloys
5	Picric acid, 2% in alcohol*		Develops the eutectic structure in iron–tungsten carbide alloys and iron–molybdenum carbide alloys. The carbides are differentiated
6	Nitric acid, 3% in alcohol		The crystal boundaries in iron–tungsten carbide and iron–molybdenum carbide alloys are developed
7	Mixture of 5 and 6		Generally effective for this class of material
8	Phosphoric acid Hydrogen peroxide	10 ml 10 ml	Used after successive treatments in Etchants 4 and 1 for molybdenum carbide–titanium carbide–cobalt materials. The titanium carbide with tungsten in solution and the cobalt are darkened; the tungsten carbide with titanium in solution is relatively unaffected[76]
9	Dilute ammonium sulphide		Used after successive treatments in Etchants 4, 1 and 8 for similar materials as recommended for Etchant 8. The carbides are unaffected, but the cobalt-rich matrix is darkened and differentiated from titanium carbide[76]
10	Potassium permanganate Potassium hydroxide Water	10 g 5 g to 100 ml	WC grey, TiC pink, TaC gold, β phase rapidly attacked

* Special handling is required for picric acid to avoid the risk of fire and/or explosion and local regulations must be consulted before use of this reagent.
§ Hydrofluoric acid produces irreversible bone damage and presents a range of other hazards. Even dilute hydrofluoric acid solutions should be handled with great care. Note that hydrofluoric acid attacks laboratory glassware.

2. For tungsten and titanium carbides in a matrix of cobalt:

Nitric acid conc.   10 ml
Hydrofluoric acid   10 ml

Titanium carbide is attacked, while tungsten carbide is not attacked.
The cobalt-rich matrix is attacked and dissolved.

ELECTROLYTIC ETCHING OF IRON–TUNGSTEN–CARBON AND
IRON–MOLYBDENUM–CARBON ALLOYS

The use of a 5% solution of potassium ferrocyanide in 5% sodium hydroxide has been suggested
The metallographic effects are very similar to those of Etchant 5 in Table 10.38.

10.3.28   Powdered and sintered metals

PREPARATION

The preparation of powders, pressed compacts, and sintered metals is a specialised process, and requires special methods.

To examine powders, mix a reasonable amount of powder into a small amount (10–15 ml, for example) of cast epoxy that has been mixed in the correct ratio. Pour this into a mould cup of the desired diameter. Then, fill up the mould cup with clear epoxy, add an identification label, and allow it to cure. The powder particles are only in the bottom several mm of the mount. Grinding, polishing and etching are then carried out as for the metal involved, as described above. Coarse powder particles have been mixed with thermosetting resins and placed into the mounting press, and cured. Generally, the use of cast epoxy is preferred as epoxy is the only resin that physically adheres to the specimens.

In compacted, sintered, and even in hot isostatically pressed specimens, voids will be present. Vacuum impregnation can be used to draw cast, low-viscosity epoxy into the voids. Voids can pick up grinding and polishing materials, and absorb etching reagents and other fluids, creating preparation problems in all stages of the preparation and examination process. Of course, some voids are not interconnected, and are not filled with epoxy. In this case, one can interrupt the preparation process after the 3 or 1 μm step, place the specimen back in the vacuum evaporation chamber, pour a small amount of mixed epoxy over the partially prepared surface (laying horizontal), and then draw the epoxy into the surface holes by alternating vacuum and atmospheric pressure steps. After the epoxy dries, carefully remove the excess epoxy on the surface by repeating the last step (it may help to switch to a polisher with individual specimen loading to do this efficiently). Then, perform the final polishing step. Some metallographers pour melted wax over the specimen surface. When the wax hardens, they take a plastic card, like a credit card, and scrap off the excess wax, then complete the preparation procedure.

10.4   Electron metallography and surface analysis techniques*

The application of electron microscopy to the study of the microstructures of metals and alloys is termed 'electron metallography'. There are basically two types of electron microscopy: transmission electron microscopy (TEM) involves the passage of an electron beam through a thin sample, and scanning electron microscopy (SEM), the rastering of an electron beam across the surface of a sample. TEM and SEM can be combined in a scanning transmission electron microscope (STEM) in which fine probes (<1 nm diameter) can be formed for the chemical analysis of small particles and boundaries. There is a wealth of references for both the principles and applications of electron microscopy[77–84] as well as a range of information available on different websites.[85]

10.4.1   Transmission electron microscopy

The sample to be examined in transmission using TEM has to have a thickness on the order of 100 nm (this is rather small, when compared with say the wavelength range of visible light ∼ 400–700 nm), although for the quantitative application of some techniques the specimen has to be less than about 30 nm in thickness. The reason for this is that when a high energy electron, travelling usually at more than 90% the speed of light, passes through a sample it is scattered not only elastically but also inelastically. Both behaviours depend on the types of atom present as well as on the form and regularity of the structure and it should be remembered that to a first order everything is viewed in projection. There is a range of approaches that can be used to prepare electron transparent samples[86,87] and their usage is dependent upon the problem at hand as well as the material to be examined.

Perhaps amongst the oldest TEM specimen preparation techniques are the replica and extraction methods. The replica method can be used for the examination of a fracture surface or surface topography of a metal and involves their reproduction in a thin film of a substance (usually carbon) that does not decompose in the electron beam. Samples can be made either in a two-stage plastic/carbon or in a single-stage direct carbon replica process. For two-stage replicas, a 20–250 μm thick sheet of triacetate cellulose is softened in acetone, laid on to the pre-polished metal surface and, as the acetone evaporates the plastic hardens and contracts into the surface features. The plastic is then carefully removed from the metal, and a 20–30 nm layer of carbon evaporated on to the replica face, after which the plastic is dissolved in acetone leaving a secondary carbon replica. The more direct single stage method is to evaporate the carbon layer on to the pre-prepared metal surface, the carbon layer then being removed by re-etching the surface to dissolve away the metal. A particularly useful variation of this technique is the carbon extraction replica method, which can be used for the examination of multiphase alloys, in which etching of the specimen is controlled so that preferential dissolution of the matrix takes place. In this way, it is relatively easy to extract the second phase particles present in most alloys. The technique is of further attraction because the original particle

---

*For a discussion of electron sources, see Chapter 18.

distribution is retained. Details of replica techniques suitable for a wide range of metals and alloys are given in references.[88–90]

The second type of TEM specimen preparation procedure involves the use of electropolishing methods to reduce the thickness of electrically conducting samples to electron transparency.[91–96] A common procedure requires the use of grinding or machining methods to make a disc that is 3 mm in diameter and <0.2 mm in thickness. Cutting can involve the use of abrasive,[86] wire[97,98] or acid string[99,100] saws, followed by metallographic grinding on wet abrasive papers.[1,101] The disc is then electropolished (anodically dissolved) through the application of an applied voltage until a small hole is formed near its centre. Classic electropolishing curves can be used to adjust the polishing conditions between those in which etching or pitting occurs,[102,103] the polishing being sensitively dependent on factors such as temperature and electrolyte concentration. The thin foil technique has been used for the microstructural characterisation of an enormous range of metals and alloys, and some suitable preparation conditions are given in Table 10.39. Further comprehensive details

Table 10.39   THIN FOIL SPECIMEN PREPARATION TECHNIQUES FOR INDUSTRIAL ALLOYS[82]

Material	Technique	Solution	Conditions
Ag–Zn	Jet	9% KCN, 91% H_2O	
Al	Window	1 part nitric acid, 3 parts methanol	$-70°C$, 40 V
Al–Cu	Chemical	94 parts phosphoric acid, 6 parts nitric acid	
Al–Au alloys	Window	20% perchloric acid, 80% methanol	16–18 V, 100 cm^{-2}, -55 to $-65°C$
Au	Window (3 mm discs)	100 ml CH_3COOH, 20 ml HCl, 3 ml H_2O	Stainless steel cathode, 32 V, 15°C
	Electrolytic	(a) 15% glycerol, 35% 50% HCl	30 V, $-30°C$, 1.5 A cm^{-2}—fast polish
		(b) 133 ml glacial CH_3COOH, 25 g CrO_3, 7 ml H_2O	Finish after (a) at 22 V, 0.8 A cm^{-2}, 0°C
Be, Be–Cu	Window	20% perchloric acid, 80% ethanol	$-30°C$, 40 V
Co–Fe	(a) Chemical	50% phosphoric acid, 50% hydrogen peroxide	
	(b) Jet	20% perchloric acid, 80% methanol	$-20°C$
Cu–Ni–Fe alloys	Chemical	20 ml acetic acid, 10 ml nitric acid, 4 ml HC1	
Cu–Ti	Jet	750 ml acetic acid, 300 ml phosphoric acid, 150 g chromic acid, 30 ml distilled H_2O	30–40 V, 45–55 A
Fe–Al–C	Chemical	HF, H_2O, H_2O_2 (1:3:16)	
Fe$_3$Si	Window	1% perchloric acid, 2.5% hydrofluoric acid in methanol	$-77°C$
Gd–Ce alloys	Window	1% perchloric acid, 99% methyl alcohol	$-77°C$
Hf	(a) Jet	45 parts nitric acid, 45 parts H_2O, 8 parts HF	
	(b) Jet	2 parts perchloric acid, 98 parts ethanol	40–45 V, 16–20 mA, $-77°C$
In	Window: from 0.1 mm thick	33% HNO_3, 67% methanol	$-40°C$
Mg		(a) 20% $HClO_4$, 80% ethanol	Fast polish, 0°C
		(b) 375 ml H_3PO_4, 625 ml ethanol	Finish at 15 V, 0°C, lowest current
	Chemical	6% nitric acid, 94% H_2O	3°C

(continued)

Table 10.39   THIN FOIL SPECIMEN PREPARATION TECHNIQUES FOR INDUSTRIAL ALLOYS[82]—*continued*

Material	Technique	Solution	Conditions
Mo	Jet	1 part sulphuric acid, 7 parts methanol	10 V
Nb	Chemical	60% HNO_3, 40% HF	0°C
Nb alloys	Window	100 ml lactic acid, 100 ml sulphuric acid, 20 ml HF	40°C, ~0.4 A cm^{-2}
Ni steels Stainless steels	Chemical	50 ml 60% H_2O_2, 50 ml H_2O, 7 ml HF	Place specimen in H_2O_2 solution, then add HF until reaction starts; produces 1000 Å foils which can then be finished by electropolishing by standard chromicacetic electropolishing (courtesy Republic Steel Corp.)
Ni alloys Cu–Ni–Fe	Jet	1 part HNO_3, 3 parts CH_3OH	6–10 V, 18–30 mA, −30°C
Ni	Jet	20% perchloric acid in ethanol	
Ni–Al alloys	Jet	20% sulphuric acid, 80% methanol	Dished at 150 V, final polish in same solution at 10–12 V
Ni and Ni–Fe	Jet	8 parts 50% sulphuric acid, 3 parts glycerine	Less than 10°C, 1.3 A cm^{-2}
Rene 95	Jet	250 ml methanol, 12 ml perchloric acid, 150 ml butylcellusolve	−35°C, 65 V
Th	Window	5% perchloric acid, 95% methanol	−77°C, 3–10 V
Pt	Electrolytic	H_2SO_4 (96%), HNO_3 (65%), H_3PO_4 (80%)	0.2–0.5 A cm^{-2}, 20–30°C
Re	Window	Ethyl alcohol, perchloric acid, butoxyethanol (6:3:1)	−40°C, 35 V
Ta	Chemical	3 parts HNO_3, 1 part HF	−10°C, immerse in Petri dish after lacquering
Ta	Jet	1 part sulphuric acid, 5 parts methanol	−5°C, current density of 0.5 A cm^{-2}
Ti	Jet	1 part HF, 9 parts sulphuric acid	
Ti–Nb	Chemical	4 parts nitric acid, 1 part HF	
TiC	Jet	6 parts nitric acid, 2 parts HF, 3 parts acetic acid	100 V
Ti and Ti alloys	Jet	30 ml $HClO_4$, 175 ml *n*-butanol, 300 ml CH_3OH	15 V, 0.1 A cm^{-2}, may need ion thinning at end to remove contamination layer
U	Jet	1 part perchloric acid, 10 parts methanol, 6 parts butylcellusolve	−20°C, 35–45 V
UO_2 (sintered)	Chemical	10 ml HOAc, 20 ml sat. CrO_3, 5 ml 40% HF, 7 ml HNO_3 ($d = 1.42$)	
	or Chemical	20 ml H_3PO_4 ($d = 1.75$), 10 ml HOAc, 2 ml HNO_3 ($d = 10.42$)	
V	Chemical	2 parts HF, 1 part nitric acid	Less than 10°C
V	Jet	20% sulphuric acid in methanol	
Zn–Al	Chemical	50–70% nitric acid in water	
Zn–Al	Window	90% methanol, 10% perchloric acid	
Zr–25% Ti	Chemical	50 ml nitric acid, 40 ml H_2O, 10 ml HF	
Zr alloys	Jet	5% perchloric acid, 90% ethanol	70 V, below −50°C

can be found in references.[77,86] The 'window technique'[104] is a low cost alternative to the use of commercial electropolishing machines and has enjoyed widespread application over the years. One of the attractions of electropolishing is that it is generally not strongly associated with the formation of artefacts, although defect structures can be altered through stress relaxation and some metastable alloys can undergo a phase transformation by shear. Titanium and zirconium alloys are also known to be susceptible to the formation of hydrides.[105]

Ion beam thinning[106–108] is a further method by which the thickness of a sample can be reduced to electron transparency. Ion milling involves the bombardment of the surface of a sample with high energy (4–6 keV) ions of an inert gas such as argon and has advantages over electropolishing methods in its use for non-conducting samples as well as those which are either difficult to electrothin or have complex geometries. Cross-sections of samples containing interfaces between materials such as metals and oxides can be prepared using ion beam thinning,[109] and there are now a number of techniques for the preparation of this class of specimen.[110,111] The ion milling process itself is a complex one and the thinning rate of a given material is dependent upon factors such as the accelerating voltage and ion current as well as the angle of incidence and distance from the source. Most commercial systems employ two ion guns into which the inert gas is introduced, subsequently ionised and then accelerated towards the surface of the sample. More specialised systems enable reactive ion milling to be performed[112] or allow the sample to be viewed during milling so as to thin specific target areas whilst the problems associated with differential milling have been combated by the development of machines with high-powered guns that can mill at very low angles of incidence (<5°). Even more specialised machines are now available which can mill at voltages as low as 200 V and are thus useful for the removal of the surface implant damage and amorphous layers created during thinning at higher potentials. Artefacts can be associated with localised compositional changes as well as phase transformations brought about by stress relief.[113,114]

Focused ion beam (FIB) thinning is a rather newer method of preparing samples for TEM examination and is a technique that has attracted considerable recent interest. The key advantages of FIB usage lie in the high spatial accuracy with which samples can be taken as well as the speed of the preparative procedure.[115] Samples are prepared in an ion microscope that generally uses a gallium liquid metal source to generate ions that are accelerated at voltages of between 10 and 50 keV.[116] Focusing is achieved through the use of two electrostatic lenses, and the beam current can be varied using apertures for which the spot size is some 7 nm at 1 pA and approximately 250 nm at 12 nA.[117,118] Gas assisted etching can be achieved by introducing a reactive gas such as iodine whilst metals can be locally deposited in the presence of Pt or W based organo-metallic precursor gases.[119] There are two general approaches that have been developed for TEM sample preparation. For the first, a small rectangular 'slab' of material that contains the site to be milled and which measures some 3 mm by 1 mm by 50 μm is prepared using standard metallographic procedures. The slab is fixed to a horseshoe shaped support grid and the site is located in the FIB microscope before its upper surface is protected by the deposition of a high atomic number 'strap'. Trenches are cut to the immediate sides of the target site at a high beam current, and the beam current subsequently decreased as the slice thickness is reduced to the point at which it is electron transparent.[120] The second approach uses a lift-out technique[121] to transfer an electron transparent section onto a support grid and does not involve loss of the integrity of the bulk sample through pre-FIB cutting, grinding and polishing. One of the disadvantages of FIB milling is associated with high rates of deposition and amorphisation of the surface of the TEM slice that may require removal using broad beam methods.[122]

Other methods that can be used for the preparation of TEM samples include crushing and grinding, ultramicrotomy and cleaving.[84] Ultramicrotomy is best suited to biological or man-made polymeric samples and requires considerable know-how whilst crushing methods can be used to disperse particles onto a support grid. Cleaving is relatively simple and can be used for layered structures that contain weak interfaces.

The fundamental strategy in the TEM characterisation of structures and compositions is based on using elastically scattered electrons to examine structure, and the various signals associated with inelastic scattering to characterise composition.[123] An understanding of the modern approaches that can now be applied centres on the realisation that such a divide is not necessarily essential. The conventional attitude is based on the idea that if a signal is to be used to provide a composition it has to come from a specific probed area, as it does in SEM.

The types of image that can be formed by selecting specific parts of the diffraction pattern are defined in Figure 10.4. A bright field image is obtained by placing an aperture around the central beam whilst a dark field image uses a beam scattered from only part of the illuminated area depending on its contribution to the selected beam. The 'structure image' uses a relatively large aperture in the back focal plane of the objective lens and, as long as two or more beams are present, interference of their amplitudes gives rise to fringes in the image which are related directly to the spacing of the associated planes in the object controlling the angles at which constructive interference takes
Figure 10.4 *Types of image that can be formed using TEM*

place in the diffraction pattern. The bigger the aperture used the smaller the spacings seen in a structure image. It should be emphasised that there may be fringes where there are not planes (by the interference of beams symmetrically disposed on either side of the central beam). The intensities of such high resolution structure images are complicated, and depend on the operating conditions, the level of focus, the thickness of the specimen and the phase changes caused by the spherical aberration of the objective lens: it focuses electrons at an angle to its axis more powerfully than electrons passing along its axis.[124–126] High-resolution data can also be extracted from dark field images of relatively poor direct resolution. The displacement across an interface, for example, can be measured at much higher resolutions than are present in the image.[127] In a related way, defects such as dislocations are best viewed in weak beam dark field images.[128–130] The idea is to put the crystal in an orientation where as a whole it does not diffract strongly, and under these conditions the parts of the crystal that are rotated into a Bragg condition appear as white lines against a dark background. The approach can allow the measurement of segregation to such defects as well as the structural assessment of defect forms.[131] Structural data can also be obtained from diffraction patterns using convergent probes on the specimen.[132] Not only does this allow the 3-dimensional structure to be determined by contributions due to interference effects with off-plane reflections but also enables the magnitude of the Burgers vector of a dislocation to be assessed from characteristic disruptions to the scattering behaviour.[133] Convergent beam methods can similarly be used for the measurement of structure factors, Debye-Waller factors and charge density.[134]

Local compositions are analysed using a small probe to allow the inelastic scattering characteristics of the projected column to be assessed (see Figure 10.5). Energy dispersive X-ray analysis (EDX),[135–138] also known as energy dispersive X-ray spectroscopy (EDS), suffers from the signal coming from places other than that probed but is rather good for the comparative analysis of areas down to about 10 nm. Analysis of the energy losses of the electrons[139–141] that pass through the specimen (parallel electron energy loss spectroscopy, PEELS) provide rather better localisation (done to about 1 nm in a dedicated STEM) but can lead to degradation of the local area because of the high local variation in the electron flux. Specialised techniques can be used to obtain structural data

from inelastic loss behaviour: fine structure in some losses can be related, for example, to band occupancies and separations.[142]

Compositional analysis is not usually performed by the analysis of bright and dark field structural images because inelastically scattered electrons make a complicated contribution to the elastic image. Various methods, however, have been developed for the determination of composition from images in which inelastically scattered electrons are present. One such approach relies on the analysis of pattern similarities rather than intensities in high-resolution structural interference images.[143] A second method[144,145] measures changes in the forward scattering potential at an interface and has been shown to be applicable for the quantitative description of the compositional abruptness of an interface at the atomic level.[146]

The situation has been changed by the development of spectrometers that enable images to be formed using either just the elastically scattered electrons or alternatively just the electrons scattered with any given loss. The principle is simple and relies on putting an image (or a diffraction pattern) at the entrance pupil of a sector magnet and then selecting the diffraction pattern at any chosen energy along the line in the exit pupil (defined by the energy dispersion of the magnet) to re-form the image.[147–149] The technology required for the reliable application of the technique has only relatively recently become commercially available and the advances mean that energy filtered structure images can be used to determine localised compositional changes.[150]

10.4.2   Scanning electron microscopy

SEM is a widely used method for the examination of the surfaces of materials. Part of the attraction lies in the ease with which samples can be prepared as well as the simplicity of the instrument operation and interpretation of the images obtained. Advances continue to be made with the introduction of digital storage systems and the improvement in image resolution brought about by the introduction of field emission guns and short-focus lenses.

SEM is analogous to the ion microscope described in 10.4.1. A beam of electrons is generated in either triode or field emission guns with energies varying between less than 1 keV to more than 30 keV. Two electromagnetic condenser lenses are used to produce a demagnified image of the electron source and a third lens then projects a focused spot on to the surface of the sample. Primary electrons are reflected and secondary electrons emitted from the surface and these are focused with an electrostatic electrode on to a biased scintillator. The light produced is transmitted to a photomultiplier and the signal generated is used to modulate the brightness of an oscilloscope spot which traverses a raster in exact synchronism with the electron beam at the surface of the specimen. Details of the principles of SEM can be found in references [151–154].

There are a number of different ways in which SEM can be performed. Most commonly, the emissive mode is used to examine surface topography using a secondary electron detector.[155] Atomic number contrast can be obtained through the detection of backscattered electrons[156] whilst more specialised approaches involve the analysis of magnetic[157] or voltage contrast.[158] Electron beam induced conductivity (EBIC) contrast[159] is limited to the examination of semiconductors, and cathodoluminescence[160] is another specialised mode of operation for the detection of defects and impurities. More typically, the SEM is used to obtain quantitative compositional data by either energy dispersive (EDX or EDS) or wavelength dispersive (WDX or WDS) spectroscopy.[161,162] Modern SEM usually enables fully automated computer measurement of the X-ray intensities to be made from which the relative emission factors are used to determine composition.

Improvements to image resolution have been brought about by the use of field emission guns and there are a number of commercial systems in which a resolution of 1.5 nm can be obtained at 30 keV using either cold emission or thermally assisted sources. Image resolution can also be improved with in-lens stages although at the expense of the size of the sample that can be examined.

10.4.3   Electron spectroscopy and surface analytical techniques

Electron spectroscopy is a technique for the investigation of the energy distribution of electrons ejected from a material when irradiated by a source of ionising irradiation.[163,164] X-ray photoelectron spectroscopy (XPS) refers to the technique when the ionising source is X-rays, and ultra-violet photoelectron spectroscopy (UPS) when ultra-violet light is used. Electron and high-energy X-ray beams can also cause the emission of auger electrons and the analysis of these electrons is known as Auger spectroscopy (AES).

XPS and AES can be used not only for the identification of an atomic species but also to provide information about its binding energy, charge and valency. Modern XPS enables quantification, depth profiling and imaging to be performed and is commonly applied in studies of interfaces as

Table 10.40   COMPARATIVE CAPABILITIES OF DIFFERENT SURFACE ANALYTICAL TECHNIQUES

Technique	Type of information	Elemental range	Effective probing depth	Lateral resolution	Sensitivity (at. %)
XPS	Elemental Chemical	Li–U	1–10 nm	10 μm–2 mm	0.01–1
AES	Elemental Chemical	Li–U	2–6 nm	10 nm	0.1–1
SAM	Elemental	Li–U	2 nm	5 nm	0.2
LEED	Crystallographic	All	3 nm	0.01 nm	–
SEM-EDS	Elemental	B–U	1–5 μm	1 μm	0.1–1
TEM-EDS	Elemental	Li–U	50 nm	2 nm	0.1–1
TEM-PEELS	Elemental	All	50 nm	1 nm	0.1–1
SIMS	Elemental	All	<5 nm	30 μm Profiling	1e14–1e17 at/cc
RBS	Elemental Depth Profiling	Be–U	2 nm–2 μm	5 μm–1 mm	10^{-6}

well as phenomena as diverse as adhesion[165] and corrosion.[166] AES is similarly a surface based technique but it is again possible to obtain quantitative data and as a function of depth. Scanning Auger Microscopy (SAM) involves rastering an electron beam over the surface of a sample to obtain elemental maps through the detection of Auger electrons for specific elements. Surface structural data can be obtained through the use of low energy electron diffraction (LEED) in which crystallographic and morphological information can be acquired. Rutherford backscattered spectroscopy (RBS) and secondary ion mass spectrometry (SIMS) are both popular techniques for the investigation of the surface composition of materials.[89] A comparison of the capabilities of a range of analytical techniques is given in Table 10.40.

10.5   Quantitative image analysis

Quantitative metallography has long been employed. Traditional, manual methods (such as mean linear intercept for grain size determination) are extremely labour intensive and do not permit a wide range of different measurements. In contrast, computerised image analysis is a rapid, flexible and (at least in recent years) sophisticated tool for quantitative metallography. At one time, dedicated image analysis hardware was employed. However modern image analysis software runs on standard personal computers (PCs).

Image analysis involves three stages:

  Stage 1: image acquisition (and post-processing)
  Stage 2: thresholding
  Stage 3: measurement(s)

Image acquisition can involve image capture by the PC hosting the image analysis software or the use of images acquired elsewhere. High quality digital cameras are available at a (relatively) reasonable cost for light microscopes. Modern scanning electron microscopes employ digital imaging (and older instruments can be retrofitted for digital imaging). Digital cameras are readily available for transmission electron microscopes, although high resolution cameras, in particular, remain expensive.

In some cases, it may be necessary to process the acquired image (prior to thresholding). However, this should be done with great care to avoid distorting the input data (industrial computerised image processing is far behind the level of sophistication of similar operations performed by the human brain).

Thresholding separates the feature(s) of interest from the background, thus allowing measurements to be performed on the former and is a key step in the image analysis process. Thresholding instructs the software to ignore all parts of the image that lie outside a defined band, typically of grey levels (although other information, such as colour, can also be considered). For example, if the features of interest are mid-tones on a light and dark background, the lower threshold would be set to exclude the dark portions of the background and the upper threshold to exclude the light portions of the background. Unfortunately, real world images are rarely as simple as this example and grey shades often overlap between the features and the background. Fortunately, a number of quite

sophisticated routines exist to process the thresholds, for example for edge detection purposes (as with image processing, processing of the thresholds should be performed with care, although thresholding mistakes are often quite easy to identify). In the case, for example, of grain size measurements, thresholding may require the accommodation of uneven etching response (after etching, not all of the boundaries may be etched to the point where these join up and further etching might serve merely to attack the entire sample).

Measurements* fall into two basic categories, namely: field measurements and object measurements. Field measurements, such as an area fraction of a given phase, are measurements of the overall characteristics of an entire region of interest and as such do not require separation of individual objects. In contrast, determination of, for example, a particle size distribution implies clearly that individual objects be identifiable separately. This can present challenges, as in the case, for example, of overlapping particles (although routines for separating overlapping objects during thresholding do exist). Some examples of object measurements (i.e., measurements involving individual objects, or groups of objects) include: length, diameter, area, perimeter, aspect ratio, circularity, angle, coordinate of object centre and extent of clumping.

Commercial image analysis software falls generally into one of two types. The first of these types is software designed to undertake a fixed palette of operations (typically, following ASTM defined methods), such as:

– determination of grain size;
– measurement of Knoop or Vickers hardness indentations;
– characterisation of the percentage of different graphite/carbide morphologies in cast irons;
– quantification of inclusion banding;
– measurement of dendrite arm spacing;
– characterisation of inclusion size and/or shape distributions.

Such software is ideal for rapid, routine measurements, as would be needed for quality control purposes and requires only a relatively low skill level on the part of the operator. The second type of software is highly configurable and supports a far wider range of measurements, but has a much steeper learning curve (of course the software's underlying image analysis engine can be the same in both cases). This second type of image analysis tool is ideal for research applications of metallography, where non-standard measurements may be required.

For further information, the extensive literature on image analysis can be consulted. However, it should be cautioned that a large portion of this literature is aimed at non-metallographic applications, such as machine vision. Two examples of recent texts on image analysis that focus on materials science applications are [167, 168].

10.6 Scanning acoustic microscopy

Scanning acoustic microscopy is a non-destructive analytical technique which uses the information from an ultrasonic probe which is scanned over the surface of the test sample to create a complete picture of the shapes, sizes and exact positions of defects, inclusions and other metallographic features which are displayed as full (false) colour screen or printed images.

The ultrasonic probe is used in pulse-echo mode as a **B-** or **C**-scan. The amplitude and phase of the reflected signal depend on the magnitude and the rate of change in acoustic impedance as it is reflected at an interface or other feature.

By time gating the returning acoustic wave train and detecting any change in phase, the variations can be encoded and analysed digitally to convert them into shades of colour or density to build up a two-dimensional image of the sample.

The scanning acoustic microscope comprises a scanning frame which carries an orthogonal *XYZ* probe transport system. Motion of the probe in the three axes is provided by three independent stepper motors. The system incorporates a pulser–receiver circuit which is driven by a computer with appropriate software.

The sample to be scanned is placed in a tank containing a liquid capable of transmitting acoustic waves from the probe into the sample. The liquid is usually water but it can be a suitable organic liquid. The motors then move the probe over the sample in a raster pattern. The computer can be programmed to follow curved as well as planar surfaces or interfaces.

---

* Statistics are clearly very important in quantitative metallography, but are not discussed here, in the interests of brevity. General information on statistical methods can be found in Chapter 2.

Scanning acoustic microscopy is suitable for imaging defects and inclusions in ceramic and composite as well as metallic materials. It is also useful for studying soldered and diffusion-bonded interfaces and for any internal artefact whether deliberately introduced or not.

10.7   Applications in failure analysis

Failure analysis is an important and significant area of metallurgy and finds application in both industry and research. The objectives of a metallurgical failure analysis typically are to determine the source or cause of the failure, and to recommend a solution or means of prevention of similar failures. A thorough failure analysis is a complex process and may incorporate many steps, including investigation and documentation of nominal service conditions, interviews with individuals that observed the failure, non-destructive evaluation of the component, stress or fracture mechanics analysis, etc. Several texts are available which detail the process and sequence of analysis,[169–175] a full description of which is beyond the scope of this book. This section briefly presents the use and relative merit of different microstructural techniques in what is considered the heart of metallurgical failure analysis—examination of the macro and microstructural features of the fractured surfaces, also known as fractography. Careful fractographic examination can conclusively identify the mode of failure, whether it was by overload, corrosion, or fatigue, and determine if material defects or unforeseen environmental factors led to the failure.

Nearly all of the techniques described in this chapter can be used in fractography, including stereo light microscopy, metallographic examination, scanning electron microscopy, transmission electron microscopy, X-ray spectroscopy and surface analysis techniques. Prior to performing analysis, however, it is important to insure that care is taken to preserve the fracture features in their original state. Techniques for preservation and cleaning of fracture surfaces are given in Brooks and Choudhury.[169] Analysis must begin with the most non-destructive techniques, and careful documentation of findings is critical.

Examination of failed components and their fracture surfaces by low-power light microscopes is a simple and powerful technique which can quickly and easily reveal the fracture initiation point and mode of fracture. The advantages of this technique are its non-destructive nature, the lack of expensive equipment, and the ability to see and document colours. Light microscopic examination of fracture surfaces is typically performed at magnifications of up to 50X. The main disadvantage is the very limited depth of field, especially at higher magnifications. Translating images seen through the lens into quality photographs can also be difficult.

Light microscopy is frequently used in examination of metallographic sections containing the fracture surface or fracture origin, enabling an observation of the interaction of the fracture path with microstructural features such as grain boundaries or inclusions. Metallographic sections can also determine whether the microstructure reflects the intended metallurgical condition of the component alloy (hardness testing is also used) and identify microstructural defects that may have led to the failure. Fine resolution of the fracture path can be obtained through sections containing secondary cracks, since these cracks frequently are not exposed to post-fracture mechanical and environmental damage. This technique, however, is inherently destructive in nature, and the resolution of features is limited to about $0.1\,\mu m$.

The scanning electron microscope (SEM) has developed into the workhorse of fractography, due to its wide range of magnification (10X to over 20,000X), good depth of field, simplicity of sample preparation, and integrated microchemical analysis capability (through X-ray spectroscopy). It has essentially replaced the combination of light microscopy and transmission electron microscopy which was popular before the commercialisation of the SEM. As with the light microscope, examination of the fracture surface is used to identify the mode and origin of fracture, with the advantage that both the macroscopic and microscopic features can be simply and quickly recorded. The SEM can also be used to examine metallographic cross-sections at higher magnifications than in the light microscope, and with the added feature of atomic number contrast in backscattered electron imaging mode. The microchemical analysis capability is used to identify inclusions, corrosion products, and chemical alterations near surfaces or in the base metal. The main limitations of the SEM are the need for some sample preparation (to fit within the vacuum chamber, and to provide a conduction path through the specimen to ground), and the relative expense of the instrument, especially compared to light microscopes (colour information provided by light microscopy can be useful in some cases).

The transmission electron microscope (TEM) was widely used for observation of fine-scale fracture features until about 1970. Carbon replicas of the surface with heavy-metal shadowing to produce contrast from topographical features are examined. This technique has higher ultimate resolution than the SEM (2 nm for a single-stage replica), but the images require interpretation

and low magnification observation is not possible. Only a limited area of the fracture surface can be examined at once, and considerable sample preparation is required. Examination of replicas is, however, non-destructive (replicas can also be examined in the SEM). Despite these limitations, TEM examination is still used in special cases, for example, to observe very fine fatigue striations.

Surface analysis techniques such as auger electron spectroscopy (AES) and secondary ion mass spectroscopy (SIMS) are occasionally used in fractography. Their principal strength lies in identification of corrosion products and surface interaction layers. They have a broader elemental analysis capability (especially for light elements), better elemental resolution, and can be used to obtain profiles of surface composition through ion sputtering. An application example is the identification of fine-scale segregation of tramp elements to grain boundaries in the temper embrittlement of steels.

11.2 Equilibrium diagrams*

References to individual diagrams are given at the end of this section. When no reference is given the reader should consult constitution of Binary Alloys by M. Hansen and K. Anderko, McGraw-Hill (1958) and the supplements by R. P. Elliot (1965) and F. A. Shunk (1969).

Diagrams updated (Reference 9) or replaced (Reference 10) are used with permission of ASM International, Materials Park OH.

---
* *Note*: M.P. = Melting point.
    B.P. = Boiling point.

11.3   Acknowledgements

The diagrams of the binary systems have been taken from the following sources and thanks are made to the publishers and authors concerned.

The source references are shown in '11.1 Index of binary diagrams' as a number in parenthesis. For those marked (8) see list below. Those without a number are from material taken from 'Constitution of Binary Alloys', M. Hansen and K. Anderko, McGraw-Hill, New York, 1958 and from the Supplements by R. P. Elliott, 1965 and by F. A. Shunk, 1969.

12   Gas–metal systems

12.1   The solution of gases in metals

The gases which can be found in solution in measurable quantities in metals are the diatomic gases hydrogen, nitrogen and oxygen and also the noble gases in Group 8 of the Periodic Table.

12.1.1   Dilute solutions of diatomic gases

A diatomic gas dissociates on solution so that equilibrium between the solute and the gas phase is written:

$$X_2 \text{ (gas)} \rightleftharpoons 2X \text{ (dissolved in metal)}$$
In systems where no gas–metal compounds are formed and where also the solute does not contribute to the stability of the metallic phase, solutions are usually so dilute that Henry's law applies. If, also, the ideal gas laws are assumed for the gas phase and the standard states selected are (1) the infinitely dilute atomic fraction for the solute and (2) the pure element at a standard pressure $p^{\ominus}$ for the gas, the equilibrium constant is given by:

$$K = \frac{a_x^2}{a_{x_2}} = \frac{N_x^2 p^{\ominus}}{p} \tag{12.1}$$

where a_x and a_{x_2} are the activities of the solute and the diatomic gas, N_x is the atomic fraction of solute and p is the pressure of the gas. In a form rearranged to express the proportionality between the solute concentration, C, and the square root of the gas pressure, p, equation (12.1) is known as Sievert's relation:

$$C = S \left(\frac{p}{p^{\ominus}} \right)^{1/2} \tag{12.2}$$

where S is the solute concentration in equilibrium with the standard pressure, $p^{\ominus}$.

Values for solubilities in dilute solutions are usually presented as solute concentrations in equilibrium with the pure gas at one atmosphere pressure (101 325 Pa). The units of concentration in common use are cm^3 of gas measured at one atmosphere pressure and 273 K per 100 g of metal for hydrogen and mass % for nitrogen and oxygen.

Application of the Van't Hoff isochore gives the variation with temperature of the equilibrium constant at constant pressure and hence also of the corresponding equilibrium solute concentration:

$$\left(\frac{\mathrm{d}\ln K}{\mathrm{d}T} \right)_p = \frac{\Delta H^{\ominus}}{RT^2}$$

where $H^{\ominus}$ is the standard enthalpy of solution of the gas. Substituting for K from equation (12.1) gives:

$$\left(\frac{\mathrm{d}\ln N_x}{\mathrm{d}T} \right)_p = \frac{\Delta H^{\ominus}}{2RT^2}$$

For a small range of temperature it is permissible to disregard the temperature-dependence of $\Delta H^{\oplus}$ so that integration then yields:

$$\log\left(\frac{N_1}{N_2}\right) = \frac{-\Delta H^{\oplus}}{2.303 \times 2R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \tag{12.3}$$

where N_1 and N_2 are the atomic fractions of solute in equilibrium at temperatures T_1 and T_2 with the same gas pressure. Standard enthalpies of solution $\Delta H^{\oplus}$ can be evaluated from experimental results fitted to equation (12.3), bearing in mind Kubaschewski's reminder[1] that thermochemical data derived from the temperature-dependence of equilibrium constants are uncertain.

12.1.2   Complex gas–metal systems

In systems where the solute contributes to the stability of the metallic phase or where near stoichiometric compounds separate, the information of interest extends to high solute concentrations where there is deviation from Henry's law and to equilibria between condensed phases. If complete, this information is most conveniently presented graphically as isotherms, i.e. expressing composition as a function of equilibrium pressure for selected temperatures. Regions where two condensed phases coexist in the system are manifest by pressure invariance between the compositions of the conjugate phases. For some systems, the available experimental results are limited to values for solute concentrations in equilibrium at selected temperatures with either a second phase or the gas at a selected pressure.

12.1.3   Solutions of hydrogen

Table 12.1 gives selected values of dissolved hydrogen concentrations in equilibrium with hydrogen at one atmosphere pressure for the metals silver, gold, aluminium, cobalt, chromium, copper, iron, magnesium, manganese, molybdenum, nickel, lead, platinum, silicon, tin, titanium, zinc and some of their alloys. These metals are endothermic occluders of hydrogen, so solubility of hydrogen increases with increasing temperature (except for α-manganese). The hydrogen solubility values in silver, aluminium, gold, magnesium and their alloys are based on combined regression analyses of the most reliable reported hydrogen solubility data.

The alkali and alkaline-earth metals form hydrides with non-metallic characteristics in which bonding is of predominantly ionic character with the hydrogen present as H^- anions. Table 12.2 gives hydrogen concentrations in equilibrium with the corresponding hydrides for barium, calcium, magnesium, sodium and strontium.

Certain of the metals in the transition, rare earth and actinide series have the remarkable ability to take hydrogen into interstitial solid solution until the atomic fraction of hydrogen approaches simple stoichiometric ratios but without loss of the metallic character of the phase so formed. Additional phases may also appear at higher hydrogen concentrations. The solute hydrogen increases the stability of the metallic phase, the solution process is exothermic and thus for a given hydrogen activity (i.e. for constant pressure of hydrogen in the gas phase) the stability decreases with temperature. Figures 12.1 to 12.11 present information for the systems formed by hydrogen with cerium, niobium, neodymium, palladium, praseodymium, plutonium, tantalum, thorium, titanium, vanadium and zirconium. Tables 12.3 and 12.4 give data for uranium and hafnium.

12.1.4   Solutions of nitrogen

Table 12.5 gives values of dissolved nitrogen concentration in equilibrium with nitrogen at one atmosphere pressure for the metals iron, cobalt, chromium, molybdenum, manganese, nickel, silicon and some of their alloys. The solutions are dilute and the solution process is endothermic, the solubility increasing with temperature.

Table 12.6 gives values for nitrogen concentrations in iron and chromium in equilibrium with nitrides, measured by methods including internal friction and calorimetry.

In the solid metals, the solute atoms are assumed to occupy interstitial sites, only a small proportion of the available sites being filled. If iron is cold-worked, the nitrogen solubility is enhanced by additional solute sites at lattice defects thereby introduced into the metal (*see* references 117 and 118).

Some transition metals dissolve nitrogen exothermically to form concentrated interstitial solid solutions of metallic character analogous to the corresponding hydrogen solutions. Figures 12.12 and 12.13 present information for the systems niobium–nitrogen and tantalum-nitrogen.

12.1.5   Solutions of oxygen

The free energies of formation of the lowest oxides of most metals are comparatively high, so that an oxide film is formed when these metals are exposed to oxygen, except for very low pressures or very high temperatures. The solubility data usually required is therefore the concentration of dissolved oxygen in equilibrium with the oxide phase. A few other metals (Os, Pt, Rh, Au, Hg, Pd, Ru and Ir) form less stable oxides so that no film is present when the metals are exposed to oxygen at atmospheric pressure at elevated temperature. Of these, only silver and palladium dissolve appreciable quantities of oxygen. Table 12.7 gives values for the dissolved concentrations of oxygen in equilibrium with the lowest oxide of the metal or with gaseous oxygen at atmospheric pressure as appropriate. These concentrations are often small and difficult to measure. The usual method of establishing equilibrium by allowing oxygen to diffuse inwards from a surface oxide phase or from the gas phase is liable to lead to erroneous results unless the metal is free from traces of impurities which form oxides more stable than its own oxide.

Some transition metals can dissolve large quantities of oxygen before a separate oxide phase appears. Figures 12.14 and 12.15 give isotherms for the systems niobium–oxygen and tantalum–oxygen.

12.1.6   Solutions of the noble gases

The solubilities in metals of the noble gases in Group 8 of the Periodic Table are so small that the quantities which dissolve by equilibrating metals with the pure gases are difficult to detect. For example, Kubaschewski's theoretical argument[1] predicts that at 600°C, only 3.5×10^{-10} atomic fraction of xenon will dissolve in liquid bismuth equilibrated with xenon gas at one atmosphere pressure. However, significant quantities of the noble gases can be inserted into metal lattices by very energetic processes such as nuclear fission or bombardment with accelerated ions. Examples of solutions produced in this manner are given in Table 12.8. Fuller information is given in a review by Blackburn.[14]

12.1.7   Theoretical and practical aspects of gas–metal equilibria

The equilibria between metals and gases are of a wide variety and the practical effects of absorbed gases in metals during industrial processes are diverse, usually deleterious and often difficult to assess. As a result, a vast amount of practical and theoretical effort has been applied in studying gas–metal interactions using numerous different approaches, as illustrated by the selection of reviews and papers of general or theoretical interest given in references 1–15.

Table 12.8   SOLUTIONS OF NOBLE GASES

Solvent	Solutes	Method of introducing solute	References
Ag	Ar, Kr, Xe	Electric discharge on metal in gas at low pressure	243, 244, 246, 247, 249
	Ar	Injection of accelerated ions	245
	Kr	Equilibration with gas phase	248
Al	Ar	Injection of accelerated ions	245
	He	Injection of cyclotron-accelerated α-particles	250, 251, 252
Al–Li	He	Radioactive decay of neutron-irradiation products	253, 254
Al–U	Kr	Radioactive decay of neutron-irradiation products	255
Au	Ar	Injection of accelerated ions	245
Be	He	Radioactive decay of neutron-irradiation products	256, 257
	He	Injection of cyclotron-accelerated α-particles	258
Cu	He	Injection of cyclotron-accelerated α-particles	250, 259
Ge	He	Equilibration with gas phase	48, 260
Pb	Ar	Injection of accelerated ions	245
	K	Equilibration with gas phase	248
Si	He	Equilibration with gas phase	48, 260
Sn	Kr	Equilibration with gas phase	248
Ti	He		261
U	Ar, Kr, Xe	Electric discharge on metal in gas at low pressure	243, 244
	Kr	Injection of accelerated ions	245
	Kr, Xe	Nuclear fission of solvent	262, 263, 264, 265, 266
Zr	Ar, Kr, Xe	Electric discharge on metal in gas at low pressure	243, 244

13   Diffusion in metals

13.1   Introduction

In an isotropic medium the diffusion coefficient D^i of species i is defined through Fick's first law,

$$J^i = -D^i \operatorname{grad} c^i \tag{13.1}$$

J^i is the instantaneous net flux of species i, or diffusion current per unit area, and grad c^i is the gradient of the concentration c^i of i. If J and c are measured in terms of the same unit of quantity (e.g. J in $\mathrm{g\,cm^{-2}\,s^{-1}}$, c in $\mathrm{g\,cm^{-3}}$), D has the dimensions $(L^2 T^{-1})$. It has usually been expressed as $\mathrm{cm^2\,s^{-1}}$, although the units $\mathrm{m^2\,s^{-1}}$ are becoming more common. Generally, D depends on the concentration.

That matter is to be conserved at each point leads to Fick's second law,

$$\frac{\partial c^i}{\partial t} = \operatorname{div}(D^i \operatorname{grad} c^i) \tag{13.2}$$

giving the rate of the change of concentration with time to which diffusion gives rise.

The fluxes J^i are referred, at least for practical purposes, to axes fixed in the volume of the sample; but volume changes which take place as a result of diffusion lead to some ambiguity in the definition of such axes. Means have been proposed[3,6] for avoiding this by using axes scaled to the volume changes, but little use is made of these and it is more usual in accurate work to restrict the range of concentration employed so that volume changes are small or negligible.

When the concentration varies along only one direction, say the x axis, (13.1) and (13.2) become

$$J^i = -D^i \frac{\partial c^i}{\partial x} \tag{13.3}$$

$$\frac{\partial c^i}{\partial t} = \frac{\partial}{\partial x}\left(D^i \frac{\partial c^i}{\partial x}\right) \tag{13.4}$$

If, furthermore, D is independent of composition, and so also of position in the sample, (13.4) becomes

$$\frac{\partial c^i}{\partial t} = D^i \frac{\partial^2 c^i}{\partial x^2} \tag{13.5}$$

In anisotropic media diffusion rates vary with direction. In general, the diffusion flux is in the same direction as grad c *only* when grad c is along one of a set of orthogonal axes known as the 'principal axes of diffusion'. (These always coincide with axes of crystallographic symmetry so there is no difficulty in identifying them, except in cases of symmetry lower than orthorhombic.) For diffusion along principal axes equations like (13.3) may still be written.

$$\left.\begin{aligned}
J_x^i &= -D_x^i(\partial c^i/\partial x) \\
J_y^i &= -D_y^i(\partial c^i/\partial y) \\
J_z^i &= -D_z^i(\partial c^i/\partial z)
\end{aligned}\right\}$$

D_x, D_y and D_z are called 'principal coefficients of diffusion'.

In general grad c and J are not in the same direction. However, if l, m, n are the direction cosines of grad c then a diffusion coefficient for this direction may be defined as the ratio of the component of J along (l, m, n), divided by grad c. This is

$$D_{lmn} = l^2 D_x + m^2 D_y + n^2 D_z \tag{13.6}$$

Thus anisotropic diffusion can be completely described in terms of the three principal diffusion coefficients. In uniaxial crystals (tetragonal, trigonal, hexagonal) symmetry dictates, if the z axis is the unique axis, then $D_x = D_y$. Thus D is the same for all directions perpendicular to the unique axis and is often denoted $D_\perp$. D_z is then denoted as $D_{||}$. Equation (13.6) may then be written

$$D_\theta = \sin^2 \theta \cdot D_\perp + \cos^2 \theta \cdot D_{||} \tag{13.7}$$

where $\cos \theta \equiv n$.

Equations (13.4) and (13.5) still hold for anisotropic diffusion, with D given by (13.6) and (13.7).

Equation (13.1) provides a formal definition of a diffusion coefficient as the ratio of J^i to grad c^i. It also assumes that J^i is determined only by grad c^i. In the very large majority of diffusion measurements that have been made this holds true so that the above simple equations provide an adequate description of the diffusion process taking place. Such measurements are of three main types and these are discussed first and the nature of the diffusion coefficients they entail. They are:

1. Measurements which entail diffusion under a chemical concentration gradient (Chemical Diffusion Measurements—Table 13.4).

   (i) Diffusion of a single interstitial solute into a pure metal.
   (ii) Interdiffusion of two metals which form substitutional solid solutions (or interdiffusion between two alloys of the two metals).

2. Measurements which entail diffusion in essentially chemically homogeneous systems. These are possible through the use of radioactive or stable isotope tracers.

The diffusion of an interstitial solute in a pure metal [1(i)] is described by a single equation like (13.1) and the D has a simple and well-defined physical significance as describing diffusion of solute relative to the solvent lattice.

The same is true for the D for diffusion into a metal or alloy of any radioactive or stable tracer. The methods employed (*see* below) require such extremely small amounts and gradients of tracer that the system remains chemically homogeneous during diffusion. Any diffusion of other constituents is altogether negligible so that D refers simply to the diffusion of the tracer species relative to the solvent lattice.

For the interdiffusion of two metals or alloys [1(ii)] the situation is a little less simple. There would appear to be two diffusion coefficients required, one for each species, but *referred to volume fixed axes* these are equal because grad $c_1 = -$grad c_2 and J_1 must be equal and opposite to J_2. Again a single equation like (13.1) suffices to describe the diffusion process and the single D refers to the diffusion rate of either species relative to these axes. It is called the *chemical interdiffusion coefficient* and usually denoted $\tilde{D}$ (Table 13.4).

For many practical purposes $\tilde{D}$ is an adequate measure of the diffusion behaviour of a binary substitutional system. But of more fundamental physical interest are the rates of diffusion of the two species relative to local lattice planes. It is well established that generally these rates are not equal in magnitude. There is therefore a net total flux of atoms across any lattice plane, and if the density of lattice sites is to be conserved each plane in the diffusion zone must shift to compensate for this imbalance of the fluxes across it. At the same time lattice sites are created on one side of the sample and eliminated at the other, processes which are achieved by the creation and annihilation of vacancies. This shift of lattice planes, known as the Kirkendall effect, is observed experimentally as a movement of inert markers, usually fine insoluble wires, incorporated into the sample before diffusion. It is clear, then, that diffusion occurs on a lattice which locally is moving relative to the axes with respect to which $\tilde{D}$ was calculated. To provide a more complete description of binary substitutional diffusion it is therefore necessary to introduce diffusion coefficients D_A and D_B to describe diffusion of the two species relative to lattice planes. It is easy to show that these are related to $\tilde{D}$ by the equation

$$\tilde{D} = N_A D_B + N_B D_A \tag{13.8}$$

where N_A and N_B are the fractional concentrations of A and B. D_A and D_B, which are of more direct physical interest than $\tilde{D}$, are known as the *intrinsic* or *partial chemical diffusion coefficients*.

The velocity v of a marker is given by

$$v = (D_A - D_B)\partial N_A/\partial x, \tag{13.9}$$

where $\partial N_A/\partial x$ is the concentration gradient at the marker; so in principle D_A and D_B can be calculated separately when $\tilde{D}$ and v have been measured. In practice this is done usually only for markers placed at the original interface between the two interdiffusing metals or alloys: in this case a measurement of the *displacement* x_m of the marker after time t allows v to be obtained simply, for $v = x_m/2t$.

Equations (13.8) and (13.9) assume no net volume change and a compensation of the flux difference which is complete and which occurs by bulk motion along only the diffusion direction. These conditions are rarely met fully in practice, as is seen from the frequent occurrence of lateral changes in dimensions and of a porosity in the *side* of the diffusion zone suffering a net loss of atoms. This porosity, attributed to vacancies precipitating instead of being eliminated at sinks, suggests abnormal vacancy concentrations may be present in the diffusion zone. Because it is difficult to take into account the effect these abnormal conditions in the diffusion zone may have on the calculated values of $\tilde{D}$ and v, and hence on D_A and D_B, chemical interdiffusion experiments may provide results of limited accuracy and, for theoretical purposes, of limited significance: their effect is of course smaller the smaller the concentration gradients employed.

By contrast, radioactive tracer methods altogether avoid these difficulties and uncertainties associated with diffusion in a chemical gradient, and so are preferred in any investigation with a theoretical objective. They have the further advantage that the diffusion coefficients of each specie of an alloy can be determined separately and directly, rather than through any composite coefficient like $\tilde{D}$. These are referred to as *tracer diffusion coefficients* (Table 13.3) and will be denoted D_A^*, D_B^* etc. to distinguish them from the partial chemical diffusion coefficients D_A and D_B determined by chemical diffusion methods.[†]

Results on the diffusion coefficient D_A^* in very dilute alloys AB containing small concentrations C_B of B are frequently represented in terms of the solvent enhancement factors b_1, b_2, etc., in the equation

$$D_A^*(C_B) = D_A^*(C_B = 0)(1 + b_1 C_B + b_2 C_B^2 + \cdots) \tag{13.9a}$$

$D_A^*(C_B = 0)$ is of course just the self-diffusion coefficient of pure A.

A similar relation describes the diffusion of the solute B in A

$$D_B^*(C_B) = D_B^*(C_B = 0)(1 + B_1 C_B + B_2 C_B^2 + \cdots) \tag{13.9b}$$

B_1, B_2 are the solute enhancement factors and $D_B^*(C_B = 0)$ is the tracer impurity diffusion coefficient of B in A.

Except at vanishingly small concentrations of A, D_A and D_A^* differ fundamentally because the presence of the chemical concentration gradient under which D_A is measured imposes on the otherwise random motion of the atoms a bias, which makes atoms jump preferentially in one direction along the concentration gradient. Simple thermodynamic considerations lead to the relation

$$D_A = D_A^* \left(1 + \frac{\partial \ln \gamma_A}{\partial \ln N_A} \right) \tag{13.10}$$

between a partial chemical D_A and the corresponding tracer D_A^* measured at the same concentration. γ_A is the activity coefficient of A. In a binary system the bracket term is the same for both species (Gibbs–Duhem relation). Thus

$$\frac{D_A}{D_A^*} = \frac{D_B}{D_B^*} \tag{13.11}$$

(13.10) and (13.11) are approximate forms of more elaborate theoretical expressions, but are reasonably well obeyed experimentally. *See*, for example, references 4 and 7.

When D_A^* is measured at the extremely small concentrations of A that tracer methods permit (by diffusion of tracer into pure metal B it is called the *tracer impurity diffusion coefficient* of A in B

[†] D_A^* and D_B^* are sometimes referred to as the *self-diffusion coefficients of the alloy*. This is a perfectly acceptable alternative terminology. But there is a tendency nowadays to employ the term 'self' to the extent of describing tracer impurity diffusion coefficients as impurity self-diffusion coefficients. This latter term is ambiguous and misleading and its use is to be discouraged.

(Table 13.2). Such coefficients are of especial theoretical interest because of the particularly simple type of diffusion they describe (*see* footnote).

Finally, tracer methods are used as the commonest means of measuring *self-diffusion coefficients* in pure metals (Table 13.1, 13.5 and 13.6). By self-diffusion is meant the diffusion of a species in the pure lattice of its own kind.

For chemical diffusion in systems of more than two components, equation (13.1) and those following are inadequate. Experimentally it is found that when three or more components are present a concentration gradient of one species can lead to a diffusion flow of another, even if this is distributed homogeneously to start with. To cater for such cases Fick's first law is generalised by writing

$$J_i = \sum_{j=1}^{N} D_{ij} \frac{\partial c_j}{\partial x} \quad (j = 1, 2, \ldots, N) \tag{13.12}$$

But if there are n interstitial and $N-n$ substitutional components, and if the J_i are referred to volume-fixed axes then the relations

$$\sum_{j=n+1}^{N} J_i = 0 \quad \text{and} \quad \sum_{j=n+1}^{N} \partial c_j / \partial x = 0$$

allow (13.12) to be rewritten

$$J_i = \sum_{j=1}^{N-1} D_{ij} \frac{\partial c_j}{\partial x} \quad (j = 1, 2, \ldots, N-1) \tag{13.13}$$

so that $(N-1)^2$ coefficients suffice to describe the diffusion behaviour. The analogue of Fick's second law is

$$\frac{\partial c_i}{\partial t} = \sum_{j=1}^{N-1} \frac{\partial}{\partial x} \left(D_{ij} \frac{\partial c_j}{\partial x} \right) \tag{13.14}$$

These equations have been applied to a few ternary systems.[7,2]

It is possible to show from the principles of irreversible thermodynamics that not all the D_{ij} are independent and that a total of only $N(N-1)/2$ coefficients are in fact sufficient to describe diffusion in an N-component system. No measurements in metals have employed this reduced scheme of coefficients, for to do so requires a knowledge of the thermodynamic properties of the system that is rarely available.

13.2   Methods of measuring D

13.2.1   Steady-state methods

These are based directly on Fick's first law. The usual procedure is to maintain concentrations of diffusant on the opposite sides of a sample, which is usually a thin sheet or a thin-walled tube, and to measure the resulting steady rate of flow J. This is generally practicable only when the diffusing element is a gas or can be supplied to and removed from the sample through a vapour phase. If the surface concentrations c_1 and c_2 in equilibrium with the ambient atmospheres are known, an average D over the concentration range is, for a sheet of thickness t for example, simply $\bar{D} = Jt/(c_1 - c_2)$ (Method Ib). Alternatively, if the steady concentration distribution across the sample is determined, $D(c)$ may be calculated from $D = -J(\partial c/\partial x)^{(-1)}$ (Method Ia). D may also be calculated from measurements of the time required to reach a steady state (Method Ic). These methods are used for measuring D only for interstitial solute diffusion: the Kirkendall effect complicates any attempt to apply it reliably to substitutional diffusion.

13.2.2   Non-steady-state methods

As a result of change in the concentration distribution in a sample D is deduced from a solution of Fick's second law [equations (13.2), (13.4), (13.5) or (13.14) appropriate to the conditions of the experiment]. There are three common types of experimental arrangements, two of which are usually employed in chemical diffusion coefficient measurements, the third in measurements of tracer diffusion coefficients.

(i) DIFFUSION COUPLE METHOD

Two metals, or two different homogeneous alloys of concentrations c_1 and c_2, are brought into intimate contact across a plane interface, say by welding. Diffusion is allowed to take place by annealing at a constant temperature for a time t. The distribution of concentration in the sample is then determined in some convenient manner, often by removal and subsequent analysis of a succession of thin layers cut parallel to the initial interface. It is usually arranged that the two halves of the couple be sufficiently thick that the diffusion zone does not extend to either end.

D generally varies with concentration, but no analytic solutions of (13.4) are available. So, a graphical method of analysis known as the Matano-Boltzmann method is employed. The concentration c is plotted against x and $D(c)$ determined graphically from

$$D(c) = (2t \cdot \partial c/\partial x)^{-1} \int_c^{c_1} x \, dc \quad \text{[Method IIa(i)]} \tag{13.15}$$

The origin of x is located by the condition

$$\int_{c_1}^{c_2} x \, dc = 0$$

and this may be shown to coincide, under ideal conditions, with the *initial* position of the interface between the two members of the couple. Thus it is $\tilde{D}$ which is measured in substitutional diffusion. Markers inserted at the interface locate its *final* position after diffusion. It has already been mentioned that measuring their displacement x_m from $x = 0$ allows the partial diffusion coefficients to be calculated.

If D varies little in the range c_1 to c_2, and this is often so if the range is sufficiently restricted, equation (13.5) may be used. The solution for this case is

$$\frac{c - c_2}{c_1 - c_2} = \frac{1}{2} \left\{ 1 - erf \left[\frac{x}{2\sqrt{(Dt)}} \right] \right\} \tag{13.16}$$

with $x = 0$ defined as before; D can then be calculated directly by a 'least squares' fit of the $c \sim x$ data to this or other appropriate equations [Method IIa(ii)].

Occasionally, the diffusion couple method is used to measure self-diffusion coefficients, one half of the couple being normal metal, the other enriched in one of its active or normal isotopes. It may also be used to measure diffusion coefficients in liquids (Shear-cell method).

With analytic solution like (13.16), D can be calculated by measuring c at one position only. This is sometimes done but it is not to be expected that values derived in this way will be as reliable as when derived from a complete $c \sim x$ curve (Method IIb).

The concentration range in a diffusion couple may span any number of phase regions in the equilibrium diagram of the system; the diffusion zone then consists of phase layers with concentration discontinuities across each boundary between two layers. In such cases equation (13.15) [Method IIa(i)] is still applicable. If D is assumed constant, analytic solutions are available and with these it is sometimes possible (Method IIc) to determine D from measurements only of the rates of movement of one or more phase boundaries and knowledge of the equilibrium concentrations at the boundary.[2,3,7]

(ii) IN-DIFFUSION AND OUT-DIFFUSION METHODS

Material is allowed to diffuse into, or out of, an initially homogeneous sample of concentration c_1 under the condition that the concentration at the surface is maintained at a constant and known value

c_0 by being exposed to a constant ambient atmosphere. c_1 is usually zero for in-diffusion experiments and so is c_0 for out-diffusion experiments.

D may be calculated from a measurement either of the total amount of material taken up by or lost from the sample (Method IIIb), or of the concentration distribution within the sample after diffusion (Method IIIa). The first method gives an average D over the range c_1 to c_0. For the second, equation (13.15) can be used again to give $D(c)$ or, if D is constant, it may be calculated from an appropriate analytic solution.

When the loss (or gain) of material from the sample entails the movement of a phase boundary, D can again be calculated from the rate of movement (Method IIIc). This method has been mostly used for interstitial solute diffusion, but also occasionally for substitutional diffusion measurements in systems with a sufficiently volatile component. A disadvantage is that conditions at the surface may not always be under adequate control so that c_0 is either ill-defined or not constant or both, with consequent uncertainty in D.

A common method of measuring liquid self-diffusion rates employs a type of out-diffusion method. A capillary tube, closed at one end and containing activated material, is immersed open-end uppermost in a large bath of inactive material. After the diffusion anneal the depleted activity content of the capillary is determined, and D calculated on the assumption that diffusion of the active species out of the tube is subject to zero concentration being maintained at the exit.

For determining the concentration distribution $c(x)$ in any of the above chemical diffusion methods a wide variety of techniques has been employed; these include the traditional methods of chemical and spectrographic analysis, X-ray and electron diffraction, X-ray absorption, microhardness measurements and so forth and the more recent, and often highly sensitive, methods of microprobe analysis, laser and spark source mass spectrometry nuclear reaction analysis and Rutherford back-scattering. Also may be mentioned are electrochemical methods where the diffusion sample is contrived as an electrolytic cell wherein diffusion fluxes may be measured as currents and/or surface concentrations as surface potentials. In this edition of the tables the method of analysis is not recorded for it is probably of less importance in assessing the reliability of a result than other features of the experimental procedure.

(iii) THIN LAYER METHODS

These are used now almost exclusively for the measurement of self and of tracer Ds. A very thin layer of radioactive diffusant, of total amount g per unit area, is deposited on a plane surface of the sample, usually by evaporation or electrodeposition. After diffusion for time t the concentration at a distance x from the surface is

$$c(x) = \frac{g}{(\pi Dt)^{1/2}} \exp\left(-\frac{x^2}{4Dt}\right) \tag{13.17}$$

provided the layer thickness is very much less than $(Dt)^{1/2}$. This condition is easy to satisfy because extremely small quantities suffice for studying the diffusion on account of the very high sensitivity of methods of detecting and measuring radioactive substances. For the same reason there is a negligible change in the chemical composition of the sample, so D is constant and equation (13.5), of which (13.17) is the solution for this case, is applicable.

After diffusion the activity of each of a series of slices cut from the sample may be determined and D calculated from the slope $(=1/4Dt)$ of the linear plot of log activity in each slice against x^2 [Method IVa(i)]. Alternatively, such a plot may be constructed from intensity measurements made on an autoradiograph of a single section cut along or obliquely to the diffusion direction [Method IVa(ii)].

Another method is to calculate D from measurements made, after the removal of each slice, of the residual activity emanating from each newly exposed surface *of the sample*. [Residual activity method; Method IVb.]

Or, D may be determined by comparing the total activity from the surface $x = 0$ after diffusion with the original activity at $t = 0$ (surface decrease, Method IVc).

Methods IVb and IVc require an integration of equation (13.17). They are generally regarded as less reliable in principle than Method IVa because they necessitate a knowledge of the absorption characteristics of the radiation concerned. In addition Method IVc is particularly susceptible to errors arising from possible oxidation and from evaporation losses of the deposited material and so is rarely used nowadays.

A recent development has been the use of the electron-microprobe, and similarly sensitive methods (*see* above), to measure even impurity diffusion coefficients: instruments are now available with a

sensitivity adequate to monitor diffusion from deposited layers of *inactive* diffusant thin enough to meet the requirements for use of equation (13.17) [Method IVa(iii)].

13.2.3   Indirect methods, not based on Fick's laws

In addition to macroscopic diffusion there are a number of other phenomena in solids which depend for their occurrence on the thermally activated motion of atoms. From suitable measurements made on some of these phenomena it is possible to determine a *D*. The more important of these are:[6,15]

1. Internal friction due to a stress-induced redistribution of atoms in interstitial solution in metals (Snoek effect and Gorsky effect, Method Va.)
2. A similar phenomenon occurring in substitutional solid solution and due, it is believed, to stress-induced changes in short range order (Zener effect, Method Va.)
3. Phenomena associated with nuclear magnetic resonance absorption, especially the 'diffusional narrowing' of resonance lines and a contribution, arising from atomic mobility, to the spin-lattice relaxation time T_1 (Method Vb).
4. Some magnetic relaxation phenomena in ferromagnetic substances (Method Vc).
5. The width of Mössbauer spectrum lines (Method Vd).
6. The intensity and shape of quasi-elastic neutron scattering spectra (Method Ve).

These methods are associated with atomic motion over only a few atomic distances, and so have the advantage of providing measurements of *D* at temperatures lower than are often practicable by conventional methods. However, some of them are of very limited application. For example, 3, 5, and 6 are obviously limited to diffusion of appropriate nuclei only. Since in every case measurements are made in homogeneous material the diffusion coefficients obtained are of the nature of tracer rather than chemical diffusion coefficients.

Most measurements of *D* are conducted at a series of temperatures so as to provide values of the constants *A* and *Q* occurring in the Arrhenius equation

$$D = A \exp\left(-Q/RT\right) \tag{13.18}$$

which usually describes very well the observed temperature dependence.[*] *A* is called the 'frequency factor' and *Q* the activation energy. Wherever possible, experimental measurements are reported in the tables in terms of *A* and *Q* alone. Occasionally, accurate measurements, particularly if over an extended temperature range, reveal slightly curved Arrhenius plots. These can usually be well represented by the sum of the Arrhenius terms

$$D = A_1 \exp\left(-Q_1/kT\right) + A_2 \exp\left(-Q_2/kT\right) \tag{13.19}$$

For such measurements A_2 and Q_2 are tabulated immediately below A_1 and Q_1. In Tables 13.3 and 13.4 A_2 and Q_2 are preceded by the sign +. (*see* e.g. CoGa in Table 13.3.)

Experiments may be made by any of the above methods either with single crystal or polycrystalline material. With polycrystals there is, in addition to diffusion through the grains (volume diffusion), diffusion at a more rapid rate locally through the disordered regions of grain boundaries. This can, however, be reduced to a negligible proportion of the whole by using large grain material and by working at relatively high temperatures because, since $Q_{gb} < Q_v$, grain boundary diffusion rates increase less rapidly with temperature than do volume diffusion rates. Obviously single crystals are to be preferred in accurate measurements of what is intended to be volume diffusion, but even in their case there may be, at too low temperatures, a contribution to *D* from diffusion along dislocations. Measured values of *D* will then tend to be above the values expected from an extrapolation of the high temperature data using (13.18) and when they do so to a noticeable extent are often discarded in estimating *Q* and *A*.

From measurements of the concentration distribution around a grain boundary—usually in a bicrystal into which material diffuses parallel to the boundary—a product $D'\delta$ may be deduced.[9,10] D' is the coefficient for diffusion *in* the boundary of width δ, an uncertain quantity generally assumed to be $\delta = 5.0 \times 10^{-8}$ cm. $D'\delta$ is found to depend on the orientation of the boundary and on the direction of diffusion within it. For an extensive range of data on $D'\delta$s, *see* reference 10.

———————————

[*] This is often true even of $\tilde{D}$, because Q_A and Q_B for the partial diffusion coefficients do not seem to differ very much.

13.3   Mechanisms of diffusion

Most theoretical discussions of diffusion are concerned with an understanding of *A* and *Q* rather than of *D* itself. On the basis of theoretical calculations of *Q* for various possible mechanisms of diffusion and comparison with observed values, it has been supposed for some time that in metals atoms diffuse substitutionally by thermally activated jumps into vacant lattice sites, i.e. by the 'vacancy mechanism'. This has been very convincingly confirmed, at least for f.c.c. metals, by thermal expansion and quenching experiments. At high temperatures, towards the melting point, there is believed to be a sizeable contribution to *D* from diffusion by bound divacancy pairs. While the same mechanism is usually thought to operate in most metal structures, there is considerable doubt at present whether this is in fact true for a number of so-called 'anomalous b.c.c. metals'— *β*-Ti, *β*-Zr, *β*-Hf, *β*-Pr, *γ*-U and *δ*-Ce—or at least whether the vacancy mechanism is the only one operating in their case. It is also believed that the noble metals and other low-valent solutes (Group II), plus the later transition elements, may dissolve interstitially, at least in part, and diffuse by an interstitial-type process in the alkali metals, in the high-valent Group III and IV elements and also in the *early* members of each of the transition groups, the lanthanide series and the actinide series of elements. This belief stems from the anomalously very large diffusion rates of these solutes in these solvents.[11,13,14]

Summary of methods for measuring *D*

STEADY-STATE METHOD with

I.	(a)	Measurement of concentration distribution within the sample or,	Ia
	(b)	Average gradient calculated from c_1 and c_2 as deduced from equilibrium data or,	Ib
	(c)	Time-delay method (measurement of time to reach steady state)	Ic

NON-STEADY METHODS

II. *Diffusion couple methods*
    (a)   With determination of $c \sim x$ curve and
        (i)   Use of Matano-Boltzmann analysis to give $D(c)$ IIa(i)
        (ii)   When it is evident (or assumed) that D is effectively constant,
            calculation of D from an analytic solution   IIa(ii)
        (iii) When it is evident that D is *not* constant and an analytic solution is used
            to calculate a D corresponding to each value of c—giving
            an approximate $D(c)$ IIa(iii)
    (b) D calculated from a single concentration measurement   IIb
    (c) D calculated from an analytic solution, assuming D constant, using
         measurements of rate of movement of phase boundaries and knowledge of
         equilibrium concentrations on the boundaries   IIc

III. *In-diffusion and out-diffusion methods* in-(i) out-(ii)
    (a) D calculated from $c \sim x$ curves   IIIa
    (b) D calculated from total gain or loss, or rate thereof   IIIb
    (c) D calculated from rate of phase boundary movement   IIIc

IV. *Thin layer methods*
    (a)   With measurement of $c \sim x$ curve
        (i)   By sectioning and counting—using radioactive diffusant   IVa(i)
        (ii)   By autoradiography—using radioactive diffusant   IVa(ii)
        (iii) By electron-microprobe or similarly sensitive method—using
            non-radioactive diffusant   IVa(iii)
    (b)   Residual activity method—using radioactive diffusant   IVb
    (c)   Surface decrease method—using radioactive diffusant   IVc

V. *Indirect methods*
    (a)   By internal friction   Va
    (b)   By nuclear magnetic resonance   Vb
    (c)   By ferromagnetic relaxation   Vc
    (d)   From Mössbauer line spectra   Vd
    (e)   From quasi-elastic neutron scattering   Ve

Notes on the tables

1. All measurements are reported whenever possible in terms of A and Q (*see* equation 13.18) or of $A_1 \cdot Q_1$, A_2 and Q_2 (equation 13.19). A in $\mathrm{cm^2\,s^{-1}}$: Q in $\mathrm{kJ\,mol^{-1}}$: ($R = 8.31441\,\mathrm{J\,mol^{-1}K^{-1}}$ eV $= 96.4846\,\mathrm{kJ\,mol^{-1}}$).
2. The 'temperature range' is the range over which measurements were used to calculate A and Q. Extrapolation too far outside this range may not in some cases give reliable values for D.
3. All alloy concentrations are in atomic percentages unless otherwise stated. Purity of material is as quoted and is presumably in weight percentages, although this is not always stated explicitly in papers.
4. s.c. = single crystals; p.c. = polycrystals.
5. In Table 13.4 a single concentration denotes the concentration at which $D(c)$ was determined. Two concentrations separated by a hyphen denote the range of concentration over which measurements were made. Where this is followed by a single D value, or a single set of A and Q values, it is also the concentration range over which these values are averages.
6. Bold type in Table 13.4. This is used: (1) To indicate the species to which the D's, or A and Q values, refer in cases where there might be ambiguity–usually for interstitial solid solutions. Where there is no bold type the data refers to the interdiffusion coefficients of the first two substitutional species. (2) To indicate which component was used in the vapour phase in experiments employing methods I and III.
7. Where several measurements exist an attempt has been made to select what appear to be the most reliable one or two. Mostly these are later measurements and references to earlier work can usually be found by consulting the references quoted.

Notes:

(*a*) Reference 2 reports measurements of self-diffusion in Li of different isotopic compositions, from which are derived values of D for Li^6 and of Li^7 diffusing in Li^6.

(*b*) Forced linear fit to slightly curved Arrhenius plot—equation 13–19.

(*c*) Although the higher Q values are confirmed by creep measurements, the indirect methods indicate lower values of Q at the lower temperatures at which they are applied. Collected results are discussed in references 29.

(*d*) Measures the 'macroscopic diffusion coefficient' D^{SD}. $D_{Tracer} = D^{SD} \times f$. f = the correlation factor ($\sim$0.5–0.7, depending on T). *See* reference 3 for details.

(*e*) Assumed in analysis of results that D in direction perpendicular to basal plane is negligible.

(*f*) *See* reference 45 for account of the highly anomalous self-diffusion behaviour of Bi and reasons for believing the often quoted results of Seith (reference 46) to be very suspect.

(*g*) Orthorhombic S crystals, $D_{\|c}$ is 2 to 4 times less than $D_{\perp c}$.

(*h*) The results quoted from (68) are from a least squares fit to the three measurements of reference 69.

(*i*) Samples pre-annealed at diffusion temperature.

(*j*) Samples all pre-annealed at 1080°C.

(*k*) References 80 and 92 give expressions for D over the α range as a function of T and of the magnetisation.

(*l*) Measurements with P^{32} (reference 87) show larger D's due to radiation enhancement from the more energetic P^{32} radiation.

(*m*) These values are very close indeed to the values $A = 0.5$, $Q = 68.0$ previously chosen by Badia (76) as best representing the combined results of a number of other investigations over the range 1050/1400°C.

(*n*) $A = 1.27$, $Q = 67.2$ are given in reference 76 as the best fit to the combined results of references 79 and 80.

(*o*) Measurements with P^{32} (reference 42) show larger Ds due to radiation enhancement from the more energetic P^{32} radiation.

(*p*) MC refers to mosaic crystal and PC refers to perfect crystal.

(*a*) Arrhenius plots in the ordered region are curved. The values of *A* and *Q* reported described straight line approximations to the data over the temperature ranges indicated.

(*b*) Ditto. The values of *A* and *Q* given here refer to the data at the lower end of the ordered temperature range investigated, viz: 300 K.

(*c*) Values of *D*** for the ordered region are shown only in graphical form in reference 48.

(*continued*)

14 General physical properties

14.1 The physical properties of pure metals

Many physical properties depend on the purity and physical state (annealed, hard drawn, cast, etc.) of the metal. The data in Tables 14.1 and 14.2 refer to metals in the highest state of purity available, and are sufficiently accurate for most purposes. The reader should, however, consult the references before accepting the values quoted as applying to a particular sample.

Table 14.1 THE PHYSICAL PROPERTIES OF PURE METALS AT NORMAL TEMPERATURES

Metal	Melting point (°C) [i]	Boiling point (°C) [i]	Density (g/cm^3) at 25°C [i]*	Thermal conductivity (W/m K) at 25°C [ii]	Mean specific heat (J/kg K) at 25°C [iii]	Resistivity (10^{-8} Ωm) at T (°C) [iv]		Temp. coeff. of resistivity (10^{-3} K^{-1}) 0–100°C	Coeff. of expansion at 25°C [i]
						T (°C)	Resistivity

14.2 The thermophysical properties of liquid metals*

Accurate and reliable information on the thermophysical properties of molten metals becomes increasingly significant as new casting techniques are developed and advancement is made in numerical modelling of these processes. To obtain precise thermophysical data for molten metals and alloys, it is necessary to know the special features of different techniques and to utilise the most suitable one for the specimen of interest.

14.2.1 Density and thermal expansion coefficient

Knowledge of the density of liquid metals is crucial in most theories related to the liquid state and for the simulation of the contraction that occurs during solidification. There are several methods for measuring the density of high-melting liquid metals: balanced columns, pycnometer, immersed-sinker, maximum-bubble, etc. However, the application of all these techniques is limited due to reaction between liquid metal sample and the apparatus. Therefore, an electromagnetic levitation technique can be considered as a good alternative for density measurements in molten metals. The density (ρ) of the specimen can, of course, be determined as

$$\rho = \frac{m}{V},$$

where m and V are the mass and the volume of the specimen, respectively. Assuming a spherical shape for the specimen, the volume can be determined from the radius of the droplet. Repeating the density measurements at different temperatures, the thermal expansion coefficient (β) can be simulated as

$$\beta = \frac{1}{V}\frac{\partial V}{\partial T}.$$

The determination of the thermal expansion coefficient of the materials requires the measurement of the linear size of the specimen as a function of the temperature.

It is experimentally found that the variation of the density of most liquid metals and alloys with temperature (T) is well represented by a linear equation

$$\rho = \rho_m + \frac{\partial \rho}{\partial T}(T - T_m),$$

where ρ_m is the density of the liquid metal or alloy at its melting point T_m. However, for certain metals (aluminium, gallium, antimony) this relationship is not linear. Table 14.3a presents density data available for liquid metals at their melting point and their temperature dependence ($\partial\rho/\partial t$) from [1, 2].

14.2.2 Surface tension

The surface tension is determined by the microscopic structure of the liquid near the surface. At a liquid–vapour interface the density changes severely from a high value in the liquid state to a very low value in the gas phase. Therefore, surface atoms experience an attraction toward the liquid phase, which is the cause of the surface tension. Due to its energetic and entropic origin, it is necessary to calculate the free energy of the system in order to determine the surface tension. Thus the surface tension is determined, as the additional free energy required to generate a unit surface area separating the liquid from its vapour phase. There are many techniques for surface tension measurements: sessile drop, pendant drop, maximum bubble pressure, maximum pressure in a drop, detachment or maximum pull, capillary-rise, drop weight, and oscillating drop methods. The sessile-drop technique has been widely used due to its many advantages. The sessile drop method utilises a molten drop resting on a horizontal ceramic substrate, and allows measurements over a wide range of temperatures. However, the surface tension data is affected by contaminants. To avoid the contamination effects the surface tension of a liquid droplet can be measured by exciting surface oscillations. The frequency of the oscillations is related to the surface tension.

---

The temperature dependence of surface tension is related to the surface entropy and the surface excesses. Therefore, the changes in the structure of the liquid specimen with temperature are reflected in the temperature coefficients of the surface tension. The variation of the surface tension with the temperature for most liquid metals can be expressed by a linear relationship

$$\gamma_T = \gamma_m - \frac{\mathrm{d}\gamma}{\mathrm{d}T}(T - T_m),$$

where γ_T and γ_m are the surface tensions at temperature T and at the melting point T_m, respectively. Experimental values of surface tension for liquid metals at their melting points, and their temperature coefficients of surface tension are presented in Table 14.3b. The data are taken from Allen.[3,2]

14.2.3   Viscosity

Viscosity is one of the most important transport properties of molten metals. It is related to the internal friction within the liquid and provides some information about the structure of the material. The most crucial hydrodynamic criteria such as the Reynolds number, the Rayleigh number, the Hartmann number, and the Marangoni number contain viscosity. The existing methods for measuring viscosities of liquids are restricted for liquid metals and alloys due to their low viscosities, high melting points, and chemical reactivity. The capillary, oscillating-vessel, rotational, and oscillating plate methods are most suitable techniques for determination of the viscosity of liquid metals and alloys. The viscosity η relates the shear stress τ to the shear rate $\dot{\gamma}$

$$\tau = \eta\dot{\gamma}.$$

By analogy to the Wiedemann–Franz–Lorenz law and the Stokes–Einstein relation, there is the following relationship between viscosity and surface tension

$$\frac{\gamma}{\eta} = \frac{15}{16}\sqrt{\frac{\kappa_B T}{m}},$$

where κ_B is the Boltzmann's constant and m is the atomic mass.

Since the viscosity measurements are not so responsive to convection as diffusion measurements, the diffusivity D may be estimated from the viscosity data using Stokes–Einstein theory

$$D = \frac{\kappa_B T}{6\pi R\eta}.$$

For most liquid metals and alloys the variation of viscosity with temperature may be determined as

$$\eta = \eta_0 \exp\left(\frac{E}{RT}\right),$$

where η_0 and E are constants, and are given in the Table 14.3a for liquid metals,[4,5] and R is the gas constant, $8.314\,4\,\mathrm{J\,K}^{-1}\,\mathrm{mol}^{-1}$.

14.2.4   Heat capacity

Heat capacity (C) is one of the most essential thermodynamic properties of metals. A knowledge of the heat capacity and its temperature dependence allows prediction of the enthalpy and entropy of a material. It is determined as

$$C = \frac{\delta q}{dT},$$

where δq is an infinitesimal heat quantity added to (or withdrawn from) the matter and dT is the resulting infinitesimal temperature change. The specific heat is traditionally measured by adiabatic calorimetry techniques. The calorimeter is isolated from the environment, and requires long relaxation times. Heat capacities determined at constant volume or at constant pressure are of most general importance. Table 14.3b lists values of constant-pressure heat capacity for liquid elements at different temperatures.[6–8]

14.2.5   Electrical resistivity

Information on the electrical resistivity of molten metals and alloys is especially important in many metallurgical processes such as electroslug remelting, electromagnetic stirring in continuous casting, electrolysis, and induction melting in foundries. Due to the disordered arrangement of ions in the liquid state, molten metals and alloys exhibit higher ($\sim$1.5–2.3 times) electrical resistivity than those in the solid state. However, relatively few studies have been reported on the electrical resistivity of molten metals and alloys, particularly at elevated temperatures, since the measurements are extremely difficult. The methods of electrical resistivity measurements can be categorised into three groups: direct resistance measurements using contact probes, contactless inductive measurements, and non-contact containerless measurement techniques.

   The technique of choice for solid materials is the direct resistance four-probe method, which is based upon application of Ohm's law. Although this direct method can be applied to low melting point, non-reactive liquid materials, reactions between the probes and the molten sample preclude using the four-probe method with high-melting point materials. Also, this technique is limited to materials with very narrow freezing ranges.

   Inductive techniques for measuring electrical resistivity are contactless and thus prevent chemical reactions between molten samples and contacting probes as in the direct method. There are two different types of contactless methods. The rotating field method is usually based on the phenomenon that when a metal sample rotates in a magnetic field (or the magnetic field rotates around a stationary sample), circulating eddy currents are induced in the sample, which generate an opposing torque proportional to the electrical conductivity of the sample.[9,10] In liquid metals and alloys the applied magnetic field also causes significant rotation of the liquid in the crucible, which decreases the angular velocity between the field and the sample.

   In both direct resistance and contactless inductive techniques chemically reactive components contained in the crucible may easily contaminate the molten sample, altering its electrical properties. The container may provide heterogeneous nucleants that generate early solid-phase nucleation. Electromagnetic levitation is another technique for containerless measurements of electrical conductivity in liquid metals.[11] It combines the containerless positioning method of electromagnetic levitation with the contactless technique of inductive electrical conductivity measurement.

   The electrical resistivity ρ_e of liquid metals (except Cd, Zn, Hg, Te and Se) increases linearly with increasing temperature

$$\rho_e = aT + b,$$

where a and b are temperature coefficients of the resistivity, and are determined experimentally. The electrical resistivities of most liquid metallic elements at different temperatures are shown in Table 14.3b.[6–8]

14.2.6   Thermal conductivity

Accurate measurement of thermal conductivity of liquid metals and alloys is usually more difficult than the measurement of electrical conductivity and thermal diffusivity. The source of difficulty is mainly related to problems with making accurate heat flow measurements. Also there is possibility

of some flows in the liquid sample. Thermal conductivity is directly related to the change in the atomic vibrational frequency. For a number of non-metallic substances it is found that

$$\frac{\lambda}{\sqrt{M}} = 2.4 \times 10^{-3},$$

where λ is the thermal conductivity, M is the molecular weight. Since free electrons are responsible for the electrical and thermal conductivities of conductors in both solid and liquid states, many researchers use the Wiedemann-Franz-Lorenz law to relate the thermal conductivity to the electrical resistivity:

$$\frac{\lambda \rho_e}{T} = \frac{\pi \kappa^2}{3e^2} \equiv L_0,$$

where κ is the Boltzmann constant, e is the electron charge. The constant

$$L_0 = \frac{\pi^2 \kappa^2}{3e^2} = 2.45 \times 10^{-8} \, W\,\Omega\,K^{-2},$$

is the Lorenz number. The validity of this relationship was confirmed experimentally with high accuracy by many researchers. The thermal conductivity values of various liquid metals at different temperatures are given in Table 14.3b.[6–8]

AC Sand cast.
T4 Solution heat treated.
T5 Precipitation heat treated.
T6 Fully heat treated.
[†] Mg–Al type alloys normally
    contain 0.2–0.4% Mn to improve
    corrosion resistance.
** Thorium containing alloys are
    being replaced by alternative Mg
    alloys.

T1 Extruded, rolled or forged.
RE Cerium mischmetal containing
approx. 50% Ce.
* Non-equilibrium solidus 420°C.
() Estimated value.
RE(D) Mischmetal enriched in
neodynium.
RE(Δ) Neodynium + Heavy Rare
Earths.

[‡] Weldability rating:
A Fully weldable.
B Weldable.
C Not recommended where
fusion welding is involved.

[§] Damping capacity rating:
A Outstanding.
B Equivalent to cast iron.
C Inferior to cast iron but better than
Al-base cast alloys.

* Where trade marks apply to the name of an alloy there may be materials of similar composition available from other producers who or may not use the same suffix along with their own trade names. The suffix alone e.g. Alloy 800 is sometimes used as a descriptive term for the type of alloy but trade marks can be used only by the registered user of the mark.

† Registered Trade Mark.

‡ A variant on alloy 800 having controlled carbon and heat treatment to give significantly improved creep-rupture strength.

14.10 The physical properties of pure tin

Melting point		231.9°C
Boiling point		2 270°C
Vapour pressure at	727°C	7.4× 10^{-6} mmHg
	1 127°C	4.4× 10^{-2} mmHg
	1 527°C	5.6 mmHg
Volume change of freezing		2.7%
Expansion on melting		2.3%
Phase transformation	$\alpha \rightleftarrows \beta$	13.2°C

Density at 20°C	7.28 g/cm^3
Specific heat at 20°C	222 J kg^{-1} K^{-1}
Latent heat of fusion	59.6 kJ kg^{-1}
Latent heat of evaporation	2 497 J kg^{-1}
Linear expansion coefficient at 0–100°C	23.5×10^{-6} K^{-1}
Thermal conductivity at 0–100°C	66.8 Wm^{-1} K^{-1}
Electrical conductivity at 20°C	15.6 IACS
Electrical resistivity at 20°C	12.6 µΩ cm
Temperature coefficient of electrical	
resistivity at 0–100°C	0.004 6 K^{-1}
Thermal EMF against platinum	
cold junction at 0°C	
hot junction at 100°C	+0.42 mV
Superconductivity, critical temperature (T_c)	3.722 K
Viscosity	0.013 82 poise at 351°C
	0.011 48 poise at 493°C
Surface tension	548 mN m^{-1} at 260°C
	529 nM m^{-1} at 500°C
Gas solubility in liquid tin:	
Oxygen at 536°C	0.000 18%
Oxygen at 750°C	0.004 9%
Hydrogen at 1 000°C	0.04%
Hydrogen at 1 300°C	0.36%
Nitrogen	Very low

Notes:
∗The values are a mean from RT up to the temperature quoted.
1. Where *specific heats* are quoted at temperatures above RT the values have been determined over a range of 50°C up to the temperature quoted.
2. *Coefficients of expansion* are mean values from RT up to the temperature quoted.
3. *Electrical resistivity* values are uncorrected for dimensional changes of the specimen with temperature. Original dimensions as at RT.

15 Elastic properties, damping capacity and shape memory alloys

15.1 Elastic properties

The elastic properties of a metal reflect the response of the interatomic forces between the atoms concerned to an applied stress. Since the bonding forces vary with crystallographic orientation the elastic properties of metal single crystals may be highly anisotropic. However, polycrystalline metals and alloys with a randomly oriented grain structure behave isotropically. Table 15.1 lists elastic constants for polycrystalline metals and alloys in an isotropic condition. Any preferred orientation or texture resulting from rolling, drawing or extrusion, for example, will result in departures from the listed values to a degree that depends upon the elastic anisotropy of the individual crystals (which may be deduced from the single crystal elastic constants of Tables 15.2 to 15.6 that follow) and the nature and extent of the preferred orientation.

Since the elastic properties are determined by the aggregate response of the interatomic forces between all the atoms in the metal, the presence of small quantities of solute atoms in dilute alloys or their rearrangement by heat treatment will have relatively little effect on the magnitudes of their elastic constants. Consequently, the elastic constants of all the plain carbon and low alloy steels will be approximately the same unless some preferred orientation is present. Similarly with Cu-, Al- and Ni- base dilute alloys, etc. In the case of concentrated alloys there may be larger variations in elastic moduli, especially where there is a drastic change in the relative proportions of different phases in a multiphase alloy. In the case of ideal solid solutions the elastic moduli vary linearly with atom fraction. The elastic moduli of non-ideal solid solutions may show positive or negative deviations from linearity. Ordering produces an increase in elastic moduli.

Increase in temperature causes a gradual decrease in elastic moduli. The decrease is fairly linear over wider ranges of temperature but sharply increases in magnitude as the melting point is approached. Discontinuities are observed when structural transformations occur.

Ferromagnetic materials having a high degree of domain mobility may exhibit considerably higher elastic moduli below the Curie point in the presence of a high magnetic field. The lower elastic moduli in the absence of a magnetic field are due to magnetostrictive dimensional changes caused by stress-induced domain movement.

15.1.1   Elastic compliances and elastic stiffnesses of single crystals

Single crystals are generally anisotropic and therefore require many more constants of proportionality than isotropic materials. The relations between stress and strain are defined by the generalised Hooke's law, which states that the strain components are linear functions of the stress components and vice versa.

That is,

$$\varepsilon_{xx} = S_{11}\sigma_{xx} + S_{12}\sigma_{yy} + S_{13}\sigma_{zz} + S_{14}\sigma_{yz} + S_{15}\sigma_{zx} + S_{16}\sigma_{xy}$$
$$\varepsilon_{yy} = S_{21}\sigma_{xx} + S_{22}\sigma_{yy} + S_{23}\sigma_{zz} + S_{24}\sigma_{yz} + S_{25}\sigma_{zx} + S_{26}\sigma_{xy}$$
$$\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots$$
$$\varepsilon_{xy} = S_{61}\sigma_{xx} + S_{62}\sigma_{yy} + S_{63}\sigma_{zz} + S_{64}\sigma_{yz} + S_{65}\sigma_{zx} + S_{66}\sigma_{xy}$$

and correspondingly

$$\sigma_{xx} = C_{11}\varepsilon_{xx} + C_{12}\varepsilon_{yy} + C_{13}\varepsilon_{zz} + C_{14}\varepsilon_{yz} + C_{15}\varepsilon_{zx} + C_{16}\varepsilon_{xy}$$
$$\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots$$
$$\sigma_{xy} = C_{61}\varepsilon_{xx} + C_{62}\varepsilon_{yy} + C_{63}\varepsilon_{zz} + C_{64}\varepsilon_{yz} + C_{65}\varepsilon_{zx} + C_{66}\varepsilon_{xy}$$

where

$\sigma_{xx}, \sigma_{yy}, \sigma_{zz}$ and $\sigma_{yz}, \sigma_{zx}, \sigma_{xy}$ represent normal and shear stresses, respectively;

$\varepsilon_{xx}, \varepsilon_{yy}, \varepsilon_{zz}$ and $\varepsilon_{yz}, \varepsilon_{zx}, \varepsilon_{xy}$ represent normal and shear strains, respectively.

The elastic constants S_{ij} and C_{ij} are called the elastic compliances and elastic stiffnesses, respectively. Many of the constants are equal, the number of independent constants decreasing with increasing crystal symmetry. For example, in the hexagonal system there are five independent constants, while in the cubic system there are only three independent elastic compliances S_{11}, S_{12}, S_{44} with corresponding elastic stiffnesses C_{11}, C_{12}, C_{44}.

The tensile and shear moduli will vary with orientation in a single crystal of a cubic metal according to

$$\frac{1}{E} = S_{11} - 2[(S_{11} - S_{12}) - \tfrac{1}{2}S_{44}](l^2m^2 + m^2n^2 + l^2n^2)$$

$$\frac{1}{G} = S_{44} - 2[(S_{11} - S_{12}) - \tfrac{1}{2}S_{44}](l^2m^2 + m^2n^2 + l^2n^2)$$

where l, m, n are the direction cosines of the specimen axis with respect to the crystallographic axes. For an isotropic crystal

$$S_{44} = 2(S_{11} - S_{12}) \text{ and } C_{44} = \tfrac{1}{2}(C_{11} - C_{12})$$

hence

$$E = \frac{1}{S_{11}} \quad \text{and} \quad G = \frac{1}{S_{44}}$$

Therefore, the degree of anisotropy is conveniently specified by

$$\frac{2(S_{11} - S_{12})}{S_{44}} \quad \text{or} \quad \frac{(C_{11} - C_{12})}{2C_{44}}$$

15.1.2   Principal elastic compliances and elastic stiffnesses at room temperature

The units are TPa^{-1} for S_{ij} (elastic compliances) and GPa for C_{ij} (elastic stiffnesses).

15.2   Damping capacity

The damping capacity of a metal measures its ability to dissipate elastic strain energy. The existence of this property implies that Hooke's law is not obeyed even at stresses well below the conventional elastic limit. In a perfectly elastic solid in vibration, stress and strain are always in phase and no energy is dissipated.

There are two important types of damping: anelastic and hysteretic.

In an anelastic solid there is a lag between the application of stress and the attainment of the resulting equilibrium strain; unless the stress changes exceedingly slowly. Processes with this characteristic give rise to an energy loss that reaches a peak at a critical frequency of vibration.

An hysteretic solid has a stress–strain curve on loading that does not coincide with that on unloading. The area between the two curves is proportional to the energy loss and does not vary with the frequency with which the load cycle is traversed but changes in a complex fashion with peak stress. Damping from this class of mechanism is often high and since it does not vary with frequency is of particular interest to the engineer since it can contribute to vibration and noise reduction and can limit the intensity of vibrational stress under resonant conditions and thus minimise fatigue failure.

Table 15.7 lists the specific damping capacity of a number of commercial alloys including some of very high damping that might be of interest to vibration engineers. In all cases the damping is predominantly of the hysteretic type.

Table 15.7   THE SPECIFIC DAMPING CAPACITY OF COMMERCIAL ALLOYS AT ROOM TEMPERATURE

The specific damping capacity which is normally measured on solid cylinders stressed in torsion is defined as the ratio of the vibrational strain energy dissipated during one cycle of vibration to the vibrational strain energy at the beginning of the cycle.

Alloy	Composition %	Specific damping capacity %	Surface shear stress MPa
Cast irons			
High carbon inoculated flake iron	2.5% C, 1.9% Si, 1.0% Mn, 20.7% Ni, 1.9% Cr, 0.13% P	19.3	34.5
Spun cast iron	3.54% C, 3.39% G.C., 1.9% Si, 0.4% Mn, 0.38% P	10.8	34.5
Non-inoculated flake iron	3.3% C, 2.2% Si, 0.5% Mn, 0.14% P, 0.03% S	8.5	34.5
Inoculated flake iron	3.3% C, 2.2% Si, 0.5% Mn, 0.14% P, 0.03% S	7.3	34.5

15.2.1   Anelastic damping

Of interest to the physical metallurgist is the fact that a phase lag between stress and strain can give rise to a peak in energy dissipation or damping as a function of temperature or frequency. Several quite distinct atomic processes have been identified with damping peaks and measurements on these peaks in a wide variety of metals and alloys have been used to give diffusion data and to study precipitation, ordering phenomena and the properties of dislocations, point defects and grain boundaries. Table 15.8 identifies the damping peaks found in a number of pure metals and alloys with the relaxation process thought to be involved and also give an indication of the magnitude of the damping peak height. Detailed information on the specific mechanisms involved can be obtained from the reviews below and the references given for the respective damping peaks. The main types of peak that are observed are as follows. In cold worked pure metals movement of dislocation lines results in a number of low temperature peaks known as Bordoni peaks. Interaction of dislocations with point defects give rise to a further series of unstable peaks at higher temperatures; these are now called Hasiguti peaks. In alloys the stress-induced redistribution of solute atoms results in two types of peak, the Zener-type peak in substitutional solid solutions and the Snoek-type peak in interstitial solid solutions. The interaction of interstitial solute atoms with substitutional solute atoms give rise to a modified Snoek peak in ternary alloys. In cold worked alloys the interaction of interstitial solute atoms with dislocations results in the Köstler-type peaks at higher temperatures than the Snoek-type peaks. In pure metals and alloys the stress-induced migration of grain boundaries and/or polygonised (sub-grain) boundaries give rise to a further series of high temperature damping peaks.

In the ideal case, for a relaxation process having a single relaxation time (τ) the logarithmic decrement (δ) will be given by

$$\delta = \pi \Delta \frac{\omega \tau}{1 + \omega^2 \tau^2}$$

where ω is the angular frequency and Δ is the modulus defect. The relaxation time, being diffusion controlled, varies with temperature according to an Arrhenius equation of the form $\tau = \tau_0 \exp$ (*H/RT*) where τ_0 is a constant, H is the activation energy controlling the relaxation process and T is the absolute temperature. The condition for maximum damping (δ_p) is that $\omega \tau = 1$ and hence

$$\delta_p = \frac{\pi \Delta}{2} (= \pi Q^{-1} \text{max})$$

The modulus defect which is a measure of the strength of the relaxation can be highly orientation dependent and therefore the values given in the table below must be interpreted with caution. It must also be noted that for many measured damping peaks a distribution of relaxation times is found to be present. This leads to a broader peak being observed than would be present if a single relaxation time were operative. The decrement will be given by

$$\delta = \pi \sum_i \Delta_i \frac{\omega \tau_i}{1 + \omega^2 \tau_i^2}$$

where each *i* refers to a component of the total peak that has the same form as that of a peak arising from a single relaxation time.

This theoretical aspect of the analysis of broad peaks in terms of a spectrum of τ's has been comprehensively dealt with by A. S. Nowick and B. S. Berry in *IBM Journal of Research and Development*, 1961, 5(4), 297–311, 312–20.

In Table 15.8, metals and alloys are listed in alphabetical order with the highest concentration constituent first. The values of the modulus defect are deduced using the equation

$$\Delta = \frac{2\delta_p}{\pi} = 2Q_{max}^{-1}$$

where δ_p is the peak decrement and Q_{max}^{-1} is the peak value of Q^{-1}. These relationships are valid only if the damping arises from a process having a single relaxation time. In most cases a distribution of relaxation times exists and the peaks are broader, but there is only rarely sufficient published data to permit this distribution to be deduced. As many authors do not make it clear which damping units they use, the quoted values of Modulus Defect in the table must not be interpreted too precisely. The aim is to record the existence of peaks and list the suggested mechanism giving rise to them, and the values of Δ serve to indicate the approximate strength of the relaxation. If detailed quantitative data are sought peaks should be analysed in particular cases using the method of Berry and Nowick.

15.3   Shape memory alloys*

15.3.1   Mechanical properties of shape memory alloys

Most shape memory alloys have compositions at which the crystallographic structure can change reversibly and reproducibly from a higher temperature phase with higher symmetry to a lower temperature phase with lower symmetry by a small change in temperature or by a change in mechanical stress at temperatures just above the transformation temperature at zero stress.

In most shape memory alloys (and in all the industrially useful alloys), the change of structure usually occurs over a narrow range of temperature by means of a self-accommodating martensitic transformation, during which a small amount of heat is evolved or absorbed depending on the direction of the temperature change. This usually gives rise to a thermal hysteresis of about 10 to 40°C over which the parent phase (usually referred to as 'austenite') and the martensite can co-exist.

If a stressed shape memory alloy is thermally cycled through its martensitic transformation temperature, the strain–temperature relationship will take the form of a closed hysteresis loop similar in shape to the *B–H* curve of ferromagnetic alloys. If a shape memory alloy is cooled to below its M_f temperature, it undergoes little change in shape or volume. If it is then deformed plastically to a new shape, it will recover its original undeformed shape on re-heating to a temperature above its A_s temperature. The amount of strain which can be recovered in this way is not unlimited but depends on the nature of the alloy. For example, the maximum recoverable strain is about 8% in Ti–Ni alloys and 10–12% in Cu–Zn alloys (although the latter cannot be achieved in industrially useful alloys).

On cooling through the transformation to the martensitic state, the temperatures at which the transformation starts and finishes at zero applied stress are denoted by M_s and M_f respectively. On re-heating, the temperatures at which the reverse transformation to the high temperature phase takes place are A_s and A_f respectively. These temperatures can be determined experimentally by thermal or dilatometric analysis or by changes in electrical resistivity. The M_s temperature is raised progressively by applied stress; the M_d temperature is the highest temperature at which the transformation can be induced by stress. Figure 15.1 illustrates these points.[11] If an alloy is deformed above the M_s but below the M_d temperature, a stress-induced martensitic strain can be obtained. This is completely recovered on unloading (*see* Figures 15.4 and 15.7).

Shape memory does not always appear to depend on the martensitic transformation. Small amounts of shape memory can be obtained in primary solid solutions of alloys of low stacking fault energy.[16] Examples are shown in Table 15.9, e.g. Cu–Al and Cu–Si primary solid solutions and some stainless steels. Although the latter undergo martensitic transformations to the alpha prime martensite, this is too brittle to deform. Shape memory is only found when the stainless steel is deformed at very low temperatures but above the M_s to form both delta and some alpha martensite. 20% deformation

---

 * Additional references on this topic may be found in Chapter 38.

may be needed to obtain 1.0–1.5% shape memory strain and it has proved to be of little industrial relevance so far.

Though most work has concentrated on Ti–Ni and related alloys because of their industrial importance, the shape memory phenomenon has been demonstrated in a wide range of alloys, some of which are listed in Table 15.9.

M_s temperatures can be varied continuously by changing the composition. Examples include: (i) changing Ni content in Ti–Ni alloys; (ii) partially replacing Ni by Fe, Co or Pd in Ti–Ni alloys; and (iii) changing Al and Zn contents in Cu–Al–Zn alloys or by partially replacing either element by others such as Sn, Mn, etc. Such variations also change the character of the alloys. Table 15.9 shows typical compositions for which data are published but it is possible to derive additional alloys within the ternary and more complex systems.

Note that if shape memory alloys are cooled under stress, the M_s temperature is raised in direct proportion to stress below M_o (*see* Figure 15.7).

Note also that the M_s, etc temperatures are not exact in that for a given composition they can be changed by heat-treatment and by cold-working. Figure 15.8 illustrates an example of the extent to which the hysteresis can be widened in a Cu-based alloy.[37]

[4] Non-linear interpolation between their compounds is possible. Relationship is of form $\log_e (M_s K) \propto x$ where x is in the range 0–1 in Zr–Ru$_x$–Rh$_{1-x}$ etc.
[5] M_s and A_s not accurately determined but are within these temperature ranges.

Table 15.10   PHYSICAL AND MECHANICAL PROPERTIES OF A TITANIUM–55% NICKEL
SHAPE MEMORY ALLOY

Property	Value
Density	6.45 g cm^{-3}
M.p.	1 310°C
Magnetic permeability	<1.002
Electrical resistivity	80 $\mu\Omega$ cm at 20°C
	132 $\mu\Omega$ cm at 900°C
Coefficient of thermal expansion (24–900° C)	10.4×10^{-6} °C^{-1}
Mechanical properties at 20°C (i.e. below M_s)	
0.2% yield stress	207 MPa
UTS	861 MPa
Elongation %	22
Reduction in area %	20
Impact (unnotched)	159 J at 20°C
	95 J at 80°C
Fatigue (rotating beam)	$>25 \times 10^6$ cycles at 483 MPa

Note
If recovery is prevented mechanicaly, the TiNi will exert a stress and is capable of doing work when heated to above the A_s temperature. Samples of Ti–55.0% Ni–0.07%C were capable of exerting a stress of up to 758 MPa at 171°C (*see* Figure 15.5). The amount of mechanical work which this alloy was capable of doing was 17–20 J cm^{-3} on heating from 24°C to 171°C.

16 Temperature measurement and thermoelectric properties

16.1 Temperature measurement*

The unit of the fundamental physical quantity known as thermodynamic temperature, symbol T, is the Kelvin, symbol K, defined as the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.[†]

Because of the way earlier temperature scales were defined, it remains common practice to express a temperature in terms of its difference from 273.15 K, the ice point. A thermodynamic temperature, T, expressed in this way is known as a Celsius temperature, symbol t, defined by:

$$t/°C = T/K - 273.15$$

The unit of Celsius temperature is the degree Celsius, symbol °C, which is by definition equal in magnitude to the Kelvin. A difference of temperature may be expressed in Kelvin or degrees Celsius.

The International Temperature Scale of 1990 (ITS-90) defines both International Kelvin Temperatures, symbol T_{90}, and International Celsius Temperatures, symbol t_{90}. The relation between T_{90} and t_{90} is the same as that between T and t, i.e.:

$$t_{90}/°C = T_{90}/K - 273.15$$

The unit of the physical quantity T_{90} is the Kelvin, symbol K, and the unit of the physical quantity t_{90} is the degree Celsius, symbol °C, as is the case for the thermodynamic temperature T and the Celsius temperature t.

The International Temperature Scale of 1990[1] was adopted by the International Committee of Weights and Measures at its meeting in 1989, in accordance with the request embodied in Resolution 7 of the 18th General Conference of Weights and Measures of 1987. This Scale supersedes the International Practical Temperature Scale of 1968 (amended edition of 1975) and the 1976 Provisional 0.5 K to 30 K Temperature Scale.

The ITS-90 extends upwards from 0.65 K to the highest temperature practicably measurable in terms of the Planck radiation law using monochromatic radiation. The ITS-90 comprises a number of ranges and subranges throughout each of which temperatures T_{90} are defined. Several of these ranges or subranges overlap, and where such overlapping occurs differing definitions of T_{90} exist: these differing definitions have equal status. For measurements of the very highest precision there may be detectable numerical differences between measurements made at the same temperature but in accordance with differing definitions. Similarly, even using one definition, at a temperature between defining fixed points two acceptable interpolating instruments (e.g. resistance thermometers) may give detectably differing numerical values of T_{90}. In virtually all cases these differences are of negligible practical importance and are at the minimum level consistent with a scale of no more than reasonable complexity: for further information on this point, see 'Supplementary Information for the ITS-90'.[2]

The ITS-90 has been constructed in such a way that, throughout its range, for any given temperature the numerical value of T_{90} is a close approximation to the numerical value of T according

---

* For details of emissivity, as needed for pyrometry—see Chapter 17.

† 'Comptes Rendus des Séances de la Treizième Conférence Générale des Poids et Mesures (1967–1968)', Resolutions 3 and 4, p. 104.

to best estimates at the time the scale was adopted. By comparison with direct measurements of thermodynamic temperatures, measurements of T_{90} are more easily made, are more precise and are highly reproducible.[3]

There are significant numerical differences between the values of T_{90} and the corresponding values of T_{68} measured on the International Practical Temperature Scale of 1968 (IPTS-68), see Figure 16.1 and Table 16.1. Similarly there were differences between the IPTS-68 and the International Practical Temperature Scale of 1948 (IPTS-68), and between the International Temperature Scale of 1948 (ITS-48) and the International Temperature Scale of 1927 (ITS-27).[3]

Between 0.65 K and 5.0 K T_{90} is defined in terms of the vapour-pressure temperature relations of ^{3}He and ^{4}He.

Between 3.0 K and the triple point of neon (24.556 1 K) T_{90} is defined by means of a helium gas thermometer calibrated at three experimentally realisable temperatures having assigned numerical values (defining fixed points) and using specified interpolation procedures.

Between the triple point of equilibrium hydrogen (13.803 3 K) and the freezing point of silver (961.78°C) T_{90} is defined by means of platinum resistance thermometers calibrated at specified sets of defining fixed points and using specified interpolation procedures.

*A discontinuity in the first derivative of $(t_{90} - t_{68})$ occurs at a temperature of $t_{90} = 630.6$°C when $(t_{90} - t_{68}) = -0.125$°C.
Figure 16.1   *The differences, $(t_{90} - t_{68})$, between ITS-90 and IPTS-68 in the range from $-260°C$ to $1\,064°C$*

Above the freezing point of silver ($961.78°C$) T_{90} is defined in terms of a defining fixed point and the Planck radiation law.

The defining fixed points of the ITS-90 together with some selected secondary reference points are listed in Table 16.2. Full details of the practical realisation of this scale can be found in refs. 2 and 3.

Table 16.2   THE DEFINING FIXED POINTS OF ITS-90 AND SOME SELECTED SECONDARY REFERENCE POINTS

Equilibrium state	T_{90} (K)	t_{90} (°C)
Cd superconducting transition point	0.519	
Zn superconducting transition point	0.851	
Al superconducting transition point	1.179 6	
^{4}He lambda point	2.176 8	
In superconducting transition point	3.414 5	
^{4}He boiling point	4.222 1	
Pb superconducting transition point	7.199 6	
*Triple point of equilibrium hydrogen	13.803 3	
*Boiling point of equilibrium hydrogen	17.035 7	
at a pressure of 33 330.6 pascals		
(25/76 standard atmosphere)		
*Boiling point of equilibrium hydrogen	20.271 1	
*Ne triple point	24.556 1	
Ne boiling point	27.098	
*O_2 triple point	54.358 4	−218.791 6
N_2 triple point	63.150	−210.000
N_2 boiling point	77.352	−195.798
*Ar triple point	83.805 8	−189.344 2
O_2 condensation point	90.196	−182.954
Kr triple point	115.776	−157.374

Sb freezing point	903.78	630.63
*Al freezing point	933.473	660.323
Ag–Cu eutectic melting point	1 053.09	779.94
*Ag freezing point	1 234.93	961.78
*Au freezing point	1 337.33	1 064.18
*Cu freezing point	1 357.77	1 084.62
Ni freezing point	1 728	1 455
Co freezing point	1 768	1 495
Pd freezing point	1 827	1 554
Pt freezing point	2 041	1 768
Rh freezing point	2 235	1 962
Ir freezing point	2 719	2 446
W freezing point	3 693	3 420

* Defining point of ITS-90. For details of experimental techniques used in the realisation of these fixed
points see references 2 and 3. All except the triple points and the hydrogen boiling point at 33 330.6 Pa
are at a pressure of 101 325 Pa (1 standard atmosphere).

16.2   Thermocouple reference tables

The introduction of ITS-90 on 1st January 1990 has led to an international programme, coordinated
by the Comité Consultatif de Thermométrie, for the revision of the internationally agreed reference
tables for thermocouples. It will take a few years, however, for the new tables to be adopted by
national and international standards organizations. Meanwhile the following old tables (BS 4937
and IEC 584-1 1977) based upon IPTS-68 should be used together with the differences $t_{90} - t_{68}$
given in Table 16.1 and Figure 16.1.

Table 16.3   THERMAL ELECTROMOTIVE FORCE (millivolts) OF ELEMENTS RELATIVE TO PLATINUM*

A positive sign means that in a simple thermoelectric circuit the element is positive to the platinum at the
reference junction (0°C). The e.m.f. generated by any two elements, A and B, can also be found from this table.
It is the algebraic difference, $A_e - B_e$, between the values (A_e and B_e) for the e.m.f. generated by each relative to
platinum; a positive sign indicates that A is positive to B at the reference junction, and a negative sign that A is
negative to B.

Cold junction at 0°C

	Temperature of hot junction °C			
	−200	−100	+100	+200

16.3   Thermoelectric materials

16.3.1   Introduction

Thermoelectric devices convert thermal energy from a temperature gradient into electrical energy (Seebeck effect), or electrical energy into a temperature gradient (Peltier effect).[1,2] Thermoelectric materials are evaluated on the basis of their thermoelectric figure-of-merit, Z, which is defined by:

$$Z = \frac{\sigma S^2}{\kappa}$$

In this equation, σ is the electrical conductivity ($\Omega^{-1}\,m^{-1}$), S is the Seebeck coefficient (VK^{-1}), and κ is the thermal conductivity ($Wm^{-1}\,K^{-1}$). Z has units of reciprocal temperature, and the product ZT is referred to as the dimensionless figure-of-merit. Good thermoelectric materials have large values of Z (or ZT). From a materials perspective, one seeks to maximise σ and S while minimising κ.

The Seebeck coefficient and the electrical conductivity are strong functions of the Fermi energy, which, in turn, depends on the free carrier concentration, the carrier effective mass and temperature. The Seebeck coefficient of most metals is typically too small for them to have any practical application beyond a simple thermocouple. On the other hand, many semiconductors have Seebeck coefficients on the order of hundreds of µV/K. Good thermoelectric materials must also have a reasonable electrical conductivity since charge transport is the basis by which heat is transferred, and resistive heating will lower the overall efficiency. In addition, the material must be a good thermal insulator to maintain the thermal gradient established by the motion of charge carriers. The relationships among the transport properties that influence the figure-of-merit are shown in Figure 16.2.

The dependence of Z on n is the basis of the general rule of thumb suggested by Ioffe that the best thermoelectric materials will be relatively highly doped semiconductors ($n \sim 10^{20}\,cm^{-3}$).[3] The effect of doping is limited in practice by the fact that although the lattice part of the thermal conductivity is not very sensitive to the free carrier concentration, n, the electronic component clearly is. It is also well known that there is a correlation between the band gap and Z for many materials. The band gap rule states that $E_G \sim 10\,k_B T_M$, where T_M is the temperature where ZT is a maximum and k_B is Boltzmann's constant.[4] The choice of majority carrier is important in determining the sign of the Peltier and Seebeck coefficients.

In a recent review, Mahan offered several criteria for good thermoelectric materials.[5] In terms of their band structures, good thermoelectric materials will have multiple degenerate bands, high carrier mobilities, and large carrier effective masses. In addition, good thermoelectric materials must have a low thermal conductivity. There are three strategies to minimise the thermal conductivity: the use of heavy atoms, complex crystal structures and alloys. In general, heavy elements have lower thermal conductivities than lighter elements, heat is transferred less efficiently in crystals with a higher density of optical phonons, and alloying reduces the lattice thermal conductivity. Alloying also lowers the charge mobility, but the effect is greater for the lattice thermal conductivity.

Materials used today in thermoelectric devices can be grouped into three categories based on the device operation temperature: the Group V chalcogenides based on Bi_2Te_3-Sb_2Te_3 alloys for refrigeration (ca. 300 K); the Group IV chalcogenides based on PbTe for power generation (700 K); and Si-Ge solid solutions for power generation at high temperature (1 100–1 200 K). Examples of the best thermoelectric materials in these temperature ranges are given in Table 16.15.

Generally, thermoelectric devices suffer from poor efficiency. For example, current thermoelectric refrigerators are about one third as efficient as their conventional (Freon based) analogues. As a result, thermoelectric devices tend to be important in niche applications where the stability and long life afforded by an all solid-state device outweighs the efficiency issue.

16.3.2   Survey of materials

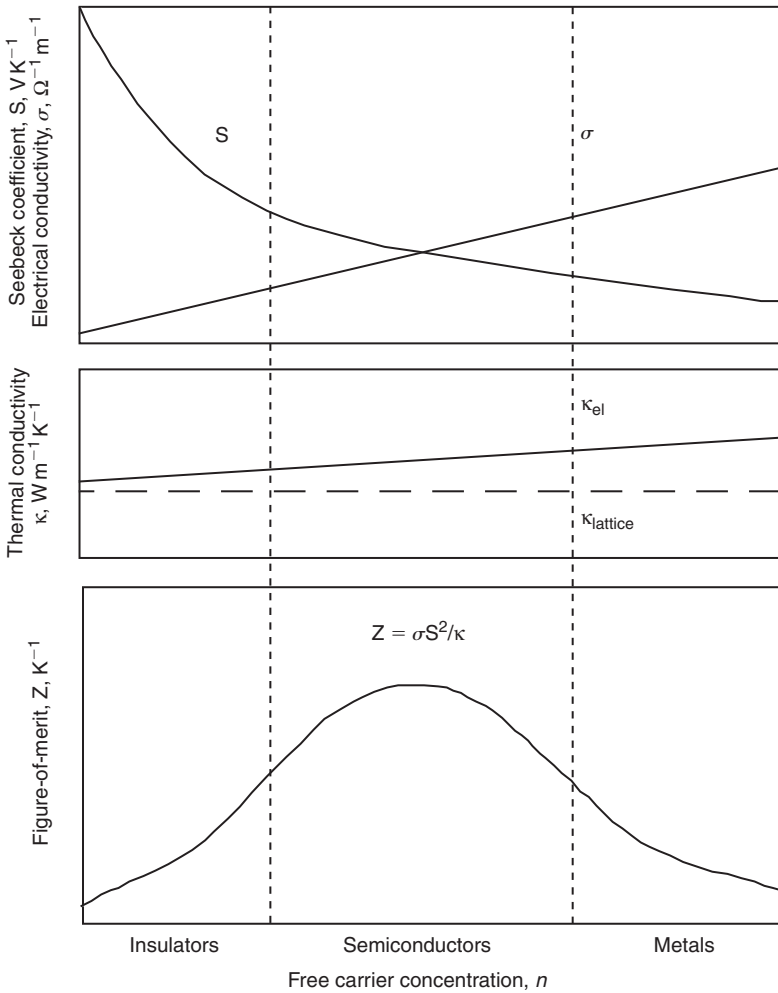
Bi_2Te_3 is composed of hexagonal, closest-packed Te layers with Bi atoms occupying two-thirds of the octahedral holes. The crystal consists of a sequence of atomic layers Te-Bi-Te-Bi-Te. Three such stacks sandwiched together along the c-axis of the crystal form the hexagonal unit cell, which repeats every nine Te layers. The band gap of Bi_2Te_3 is 0.15 eV, and increases upon doping. Both p- and n-type materials can be prepared by alloying with compounds such as Sb_2Te_3 or Bi_2Se_3, which have the same crystal structure as Bi_2Te_3. Bi_2Te_3 is the most important thermoelectric material for cooling applications at temperatures near 300 K. All devices that operate near room temperature are based on Bi_2Te_3 and its alloys. Alloys are used in order to lower the thermal conductivity and thereby increase ZT.


Figure 16.2 *Schematic depiction of the dependence of the Seebeck coefficient, electrical conductivity, thermal conductivity, and thermoelectric figure-of-merit on the free carrier concentration*

Table 16.15 THERMOELECTRIC MATERIALS FOR REFRIGERATION AND POWER GENERATION

Material	Type	T(K)	ZT
$Bi_{24}Sb_{68}Te_{142}Se_6$	p	300	0.96
$Bi_{0.5}Sb_{1.5}Te_{3.13}$	p	300	0.90
$Bi_{1.75}Sb_{0.25}Te_{3.13}$	n	300	0.96
PbTe	n	700	1.10
SiGe	p	1 100	0.505
SiGe	n	1 200	0.938

PbTe has the NaCl crystal structure and a band gap of 0.31 eV at room temperature. PbTe and its alloys are good thermoelectrics near 700 K and are used in power generation applications. PbTe frequently is alloyed with Sn to form $Pb_{1-x}Sn_xTe$, which is a good n-type thermoelectric with a *ZT*

of about 1.1 at 800 K. The p-type material is not thermally stable and has poor mechanical properties and therefore is not used in any devices.

TAGS (tellurium-antimony-germanium-silver) alloys make good p-type thermoelectric materials in a temperature range similar to that of PbTe (which is n-type), and they are often used together. In fact, TAGS were developed as a direct result of the search for a replacement for p-PbTe. TAGS is an alloy of GeTe with $AgSbTe_2$ (10–20%). The 20% alloy has a $ZT > 2$, which is among the highest ever reported. The measured value of Z was 3×10^{-3} K^{-1} at $T = 700$ K.[6]

The transport properties of Si make it an excellent choice for high temperature power generation, although its thermal conductivity is too high. Typically, Si is alloyed with Ge to lower the thermal conductivity. Overall, Si-Ge solid solutions are the best materials for high temperature applications. The composition that gives a maximum ZT is approximately $Si_{0.7}Ge_{0.3}$. These materials are used in the thermonuclear thermoelectric generators that supply power for deep-space vehicles such as the Voyager spacecraft.

Bi-Sb is the only material other than Bi_2Te_3 that displays good thermoelectric performance near room temperature. The ZT is fairly low, however, only about 0.6 near 300 K. Interestingly, ZT can be increased by almost a factor of 2 by placing the material in a magnetic field. This is known as the thermomagnetic effect.

The skutterudites have the formula MX_3 where M = Co, Rh, Ir and X = P, As, Sb. The parent compound, $CoSb_3$, was first discovered in the town of Skutterude in Norway. One of the most interesting properties of the skutterudites is the extremely high hole mobility in the p-type materials (ca. 2 000 cm^2/Vs). Unfortunately, the thermal conductivities of these compounds are too high for thermoelectric applications. Due to their open crystal structures, however, these compounds may be doped with 'rattler' atoms that function to lower the overall thermal conductivity of the material without significantly altering the carrier mobility. The family of compounds called the 'filled' skutterudites has the general formula RM_4X_{12}. These compounds are cubic with a 34-atom unit cell. The rare earth atom (R) acts as the 'rattler' atom. These materials are promising candidates for high temperature applications. For example, Sales *et al.* report a value of ZT of about 1 for $LaFe_3CoSb_{12}$ at $T \sim 800$ K.[7] For comparison, the ordinary skutterudites have ZT's of about 0.3. The 3-fold increase in ZT in the filled skutterudites is attributed to the lowering of the thermal conductivity due to the lanthanum 'rattler' atom.

Quantum wells are interesting composite materials that are under development for potential thermoelectric applications. It has long been known that modulation doping can increase carrier mobilities, and it is hoped that the Seebeck coefficient can be enhanced in quantum well structures in an analogous fashion. In multiple quantum well structures, the thermal conductivity is lowered due to the presence of multiple interfaces that increase phonon scattering. This is an example of an 'electron transmitting/phonon blocking' structure. Recently Venkatasubramanian *et al.* have reported a ZT of 2.4 for Bi_2Te_3/Sb_2Te_3 multiple quantum wells prepared by molecular beam epitaxy.[8] The thickness of the Bi_2Te_3 layers in these materials was only 1.0 nm.

16.3.3   Preparation methods

Most thermoelectric materials are either compounds or solid solutions, and are easily prepared using standard solid-state synthesis procedures.[9] A variety of melt techniques, including both stoichiometric and non-stoichiometric melts, are commonly used, typical examples being the Bridgman method and liquid phase eptitaxy, respectively. Powder metallurgy, in which a compact powder is sintered at elevated temperature, is also often used. Other synthetic approaches, including mechanical alloying and PIES (pulverised and intermixed sintering method) have also been developed. For the fabrication of thin film structures, molecular beam epitaxy, liquid phase epitaxy as well as electrochemical deposition all can be used.

17   Radiative properties of metals

The ability of a surface to radiate energy is governed by the material of which the surface is composed and its physical condition. Any attempt, therefore, to place a numerical value on its radiating ability must be related to a definition of the surface condition. It is usual to choose smooth polished surfaces for this purpose and thus arrive at values which are comparable from one metal to another.

A perfect radiator (blackbody) provides a standard of comparison for defining the radiating ability of any other body or surface by determining the ratio of the emission of the surface to that of a blackbody when they are at the same temperature. An examination of the ratios thus obtained shows that the radiating ability of a metal surface varies with wavelength, temperature and angle of emission. The definition of the emittance, as this ratio is called, must therefore take into account these variations.

DEFINITIONS OF EMITTANCE

Spectral, directional emittance, ε_λ, of a surface is the ratio of the energy emitted over an infinitesimally small wavelength range at wavelength λ into a specified direction, per unit area of the surface, to the energy emitted by a unit area of a black surface at the same temperature. The emittance in a direction normal to the surface, called the *normal, spectral emittance*, $\varepsilon_{n\lambda}$, is most commonly employed.

The *spectral, hemispherical emittance*, ε_λ, is a directional average of the spectral, directional emittance, and gives the ratio of emitted radiative flux of the given surface to that of a blackbody at the same temperature. While normal emittances are the ones that are generally measured and tabulated, it is the hemispherical emittance that governs heat transfer rates between surfaces. For metals, the hemispherical emittance is always a little greater than its normal value, usually by about 10 to 20 percent.

Total emittance is a weighted spectral average of the spectral emittance, and is the ratio of radiative emission of a surface over the entire spectrum, compared that of a blackbody at the same temperature. Again, we distinguish between directional and hemispherical values; and again, the more important hemispherical values exceed the total, normal emittance by roughly 10 to 20 percent for metals.

The absorptance (α) and reflectance (ρ), for an opaque polished surface, are defined as the ratio of the rate of absorption or reflection of energy to the rate of incidence of radiative energy. Since the incident energy must be either reflected or absorbed, the sum of reflectance and absorptance must be unity. For spectral, directional values the absorptance is equal to the emittance and, with reasonable accuracy, this is often also true for hemispherical and/or total values.[1] Thus,

$$\varepsilon \cong \alpha = 1 - \rho$$

Hence the emittance may be derived from the reflectance, which is sometimes more convenient than a direct determination.

The following equation relates the normal reflectance of a well-polished surface to the *complex index of refraction*, given by $m = n - ik$, where n is the real part ('refractive index') and k is the complex part ('absorptive index' or 'extinction coefficient'):

$$\rho_{n\lambda} = \frac{n^2 + k^2 + 1 - 2n}{n^2 + k^2 + 1 + 2n}$$

where the absorptive index is related to the fraction of light transmitted perpendicularly through a layer of thickness d by $\exp(-4\pi dk/\lambda)$, λ being the wavelength in air.

Normal emittance follows as

$$\varepsilon_{n\lambda} = 1 - \rho_{n\lambda} = \frac{4n}{n^2 + k^2 + 1 + 2n}$$

For a homogeneous material the complex index of refraction can be related to material properties through Maxwell's electromagnetic wave theory,[1]

$$n^2 = \frac{1}{2}\left[\sqrt{\left(\frac{\varepsilon}{\varepsilon_0}\right)^2 + \left(\frac{\sigma\lambda}{2\pi c_0 \varepsilon_0}\right)^2} + \frac{\varepsilon}{\varepsilon_0}\right]$$

$$k^2 = \frac{1}{2}\left[\sqrt{\left(\frac{\varepsilon}{\varepsilon_0}\right)^2 + \left(\frac{\sigma\lambda}{2\pi c_0 \varepsilon_0}\right)^2} - \frac{\varepsilon}{\varepsilon_0}\right]$$

where σ is the electrical conductivity, ε and ε_0 are the electrical permittivity of the material and of vacuum, respectively, c_0 is the speed of light and λ the wavelength, both in vacuum or air. For metals with their large electrical conductivities, and for reasonably large wavelengths, $\sigma\lambda \gg 2\pi c_0 \varepsilon$, leading to

$$n \approx k \approx \sqrt{\frac{\sigma\lambda}{2\pi c_0 \varepsilon_0}} \gg 1$$

and

$$\varepsilon_{n\lambda} \cong \frac{0.365}{\sqrt{\sigma\lambda}} - \frac{0.0667}{\sigma\lambda}, \quad \sigma\lambda \text{ in } \Omega^{-1}, \tag{17.1}$$

which is commonly known as the Hagen-Rubens relation.[1]

The equations show that the spectral emittance of metals should increase as the wavelength decreases and this is in general agreement with experiment. However, these relations are valid only for sufficiently large wavelengths and, indeed, there generally is a lack of agreement between experimental and theoretical values in the visible and ultraviolet (see Fig. 17.1 for tungsten).

EFFECTS OF SURFACE TEMPERATURE

The Hagen-Rubens relation predicts that the spectral, normal emittance of a metal should be proportional to $1/\sqrt{\sigma}$. Since the electrical conductivity is approximately inversely proportional to temperature, the spectral emittance should, therefore, be proportional to the square root of absolute temperature for long enough wavelengths. This trend should also hold for the *spectral, hemispherical emittance*. Experiments have shown that this is indeed true for many metals. A typical example is given in Fig. 17.1, showing the spectral dependence of the hemispherical emittance for tungsten for a number of temperatures.[2,3] Note that the emittance for tungsten tends to increase with temperature only beyond a *crossover wavelength* of approximately 1.3 μm, while the temperature dependence is reversed for shorter wavelengths. Similar trends of a single crossover wavelength have been observed for many metals.

DIRECTIONAL DEPENDENCE OF EMITTANCE

The spectral, directional reflectance of a perfectly smooth surface is governed by the so-called *Fresnel's relations*.[1] For metals in the infrared this implies relatively small and constant values of emittance for most angles of emission, accompanied by a sharp increase in emittance at near-grazing angles, followed by a sharp drop back to zero at 90° off-normal. As an example, experimental results for platinum at 2 μm are compared with Fresnel predictions in Fig. 17.2.[1] For shorter wavelengths the directional behaviour follows the behaviour of nonmetals, i.e. relatively large and constant values of emittance for most angles of emission, accompanied by a gradual decrease beyond about 60° off-normal until zero emittance is reached at 90°.
Figure 17.1 *Spectral emittance of tungsten as a function of wavelength for different temperatures. Dotted lines calculated from equation 17.1. References 2 and 3*

Figure 17.2 *Spectral, directional emittance of platinum at* $\lambda = 2\,\mu m$

TOTAL EMITTANCES

The total, normal or hemispherical emittances are calculated by integrating spectral values over all wavelengths, with the blackbody emissive power as a weight function. Since the peak of the blackbody emissive power shifts toward shorter wavelengths with increasing temperature, it follows that hotter surfaces emit a higher fraction of energy at shorter wavelengths, where the spectral emittance is greater, resulting in an increase in total emittance.

The total, normal reflectance and emittance may be evaluated from the simple Hagen-Rubens relation. While this relation is not accurate across the entire spectrum, it does predict the emittance *trends* correctly in the infrared, and it does allow an explicit evaluation of total, normal emittance. Using Equation (17.1) in the weighted spectral averaging process and retaining the first two terms of the series expansion, leads to

$$\varepsilon_n = 0.578(T/\sigma)^{1/2} - 0.178(T/\sigma), \quad T \text{ in K}, \quad \sigma \text{ in } \Omega^{-1}\text{cm}^{-1} \tag{17.2}$$

The total, hemispherical emittance of a metal may be evaluated in a similar fashion, using Fresnel's relations for directional dependence, leading to slightly larger values, or[1]

$$\varepsilon(T) = 0.766(T/\sigma)^{1/2} - [0.309 - 0.089\,9\ln(T/\sigma)](T/\sigma), \quad T \text{ in K}, \quad \sigma \text{ in } \Omega^{-1}\text{cm}^{-1} \tag{17.3}$$
Figure 17.3   *Total, hemispherical emittance of various polished metals as function of temperature. Reference 4*

Because the Hagen-Rubens relation is only valid for large values of $(\sigma\lambda)$, this relation only holds for small values of (T/σ), i.e. the temperature of the surface must be such that only a small fraction of the blackbody emissive power comes from short wavelengths (where the Hagen-Rubens relation is not applicable). For pure metals, with its electrical conductivity inversely proportional to absolute temperature, the total emittance should be approximately linearly proportional to temperature. Comparison with experiment (Fig. 17.3)[4] shows that this nearly linear relationship holds for many metals up to surprisingly high temperatures; for example, for platinum $(T/\sigma)^{1/2} = 0.5$ corresponds to a temperature of 2700 K.

TEMPERATURE MEASUREMENT AND EMITTANCE

Radiation pyrometers, both spectral and total, are usually calibrated in terms of blackbody radiation and, thus, measure what is known as *radiance temperature*. The radiance temperature, T_r, measured by a total radiation pyrometer is related to the *true temperature*, T, by the formula

$$T = T_r/\varepsilon^{1/4}$$

where ε is the total emittance of the surface. True temperature *always* exceeds radiance temperature.

For an optical pyrometer which measures irradiance from a narrow spectral interval only, the radiance temperature T_r is related to the true temperature by the equation

$$\frac{1}{T} = \frac{1}{T_r} - \frac{\lambda}{C_2} \ln \frac{1}{\varepsilon_\lambda}$$

where ε_λ is the spectral emittance and $C_2 = 1.438\,8\,\text{cm K}$ is the constant in Wien's approximation for the blackbody emissive power. For the same emittances the correction is considerably greater for total radiation than for spectral radiation. For metallic surfaces the difference in correction is even greater, since the spectral emittance in the visible region for a given temperature is always greater than the total emittance.

EMITTANCE VALUES

The values of emittance given in Tables 17.1 to 17.5 pertain, as far as is known, to emission from plane polished or plane unoxidised liquid metal surfaces. Emittance tends to be considerably higher if the surface is oxidised and/or rough. In any practical application, therefore, the values in the tables must be used with discretion and, where precise measurement is of importance, a determination of the emittance should be made for the prevalent surface conditions. As a rough guide the emittances for various oxidised surfaces are given in Tables 17.4 and 17.5.

18 Electron emission*

Under normal conditions electrons are prevented from leaving a metal by a potential step at the surface. In the absence of an electric field, the height of this potential step is called the work function ϕ. Electrons can, however, escape if they are given enough energy. This energy can be supplied in a number of different ways, giving rise to the various types of electron emission.

18.1 Thermionic emission

When a metal is heated, some electrons with energies near the Fermi level are enabled to escape by acquiring extra thermal energy. An adjacent anode carrying a sufficiently positive potential will collect all the electrons emitted, and the saturated emission current will flow. A further increase of anode potential causes a positive field at the metal surface; this lowers the potential barrier slightly and increases the current. The 'zero field' saturated emission current per unit area of the cathode J, is related to the temperature according to the Richardson-Dushman equation.

$$J = AT^2 \exp\left(-e\phi/kT\right)$$

where A is a constant, e the magnitude of the electronic charge, k Boltzmann's constant and T the absolute temperature.

For a metal, the theoretical value of A is 1.2 MA m^{-2}. In practice ϕ usually has a temperature dependence and this results in a different value of A. The work function ϕ cannot be calculated reliably, but tends to increase with the density of the metal. The observed values of A and ϕ are shown in Table 18.1 for polycrystalline surfaces of a number of metals.

To calculate the emission from the values of A and ϕ in the table, the emission formula may be written as

$$\log_{10} J = \log_{10} A + 2\log_{10} T - 504\,0\,\phi T^{-1}$$

where J is in kA m^{-2}, T is in K.

The work function of a metal is lowered when a layer of a more electropositive material is adsorbed on its surface. This increases the thermionic emission, which has a maximum value when the adsorbed layer is approximately monatomic. Table 18.2 shows typical values of thermionic constants for various such surfaces. The emission may also be increased by a coating of a refractory metallic compound, usually about 100 µm thick. The thermionic emission follows the usual law but in the case of a semiconductor layer the quantities A and ϕ have a different significance.

Table 18.3 shows the emission constants for various carbides, borides and oxides, and the emission available at a particular operating temperature.

For a thermionic cathode to be technically useful it must have an adequate emission at a temperature where the rate of evaporation is not excessive. This limits the practical cathodes to a relatively small number. Table 18.4 gives the most important of these with their normal maximum operating temperatures and maximum operating emission densities for a generally acceptable life.

An 'L' cathode consists of a block of porous tungsten, the front emitting surface of which is activated with barium. A reaction between the tungsten and barium oxide at the rear surface produces free barium which diffuses through the porous tungsten.

---

Thoriated tungsten	1 900	10
Figure 18.1   *Thermionic emission of practical cathodes as a function of temperature*

Impregnated tungsten is a porous tungsten block whose pores are filled with barium calcium aluminate by infiltration in the molten phase at 1 700°C. The emitting surface is partly the compound and partly barium activated tungsten.

The thoriated tungsten is a high density rod or wire containing about 1% thorium oxide. The surface is carburised to form a layer of W$_2$C. In operation a reaction between the oxide and the carbide produces free thorium, which activates the surface.

Figure 18.1 (reference 13) shows the saturated emissions available from some of these cathodes as a function of temperature. In practice it is usual to operate cathodes at rather less than the saturated emission. The full lines show the region where a useful life is obtainable. The cathode life is usually limited by the evaporation rate and lowering the temperature increases the life considerably. Typically,

lowering the temperature of an 'L' or impregnated tungsten cathode by 80 K increases its life by an order of magnitude.

For an oxide cathode, the continuously drawn emission must be limited to about $10 \, kA \, m^{-2}$, but if the current is drawn in microsecond pulses the pulse current may be increased to $100 \, kA \, m^{-2}$.

The emissions shown on Figure 18.1 are obtainable only in an environment free from oxidising gases. In general the partial pressure of gases such as O_2, CO_2, and H_2O should not exceed approximately 10^{-5} Pa. The emission is unaffected by rare gases except when the cathode is bombarded excessively with positive ions; the presence of H_2 may counteract to some extent the effect of oxidising gases.

18.2   Photoelectric emission

When light of sufficiently high frequency is incident on the surface of a metal, electrons are emitted. In order that electrons shall be emitted with zero velocity from a metal at absolute zero of temperature, the energy of the light photons must equal the energy corresponding to the work function. Thus there is a threshold frequency v_0 at which $hv_0 = e\phi$ where h is Planck's constant. If the frequency of the light is v, where v is greater than v_0, the maximum energy of the emitted electrons is hv-hv_0. At temperatures above absolute zero the threshold is not sharp since light of a frequency less than v_0 can liberate a small number of electrons. An experiment measuring the energy of photoelectrons emitted for monochromatic light of known energy enables ϕ to be determined fairly accurately, the accuracy improving as the temperature is lowered.

Table 18.5 shows the values of ϕ for a number of metals determined using the photoelectric effect. The values obtained in this way should correspond to the thermionic values in Table 18.1; discrepancies are probably due to contamination of the surface.

For practical uses it is required to obtain the maximum photoelectric current for a given light flux. For extracting photocurrent, the efficiency of the conversion process (yield) must be separated from effects due to space charge in shielding the surface. The photoelectric efficiency of a surface may be defined in various ways, the most fundamental being the quantum efficiency Y. This is the ratio of the number of electrons released to the number of incident photons. For clean metals this is very low (10^{-4} approximately) so they are not often used. The efficient photoemitters as used in photocells and photomultipliers are semiconductors with a low effective photon threshold. They are usually formed by combination of one or more alkali metals with an evaporated thin film of

antimony (apart from the type consisting of caesium on oxidised silver). Table 18.6 gives the value of maximum photoelectric yields for various such surfaces. This maximum is reached at photon energies 1–1.5 eV above the threshold value, which is also shown.

The corresponding wavelength of light λ in nm is related to the photon energy $e\phi$ in electron volts by the (non-relativistic) relationship

$$\lambda = 1.24 \times 10^3 \phi^{-1}$$

18.3   Secondary emission

When electrons (primaries) are incident upon a surface of a solid, electrons (secondaries) are produced which leave the surface in the direction from which the primaries arrive. The total flow of secondaries consists of:

1. Primaries elastically scattered.
2. Primaries reflected inelastically with an energy loss of some tens of volts.
3. True secondaries with an energy independent of the primary energy and a mean value of about 10 eV. Electrons with an energy up to about 50 eV are usually considered to be true secondaries.

The ratio of the total flow of secondaries to that of the primaries is called the secondary emission coefficient δ. As the primary electron energy is increased from zero, δ rises to reach a maximum value δ_{max} for a primary energy V_{max} in the range of 200–2 000 eV for metals, and it falls off more slowly at energies above V_{max}. The shape of the curve relating δ to V is approximately similar for most metals, and a (universal) curve normalised to δ_{max} and V_{max} is shown in Figure 18.2.

The values of δ_{max} and V_{max} are shown for most metals in Table 18.7. These values are for clean smooth polycrystalline surfaces. It is impossible to remove oxide films from many metals, such as aluminium or magnesium, by heating. These metals are usually deposited as clean layers either by evaporating in high vaccum or by sputtering. Alternatively the surface of the bulk metal may be cleaned by sputtering in an electric discharge in argon.

It should be noted that the total (integrated) secondary emission is reduced by roughening the surface, as some of the secondaries released in the valleys in the surface may be intercepted by the adjacent high spots. An example of this is carbon; the value of δ_{max} for polished graphite is approximately 1, while that for soot is only about 0.5.

The secondary emission of metal oxides is usually higher than that of metals. Surfaces with high values of δ are used in secondary electron multipliers and are prepared by oxidising metals containing small quantities, usually about 2%, of magnesium, beryllium or aluminium. Oxidised metal surfaces with caesium evaporated on to them also have high values of δ and are used in photomultipliers. Table 18.8 shows maximum (at $V/V_{max} = 1$) values of δ obtained from various such surfaces.

Table 18.9 shows the secondary emission from a number of insulating metal compounds either as evaporated films (e) or surface layers on the parent metal (s). These layers must be very thin to avoid accumulating a charge. The secondary electrons originate normally within 10 nm of the surface, so provided films are thicker than this a true value of δ will be obtained.

18.4   Auger emission

When the energy distribution of secondaries is examined closely, small peaks can be seen superimposed on the basically smooth background. These peaks can be made much more visible by electronic differentiation, and have been shown to originate in Auger transitions, as follows (reference 22). A

primary electron removes an electron from an electron shell in an atom. Subsequently another electron in a higher energy shell transfers to the vacancy. The energy thus released is given to a third electron which is emitted. It may be seen that the energy of the third electron is independent of the energy of the primary and is characteristic of three energy levels in the excited surface atom. A large number of these Auger energies have been measured for many elements and they provide identification of the element concerned. Auger electrons have a very short mean free path and hence, in order to escape the surface, must originate within the top 10 nm of the surface. Fractions of a monolayer of an element can be detected using Auger electron spectroscopy. This relatively new technique of analysis appears to have a considerable number of possible uses.
Figure 18.3   *Strongest Auger emission peaks as a function of the atomic number*

The energy of the primary bombarding electrons is usually greater than 2.5 keV, and the Auger peaks are detected from about 50 eV up to 2 kV. Figure 18.3 shows the Auger energies of the stronger peaks plotted against the atomic number Z. The letters are the electron levels involved in the Auger transition (reference 23).

18.5   Electron emission under positive ion bombardment

When an electrical discharge takes place between two electrodes in a low gas pressure the cathode is bombarded with positive ions and emits electrons. These electrons are essential for maintaining the discharge. The number of electrons released for each arriving ion is usually called γ, the second Townsend coefficient. The coefficient is generally approximately constant for positive ion energies from zero up to about 1 kV. The energy required to release the electron is supplied by neutralisation of the positive ion as follows. When the ion is very close to the metal surface the electrostatic force is sufficient to extract an electron which neutralises the positive ion. This releases a photon of energy $(I - \phi)e$, where I is the ionisation potential of the gas atom. This photon can then release a photoelectron from the metal provided $(I - \phi)e > \phi e$ or $I > 2\phi$.

The value of γ thus tends to increase with increasing I and decreasing ϕ. Values of γ for various inert gas ions and metals are shown in Table 18.10. At energies above a few keV the value of γ usually increases approximately linearly with energy, the extra electrons being released as a result of kinetic energy transfer.

18.6   Field emission

When a very high positive electric field is applied to the surface of a metal, the potential just outside the metal becomes more positive than the Fermi level in the metal. The work function barrier, instead of being a step becomes very thin, and electrons can 'tunnel' through the barrier and be emitted. This emission is usually called field emission (sometimes tunnel emission), and the emission density

is related to the field by the Fowler-Nordheim law. Table 18.11 shows values of $\log_{10}$ (emission density) for various fields for clean tungsten ($\phi = 4.5\,\text{V}$) and also for a barium contaminated surface ($\phi = 2.0\,\text{V}$) and an oxygen contaminated surface ($\phi = 6.3\,\text{V}$).

High fields which produce appreciable emissions usually result from field concentration at the tips of small projections, spikes or whiskers on metal surfaces. As these usually have submicron tip diameters the emission current in A for an area of 10^{-14} m^2 is also shown in Table 18.11.

The field at the tips of emitting projections is greater than the 'macroscopic' field at an electrode by a factor which varies between about 1 000 for a rough surface, down to less than 100 for a highly polished and voltage conditioned hard metal surface. When the field emission from a projection reaches an appreciable fraction of an ampere, the projection will melt and vaporise and this may initiate electrical breakdown between the electrodes in vacuum. Alternatively the field emission may heat the anode electrode and release gas or metal vapour which can also initiate a breakdown. From

Table 18.11 the necessary tip field is likely to be $2 \times 10^9 - 10^{10}\,\mathrm{V\,m^{-1}}$, depending on work function while the macroscopic field will usually be of the order of 1% of this.

Single field emitting sources can be made, consisting of a point 0.1–1.0 μm diameter etched on the end of a refractory metal wire. An anode electrode near the point and carrying a positive potential of a few kV is sufficient to cause field emission. The point usually emits over most of its approximately hemispherical tip. The intensity of the emission varies with direction, as different crystal planes on its surface have different work functions (reference 25). The close packed planes, e.g. the (110) plane of a body centred crystal such as tungsten, have the highest work function and lowest field emission. This effect is shown visually in a field electron microscope where the emission from the tip is viewed on a screen. This arrangement has been used extensively to study surface migration and adsorption phenomena. Measurements can however only be carried out in ultra high vacuum (pressure $<10^{-7}$ Pa) otherwise positive ions are formed in the gas and these quickly destroy the point by ion bombardment.

19   Electrical properties

19.1   Resistivity

The resistivities of a number of pure metals and alloys are given in Tables 19.1 to 19.4. Resistivity varies with the condition of the material and is sensitive to purity. In general, cold working increases and annealing decreases the resistivity. Common reactive gases such as oxygen, nitrogen and hydrogen may also affect the resistivity, either through selective chemical action with existing metallic impurities (which may even reduce the resistivity) or through solution in the host matrix itself.[1] Thermal cycling through phase transformation, quenching from high temperatures and irradiation, all introduce lattice defects which increase resistivity. These defects include vacancies, dislocations and interstitial atoms. Annealing will promote the movement and eventual removal of these defects. This recovery generally takes place in discrete stages at certain temperatures corresponding to the annealing out of each type of defect. Recovery is complete after treatment at the recrystallisation temperature.

Resistivity is often expressed approximately as the sum of the residual resistivity at absolute zero (arising from impurities and lattice defects) and a temperature-dependent intrinsic resistivity (arising from the effect of lattice vibrations upon conduction electrons). The form of temperature dependence is complex, and theories governing it in both solid and liquid metals have been recently discussed in, for example, references 2–15. Over a limited temperature interval, resistivity may be conveniently expressed as a linear relation of the form $\rho_1 = \rho_0(1 + \alpha T)$, where T is the interval between two temperatures T_1 and T_0, and α is the temperature coefficient of resistivity (TCR). In Table 19.1,

* Liquid resistivity at temperature above melting point.
† TCR for the interval 250–300 K.
‡ TCR for the liquid phase.

TCR values are given for the temperature range 273–373 K, except for some lower-melting-point elements as indicated.

Resistivity values given in Table 19.1 are for bulk material. If the metal is deposited as a thin film, resistivity may deviate from the bulk value, being affected by parameters such as film thickness and grain size. Many recent investigations have been made on these effects (*see* references 39–41).

The resistivity and temperature coefficient of alloys is often dependent upon the method of preparation and heat treatment. The values given in Table 19.2 relate to particular samples and should not be assumed to apply accurately to other samples of similar composition. In systems which exhibit complete mutual solid solubility, there is often a resistivity maximum near 50/50 composition (e.g.

Figure 19.1). The transition elements show complex resistivity and TCR behaviour upon alloying. Very low TCRs, which may be of importance industrially, are obtained in some quaternary Ni–Cr alloys after suitable heat treatment. TCR values given here are for the temperature interval 273–373 K.

Theoretical predictions for the resistivity of alloys have recently been discussed in references 42–46.

Dilute copper and aluminium alloys have important applications as electrical conductors. Table 19.3 lists specified resistivity values for certain copper alloys (*see* references 54–56). Table 19.4 shows the effect on the resistivity of EC aluminium (99.45 wt% Al) of the addition of 1 at.% of various solutes. When considering aluminium as an electrical conductor, it is important to achieve strengthening by the addition of suitable solutes without undue reduction in conductivity. The least detrimental additions form intermetallic compounds that remain out of solid solution (*see* references 57 and 57A).

19.2   Superconductivity

Below a transition temperature T_c some elements, compounds and alloys become superconducting. In this state they exhibit zero electrical resistance and some become perfectly diamagnetic. The application of a magnetic field whether applied externally or generated by a current passing along the superconductor in excess of a critical or limiting value restores the material to its normal resistive state.

Table 19.5 lists the elements which become superconducting when cooled to a sufficiently low temperature together with their transition temperatures and critical fields at 0 K (H_0).[58–60] The critical field H_c at temperature T is closely represented by the releationship

$$H_c = H_0 \left[1 - \left(\frac{T}{T_c} \right)^2 \right]$$

Table 19.5   TRANSITION TEMPERATURES AND CRITICAL FIELDS FOR SUPERCONDUCTING ELEMENTS

Element		T_c K	H_0 10^4 T	Element	T_c K	H_0 10^4 T
Aluminium		1.18	99	Osmium	0.61	82

Nb_3Pt	10	63	$ZrIr_2$	4.1	72

*at. %

The maximum axial current which a superconducting material of cylindrical form, radius r, will sustain while remaining superconducting is given by

$$I_c = 0.5H_c r$$

Superconductivity is observed in indium and molybdenum only when these elements are very pure.[60] Traces of magnetic impurity, e.g. Fe > 0.02%, prevent its occurrence.

A large number of intermetallic compounds, non-stoichiometric alloys and solid solutions exhibit superconductivity. Among the compounds, the sodium chloride structure (e.g. NbN) and the A–15 or 'beta-tungsten' structure (e.g. Nb_3Sn) are two of the more common crystal types. There are currently nearly fifty A–15 compounds known to be superconducting. These alloys and compounds are potentially of considerable technological importance. Table 19.6 lists those with critical temperatures greater than 1 K.

Ternary additions can often lead to increase in critical temperature. Useful results have been discussed in references 68 and 73–77. Increased current-carrying capacity has also been seen to result from energetic particle irradiation.[78]

Superconducting compounds are usually brittle in bulk, and special techniques are required to fabricate them into useful forms. Powder metallurgical techniques may be used, while another typical method results in a composite of multifilamentary superconducting phase in a copper matrix. Superconductors may also be produced as thin films by chemical vapour deposition or sputtering (*see* references 79–83 and chapter 35).

Superconducting properties tend to be dependent upon the method of preparation and heat treatment; this observation is discussed in many of the references quoted.

For overall discussion of superconductivity, its applications, and the prospects of further developments of industrial importance, see references 64 and 84.

Much of the recent interest in superconductors has focused on high T_c ceramic materials. Ceramics are beyond the scope of the present work. However some reviews on high T_c materials may be found in references 85–89. Information on potential applications of these materials is contained in references 90–93.

20 Magnetic materials and their properties

20.1 Magnetic materials

All materials have magnetic properties. These characteristic properties may be divided into five groups: diamagnetic, paramagnetic, ferromagnetic, antiferromagnetic and ferrimagnetic. Only the ferromagnetic and ferrimagnetic materials have properties which are useful in practical applications.

Ferromagnetic properties are confined almost entirely to iron, nickel and cobalt in their alloys. The only exceptions are some alloys of manganese and some of the rare earth elements. Of these gadolinium has the highest Curie temperature, about 16°C (see the Appendix for definitions and conversion factors). Some of the magnetic properties of the ferromagnetic elements including the rare earths are given in Tables 20.1 and 20.2. Ferrimagnetism is the magnetism of the oxides of the ferromagnetic elements. These are variously called ferrites and garnets. The basic ferrite is magnetite (Fe_3O_4) which can be written as $FeO \cdot Fe_2O_3$. By substituting for the FeO with other divalent oxides a wide range of compounds with useful properties can be produced. The main advantage of these materials is that they have high electrical resistivity which minimises eddy currents when they are used at high frequencies.

Ferromagnetic and ferrimagnetic materials are characterised by moderate to high permeabilities (*see* Tables 20.4, 20.5 and 20.7–20.11). The permeability varies with the applied magnetic field, rising to a maximum at the knee of the *B–H* curve and reducing to a low value at very high fields. They also exhibit magnetic hysteresis whereby the intensity of magnetisation of the material varies according to whether the applied field is being increased in a positive sense or decreased in a negative sense. A typical hysteresis loop is shown in Figure 20.1 together with some of the more important derived magnetic properties. When the magnetisation is cycled continuously round a hysteresis

Table 20.1 FERROMAGNETIC ELEMENTS[9]

	$J_s(T)$		Curie temperature °C	σ_{4K}	$\sigma_{20°C}$
	20°C	4K			
Fe	2.153	2.193	770	221.7	217.6
Ni	0.617	0.656	358	58.6	55.1
Co	1.790	1.797	1 121	162.5	161.9
Gd	0	2.47	16	250	0

Table 20.2 RARE EARTH ELEMENTS[9]

σ_0 4 K	250	330	350	345	300	230
T_c K	289	222	85	20	20	25
Figure 20.1   *Typical hysteresis loop*

loop, as for example when the applied field arises from an alternating current, there is an energy loss proportional to the area of the included loop. This is termed hysteresis loss, and is measured in joules per metre.[3] High hysteresis loss is associated with permanent magnetic properties exhibited by materials commonly termed 'hard' magnetic materials as these often have hard mechanical properties. Those materials with low hysteresis loss are termed 'soft' and are difficult to magnetise permanently. The ferromagnetic properties of these elements, alloys, and compounds disappear reversibly if heated above the Curie temperature, when they become paramagnetic.

Paramagnetic substances of elongated shape tend to align themselves with an applied magnetic field as do the ferromagnetics, but do not exhibit any permanent magnetic properties when the field is removed as hysteresis is absent. Their magnetic susceptibility is very small but positive, and consequently their relative permeability is only slightly greater than unity. The susceptibility is generally independent of field strength but may decrease with increasing temperature. Among the paramagnetic substances are included many iron salts and rare-earth elements salts, palladium and platinum, sodium, potassium, and oxygen, and the ferromagnetics above their Curie point.

The diamagnetic substances take on a very small magnetisation which is opposed to the sense of the applied field. Thus an elongated specimen will align itself transversely to a non-uniform field. The diamagnetics have negative susceptibilities and consequently permeabilities which are very slightly less than unity. Many of the metals and most non-metals are diamagnetic. It is usual to compare paramagnetic and diamagnetic substances by their susceptibilities rather than by permeability or saturation magnetisation as for the ferromagnetic materials. The mass susceptibilities of the elements at room temperature are given in Table 20.3.[5–9]

For bulk applications of magnetic material, iron, steel or cast iron are used. They have the advantage of cheapness and strength. These materials should only be used for d.c. applications as they have low electrical resistivity which would give rise to eddy currents if used in alternating fields. The properties of some steels and cast irons are given in Tables 20.4 and 20.5.[10–13]

For a list of current reviews, at the time of writing, on magnetic materials see references 14–19.

20.2   Permanent magnet materials[20,21]

The properties of a permanent magnet material are given by the demagnetisation curve, Figure 20.2, the second quadrant of the B–H hysteresis loop. This extends from the remanence B_r to the coercivity

Table 20.3   MASS SUSCEPTIBILITIES OF THE ELEMENTS[5-9]

H_{cB}. It can be shown that when a piece of permanent magnet material is put into a magnetic circuit, the magnetic field generated in a gap in the circuit is proportional to BHV, where B and H are the corresponding points at a point on the demagnetisation curve and V is the volume of permanent magnet. So to obtain a given field with the minimum volume of magnet material we require the product BH to be a maximum. The magnet is then designed so that its B, H value is as close as possible to the $(BH)_{max}$ value. It is also useful to use the BH_{max} value to compare the characteristics

Figure 20.2   *Demagnetisation curve and recoil loop*

of materials. Generally the material with the highest $(BH)_{max}$ will be chosen but this has to be weighed against such considerations as cost, shape, manufacturing problems and stability.

When the magnet is fully magnetised in a completed magnetic circuit, the working point is the remanence B_r. When a gap is made in the circuit, the magnet will be partly demagnetised and its working point will fall to, say, the point P. If now a further demagnetising field is applied to the magnet corresponding to H_1–H_2 the flux density will be reduced to B_2. If this extra field H_1–H_2 is removed the field will recoil along the narrow loop QR to the point R. The corresponding flux density is B_3. This narrow loop is called the recoil loop and its slope is $\mu = \mu_0 \mu_r$ where μ_r is the relative recoil permeability and μ_0 is the magnetic constant ($= 4\pi \times 10^{-7}$). This is an important consideration in dynamic applications such as motors, generators and lifting devices where the working point of the magnet changes as the magnetic circuit configuration changes. It is also important when considering premagnetising before assembly into a magnetic circuit. If μ_r is nearly equal to unity as it is for ferrites and for rare earth alloys then the magnets can be premagnetised before assembly into a magnetic circuit without much loss of available flux. However, if μ_r is considerably greater than unity, care must be taken to magnetise the magnet in the assembled magnetic circuit.

The dotted curve in Figure 20.2 is the *J–H* curve where $B = \mu_0 H + J$. For materials with B_r much greater than $\mu_0 H_{cB}$, e.g. Alnico, the two curves are almost identical, but for ferrites and rare earth alloys where B_r and $\mu_0 H_{cB}$ are close in value the curves become quite different. The *J–H* curve has only a very gradual slope from B_r; this indicates that the magnetisation in the material is nearly uniform and a new parameters H_{cJ} is introduced. This intrinsic coercivity H_{cJ} is a measure of the difficulty or ease of demagnetisation. As the value of H_{cJ} is increased the more the material will resist demagnetisation due to stray fields, etc. However, as a field of at least three times H_{cJ} must be applied to the magnet for magnetisation, difficulties may be encountered in attaining the full magnetisation if H_{cJ} is too high.

Magnets in the three main groups Alnico, ferrites and rare earth alloys are generally made anisotropic with the properties in one direction considerably better than in the other directions. This best direction is called the preferred direction of magnetisation. The curves and parameters supplied for such a material refer to the properties in this preferred direction.

To choose between these three materials for a particular application, Alnico must be used where magnetic stability is a requirement and this would apply in any type of instrument application. Ferrite will be used where cost is the main consideration and rare earth magnets will be used if the highest possible strength is required or if miniaturisation is needed.

20.2.1 Alnico alloys

A wide range of alloys with magnetically useful properties is based on the Al–Ni–Co–Fe system. They are characterised by high remanence, available energy and moderately high coercivity. They are very stable against vibration and have the widest useful temperature range (up to over 500°C) of any permanent magnet material. But they are mechanically hard, impossible to forge, and difficult to machine except by grinding and special methods such as spark erosion.

The preferred form of magnet is a relatively simple shape made by casting or sintering, precision ground on essential surfaces only. Soft-iron pole pieces may be clamped on or held by a suitable adhesive such as Araldite. Soldering, diecasting and even brazing (with precautions against overheating) may be used.

The commonest alloys contain 23–25% cobalt, 12–14% nickel, about 8% aluminium, a few percent copper and sometimes small additions of niobium and silicon, with the balance iron. They are cooled at a controlled rate in a magnetic field applied in the direction in which the magnets are to be magnetised. The properties are much improved in this direction at the expense of those in other directions. There is finally a fairly prolonged and sometimes rather complicated treatment at temperatures in the range 650–550°C.

The field cooling is much more effective in producing anisotropic properties if the magnets are cast with a columnar structure. Basically a columnar structure is produced by casting the alloy into a hot mould with a cold chill. The mould may be made of special materials which can be preheated to at least 1 250°C in a furnace, or alternatively contain chemicals which heat it by an exothermic reaction. Either method is inconvenient and expensive; there are also limitations on the lengths and shapes of magnets that can be made columnar. This Columax is therefore regarded as a rather expensive, quality material.

The coercivity of Alnico can be improved by a factor of two to three by increasing the cobalt content to 30–40% and adding 5–8% of titanium with possibly some niobium. For the best properties it is necessary to hold these alloys for several minutes in a magnetic field at a constant temperature, accurately controlled to $\pm 10°C$, instead of the usual field cooling process. This heat treatment as well as the high cobalt content makes these alloys expensive and they are only used where the higher coercivity is required. Columnar versions of these alloys can also be made but these are only used for very specialised applications.

The Alnico alloys can be produced as castings of up to 100 kg and down to a few grams in weight but it is found more economical to produce the smaller sizes of 50 g and less by the sintering process. In all cases it is advisable to contact the manufacturers before any design is considered.

20.2.2 Ferrite

The permanent magnet ferrites (also called ceramics) are mixed oxides of iron (ferric) oxide with a divalent heavy metal oxide, usually either barium or strontium. These ferrites have a hexagonal crystal structure, the very high anistropy of which gives rise to high values of coercivity, e.g. 150–300 kA m^{-1} (compared with about 110 kA m^{-1} for the best Alnico alloys). The general formula is $MO \cdot 5.9Fe_2O_3$ where M is either barium or strontium, and the crystal structure is called magneto plumbite as it was originally found in the equivalent lead oxide compound. These ferrites are made by mixing together barium or strontium carbonate with iron oxide in the correct proportions. The mixture is fired in a mildly oxidising atmosphere and the resulting mixture is milled to a particle size of about 1 micron. This powder is then pressed in a die to the required shape (with a shrinkage allowance), and anisotropic magnets are produced by applying a magnetic field in the direction of pressing. After pressing, the compact is fired. This material is a ceramic and can only be cut by high speed slitting wheels. Ferrite magnets are produced in large quantities in a variety of sizes for different applications. Flat rings are made for loudspeakers ranging up to 300 mm in diameter with a thickness of up to 25 mm. Segments are made for motors with ruling diameters from 40 to 160 mm and rectangular blocks are made for separators with dimensions of up to $150 \times 100 \times 25$ mm. These blocks can be built up into assemblies or cut down into smaller pieces for a variety of applications. In each of these cases the preferred direction of magnetisation is through the shortest dimension. Generally the magnetic length does not exceed 25 mm and if a longer length is required this is built up with magnets in series.

The great success of permanent magnet ferrites is due to the low price per unit of available magnetic energy, the high coercivities, the high restivities and the low density. The isotropic grades are the least expensive to manufacture and may be magnetised into complex pole configurations; they are used for a wide range of relatively small-scale applications. The largest application in terms of market volume is for magnets for loudspeakers; here the high-remanence anisotropic grades

are used. The other high-volume application is for field magnets in small d.c. motors, particularly those used in the automotive industry, e.g. for windscreen wipers, blowers, etc. In this application the high-coercivity anisotropic ferrite is formed into an arc-shaped segment, magnetised radially; a pair of segments embrace the armature and provide the stator field. Other applications of anisotropic hard ferrites include magnetic chucks and magnetic filters and separators.

20.2.3   Rare earth cobalt alloys

These are the results of a fairly recent development and the first commercial material was $SmCo_5$. The alloy powder is produced either by reducing the rare earth powder together with cobalt powder or by preparing the alloy and powdering it down. The powder is compacted and pressed, almost invariably in a magnetic field, to produce an anisotropic compact. This is then sintered at $1\,155 \pm 15°C$ and followed by a tempering treatment at about $900°C$. It must be emphasised that during all the processing of these rare earth alloys a protective atmosphere is used to prevent the oxidation of the rare earth metals which are very reactive.

Another development in this series is the Sm_2Co_{17} composition which is really the generic name for a whole series of binary and multi-phase alloys with other transition elements replacing cobalt. These other elements include copper, chromium, manganese, zirconium and iron. The ratio of transition elements to rare earth may be less than the 8.5 given by the composition. An anisotropic compact is produced and sintered at $1\,150$ to $1\,250°C$, and this is followed by a solution treatment at $1\,100$ to $1\,250°C$. The compact is then step aged at temperatures from $900°C$ down to $400°C$ over a period of at least 20 h. This complicated heat treatment and difficulties with powder production have made the magnets rather difficult to produce with consistent properties. It is however the most stable of the rare earth alloys and has a higher remanence and $(BH)_{max}$ than the $SmCo_5$ alloy.

In both of these alloy systems the properties are due to a very strong magnetocrystalline anisotropy related to the hexagonal crystal structure. The range of sizes which can normally be produced is from about 1 mm cubes up to blocks of $50 \times 50 \times 25$ mm, the short dimension being the preferred direction. These magnets are very brittle and must be handled with care to prevent chipping or cracking. They can only be machined by grinding or slitting, and they cannot be drilled or turned. The magnets may be magnetised prior to assembly without flux loss because they combine a relative recoil permeability close to unity with a high coercivity. However, because of the handling problems with these brittle magnets it is often more convenient for the user to magnetise during assembly.

20.2.4   Neodymium iron boron

This alloy was announced in 1983 and it has generated a great deal of interest because at room temperature it has better properties than any previously known alloy. It is also a cobalt-free alloy and uses neodymium which is more abundant than samarium. These two factors make the raw material costs quite considerably less than those of the samarium cobalt alloys.

There are two main routes for the production of magnets from these alloys. The first is the conventional route similar to that used for $SmCo_5$. The constituents of the alloy are melted together, and the material is then powdered, pressed in a magnetic field and sintered. The basic alloy with this route is the atomic composition $Nd_{15}B_8Fe_{77}$. The second method is to use the melt spinning process where the molten alloy is ejected under pressure onto a water cooled wheel which is rotating at high speed. This cools the alloy very rapidly and an amorphous glass-like tape is produced. This tape is annealed at $650°C$, which recrystallises the alloy, and then it is mechanically broken into flake. The basic atomic composition of the alloy for this process is 13.5% Nd 4.75% B 81.75% Fe. There are advantages in each of these methods. To get the best properties the conventional sintering route must be used but the production of the powder is rather slow and expensive. Melt spinning allows the powder to be produced more easily and cheaply. This method is ideal for the production of flake for use in the manufacture of isotropic bonded material, this product being called Magnequench I. The production of anisotropic material from the flake is more difficult and expensive.

The mechanism which provides the high value of the coercivity is crystal anisotropy, in the tetragonal crystals of the alloy. The particle size required for optimum properties is about $3\,\mu m$. Powdering can be achieved by ball milling; however the hydrogen decrepitation process has been applied very successfully. This process, which involves the absorption of large volumes of hydrogen by the alloy followed by desorption, produces much less damage to the particles, resulting in better properties.

There are two disadvantages of these neodymium alloys when compared to the rare earth cobalt alloys. They suffer from corrosion and rusting, although this can be prevented by the use of a suitable

coating. They also have a relatively low Curie temperature of 330°C resulting in instability with a rapid decrease in flux with increasing temperature. The stability can be improved by additions of dysprosium, niobium and/or vanadium, making the alloy useful up to 150°C. Similar comments to those for the rare earth cobalt alloys apply here regarding sizes, machining and magnetising but these neodymium alloys are much less brittle.

These alloys are being used in a wide range of rotating machine applications for both a.c. and d.c. generators and motors including stepper motors. They are also used for holding and lifting devices and for motors for compact discs. More specialised applications include body scanners using magnetic resonance imaging (MRI) and particle beam focusing devices.

20.2.5 Bonded materials

Each of the above materials can in the powdered form be mixed with a bond. These bonds can be rubbers, polymers or plastics, and they may be flexible or rigid. The flexible rubber bonded ferrites have found wide application in holding and display services and the best quality anisotropic material is used in small motors. Alnico and rare earth cobalt are also made in bonded forms and they have the advantages of a uniform level of properties and freedom from cracking. Their magnetic properties are not so good as the unbonded materials: at best the BH_{max} is about 50% lower.

For recent research, at the time of writing, in the field of bonded magnetic materials see references 22–24.

20.2.6 Other materials

There are a number of other permanent magnet materials with minor applications. These materials make up less than 1% of the total production. They mainly find applications because they can be mechanically formed into shape, which is not possible for Alnico, ferrites or rare earth alloys. It must be emphasised that these other materials are only available in a limited range of sizes and shapes. Steels which were the original permanent magnets are now almost obsolete because their properties are inferior to those of the materials mentioned above. They do, however, find applications in hysteresis motors where intermediate coercivities are required. Cunife (Cu Ni Fe) and Cr Fe Co are alloys which can be rolled and drawn into wire and the anisotropy is produced by this rolling or drawing. Cr Fe Co produced by rolling can have properties similar to those of anisotropic Alnico. Platinum cobalt (Pt Co), which has a very high coercivity, was much used in the early days of space research. For most applications it has now been replaced by rare earth alloys. However, it is still used for medical and other applications where the resistance to corrosion is required. Other materials which were used in the past are Lodex, which consisted of fine electrolysed particles of iron cobalt, Vicalloy (V Co Fe) and Mn Al C alloys. These materials are now obsolete because of cost, lack of demand and production difficulties.

Non-metallic magnetic materials are of great commercial importance. These are beyond the scope of the current work but are discussed in references 25–27.

20.2.7 Properties, names and applications

The range of properties for each class of material is given in Table 20.6. These ranges include deliberate variations in properties obtained by small changes in composition and heat treatment.

Applications of magnetic materials, especially in electronics, are changing rapidly. See references 28–31 for examples current at the time of writing. Trade names of these materials are not included here, as these are subject to change.

20.3 Magnetically soft materials

Materials or alloys which are classed as magnetically soft, and generally with a relatively high permeability, are used for a wide range of applications including transformer laminations, armature stampings and cores in electrical machinery. They also include materials of considerable importance in the electronic and communication industries. Many special materials of widely different chemical compositions have been developed to meet specialised requirements. These are not confined to metallic alloys and ceramic oxides have become increasingly important.

Table 20.6   CHARACTERISTICS OF PERMANENT-MAGNET MATERIALS

Others				
Cunife	0.54	10	40	—
CrFeCo	1.3	40–46	46	3–4
PtCo	0.62	72	370	1.1

Intrinsic coercivity H_{cT}(kA m^{-1}) [a] 160–3.10; [b] 800–1 500; [c] 600–1 300; [d] 750–1 900.
The Curie temperature of Alnico is 800–8.50°C, of ferrite 450°C, of SmCo over 700°C and for NdFeB it is 300°C. The Alnicos have a resistivity of about 50×10^{-8} Ωm, for the ferrites it is about 10^4 Ωm and for the rare earths 90–140×10^{-3} Ωm.

Sometimes several conflicting attributes are required in magnetically soft materials for a given application. It is for this reason that a range of materials from iron through to silicon steels, high nickel–iron alloys and ferrites have emerged. Usually, the most important requirement is that the hysteresis loss due to cyclic magnetisation should be as low as possible. The eddy current loss, which is due to the induction of electric currents in the material by the changing magnetic flux, should also be small. Generally the magnetic permeability should be as high as possible, particularly the maximum permeability, and in certain special cases the initial permeability. Sometimes the requirement is for a high permeability at low field strengths. In general, the saturation intensity should be as high as other conditions will permit. For magnetic temperature compensation there should be a linear relation, over a known range of temperature, between permeability and temperature.

Relevant data concerning a wide selection of materials are given in Tables 20.7–20.11 and are discussed in the corresponding sections.

20.3.1   Silicon–iron alloys

For the magnetic circuits of the larger pieces of electrical equipment normally operated at power frequencies of 50 Hz, such as power transformers, alternators and electric motors of all sizes, a magnetic material is essential which will have a low hysteresis, high resistivity and a high value of magnetic saturation. Its production in the form of thin sheet or strip must also be possible, and in view of the big tonnages essential for such purposes it must not be expensive. Silicon–iron alloys are the only ones which meet all these conflicting requirements.

Over the years, the quality of silicon steels has been continuously improved and more has been learned about the effects of silicon on the magnetic properties. These effects are briefly as follows:

1. Silicon precipitates the major portion of the oxygen dissolved in the steel, which reduces hysteresis loss and magnetic ageing.
2. Silicon increases the electrical resistivity and thus reduces the eddy current loss, which is proportional to the resistivity (*see* Figure 20.3).
Figure 20.3   *Electrical resistivities of iron-rich iron–silicon alloys*
Figure 20.4   *The gamma phase region*

3. With over 2.5% silicon the alloys are outside the gamma loop on the equilibrium diagram, i.e. the alpha–gamma change point is suppressed (*see* Figure 20.4). Alloys of more than 2.5% silicon can therefore be annealed at high temperatures without recrystallisation occurring on cooling. As a result it is easier to produce large grain size in the finished sheet, with a corresponding reduction in hysteresis loss.

4. Silicon precipitates the carbon as graphite if it exceeds about 0.05%. Carbon present as graphite has no effect on hysteresis loss.

It is possible to orient the grains in silicon steels by cold rolling and heat treatments. Improvements in this grain-oriented sheet have been made as follows:

1. Limitation of the silicon content to about 3%. Above this value it is difficult to produce good quality sheet because of mechanical difficulties.

2. Reduction in the sheet thickness. The minimum thickness is 0.23 mm, which is limited by grain growth considerations.

3. Reductions of impurities to the minimum economic value. Impurities which increase hysteresis are those which occupy interstitial positions in the crystal lattice, e.g. carbon, oxygen, nitrogen and sulphur.

4. Improvements in the control of annealing equipment and protective atmospheres during final annealing.

The grain-oriented steel strip is used for transformers. The grain orientation is parallel to the rolling direction and in the transformer the flux is arranged so that it is parallel to this direction. This gives the advantage that the permeability is better and the hysteresis is lower with the direction of magnetisation parallel to the cube edge of the crystal lattice (*see* Figure 20.5).

During the annealing process a glass film is produced on the steel surface and this film gives a longitudinal tension in the sheet and provides insulation. This tension improves the magnetic properties of the steel, including a reduction in the magnetostriction which reduces the acoustic noise of the transformer. A phosphate coating is applied to complete the tensioning and insulation. The grain size of these sheets is comparatively large and the resulting domain boundaries are quite widely spaced. Artificial grain boundaries can be produced by laying down lines of ablated spots on the steel surface to give a stress and atomic disruption pattern which pins domain walls and leads to a smaller wall spacing. Various methods have been used to produce this ablating including spark and laser techniques.

In addition to the grain oriented material there is a need in rotating machinary applications for sheets which are comparatively isotropic and less expensive. The silicon content is generally lower as
Figure 20.5 *Magnetisation curves for 3.85% silicon-iron single crystals at high field strengths in three directions*

the minimum core loss is less important than the high-saturation magnetisation needed for maximum torque.

Manufacturers offer a series of alloys whose properties are given in Table 20.7. These alloys conform to the British Standards and their international equivalents given in ref. 38. Methods of test are also given in these standards. In the past the Epstein square has been used by there is a rapidly growing trend towards the use of single-sheet testers which greatly reduce the labour involved.

20.3.2 Ferrites[34–36] and garnets[36]

Ferrites are iron oxide compounds usually containing at least one other metallic ion. The magnetic iron oxides Fe_3O_4 and Fe_3O_3, both of which are used in magnetic recording, are also included with the ferrites. The most important of the many ferrite materials now known are sintered ceramics of high resistivity, together with saturation magnetisations up to 0.5 T at room temperature. One structural class is the barium hexaferrites with high coercivities used as permanent magnets. The other two structural classes are the spinels and the garnets.

The spinel-structured ferrites are mixed oxides with the general composition $MO \cdot Fe_2O_3$ where M may be Fe, Ni, Mn, Zn, Co, Cu, Li or Al or mixtures of these. They are prepared from the constituent oxides which have been milled to a fine powder, preferably of the same particle size and intimately mixed. This mixture is calcined at about $1\,000°C$ followed by crushing and milling and pressing the powder in a die or extrusion to the required shape. The resulting compact is a black brittle ceramic and any subsequent machining must be by grinding. They may be prepared with high permeability, and by virtue of the high resistivity, which renders eddy current levels negligible, can be used at frequencies up to 10 or 20 MHz as the solid core of inductors or transformers. The losses which do occur are a combination of hysteresis, eddy current, and residual losses which may be separately controlled by composition and processing conditions with due regard to the permeability required and frequency of operation.

The saturation flux density of ferrites is low, making them unsuitable for use in power or high flux transformers. Their use is therefore almost entirely in the electronic and telecommunications industry where they are now largely replacing laminated alloy and powder cores.

Typical properties of the commonly employed manganese–zinc and nickel–zinc ferrites are given in Table 20.8.

For higher frequencies of 100 mHz and above garnets are used. They have resistivities in excess of 10^8 Ωm compared with the ferrites, restivities of about 10^3 Ωm at best. This means that eddy current losses which are dependent on resistivity are minimised. The basic Yttrium Iron Garnet (YIG) composition is $3Y_2O_3 \cdot 5Fe_2O_3$. This is modified to obtain improved properties such as very low loss and greater temperature stability by the addition of other elements, including aluminium

Table 20.7 TYPICAL PROPERTIES OF SILICON STEELS[32]

Grade identity	Thickness mm	Typical specific total loss at $B = 1.5$T; 50 Hz (or 1.7T; 50 Hz where stated) (W kg)	Typical specific apparent power at $B = 1.5$T; 50 Hz (or 1.7T; 50 Hz where stated) (VA kg^{-1})	Nominal silicon content %	Resistivity Ωm $\times 10^8$	Stacking factor %	$\hat{B}$ at $H = 5\,000$ A m^{-1} (or $1\,000$ A m^{-1} where stated) T	Typical applications

and gadolinium. The garnets are prepared by heating the mixture of oxides under pressure at over 1 300°C for up to 10 h. This material is used in microwave circuits in filters, isolators, circulators and mixtures. Some of their properties are given in Table 20.9.

Table 20.9   GARNET MATERIAL

	J_s T	T_c °C	ΔH (kA m^{-1})* Maximum
Y Al Fe	0.3–1.76	110–280	45–60
Y Gd Fe	0.67–1.22	280	110–250
Y Gd Al Fe	0.6–1.1	190–250	70–120

*This is the gyromagnetic resonant linewidth ΔH (−3 dB).
 The values of other parameters for these garnets are:
 dielectric constant ε' 13.8–15.2,
 $10^4 \tan \delta$ 2.5–3.

20.3.3   Nickel–iron alloys

The high permeability of nickel–iron alloys makes them very useful materials for the electronic communications and electrical power engineering industries. This high permeability at low fields (despite the low saturation magnetisation) gives scope for minimising core sizes in a wide range of applications.[32,33]

There are three main groups of high-permeability nickel–iron alloys. The 80% nickel alloys variously called Mumetal and Permalloy have the highest permeability due to the almost zero crystalline anisotropy and magnetostriction at this composition. The commercial alloys have additions of chromium, copper and molybdenum to increase the resistivity and improve the magnetic properties. This material is used in specialised transformers, for magnetic screens and magnetic recording heads.

The 50% nickel alloys have the highest saturation magnetisation of 1.6 T in this range of alloys. They have a higher permeability and better corrosion resistance than silicon–iron alloys but they are more expensive. Another advantage is they have a high incremental permeability over a wide range of polarising d.c. fields. A wide range of properties can be produced by various processing techniques. Severe cold reduction produces a cube texture and a square hysteresis loop in annealed strip. The properties can be tailored by annealing the material below the Curie temperature in a magnetic field. Applications of this material include chokes, relays and small motors.

The 36% nickel alloys have higher resistivity and are less costly than the 50% alloy but the saturation magnetisation and permeability are lower. This alloy is of the Invar type and has a very low coefficient of expansion of 1×10^{-6}°C^{-1}. The main applications are relays, inductors and high-frequency transformers where the higher resistivity limits the eddy currents. The properties of the various nickel–iron alloys are given in Table 20.10.

Table 20.10   PROPERTIES OF NICKEL–IRON ALLOYS[32]

Alloy	36% Ni	45% Ni	50% Ni	54% Ni	65% Ni	77% Ni
Initial permeability $\times 10^{-3}$	3	6	0.5–11	65	—	60–200
Saturation flux density (T)	1.2	1.6	1.54–1.6	1.5	1.3	0.8
Coercivity force (Am^{-1})	10	10	3–10	2.5	2–10	0.5–1

Resistivity ($\mu\Omega$ m)	0.8	0.45	0.4	0.45	0.6	0.6
Density (kg m^{-3})	8 100	8 300	8 300	8 300	8 500	8 800
Curie temp. (°C)	280	530	530	550	520	350
Expansion coefficient (°C^{-1} $\times 10^6$)	1	8	10	11	12	13

20.3.4   Amorphous alloy material

The rapidly solidified alloy materials called metallic glasses are now an established group of soft magnetic materials. These materials are produced by rapid solidification of the alloy at cooling rates around a million degrees centigrade per second. The alloys solidify with a glass-like atomic structure which is a non-crystalline frozen liquid. The rapid solidification is achieved by causing the molten alloy to flow through an orifice on to a rapidly rotating water cooled drum. This can produce sheets of the alloy as little as $10\,\mu m$ thick and up to a metre or more wide.

There are two main groups of amorphous alloys. The iron-rich magnetic alloys have the highest saturation magnetisation among the amorphous alloys and are based on inexpensive raw materials. The other group are the cobalt-based alloys which have very low or zero magnetostriction which leads to the highest permeability and the lowest core loss. All of these alloys have high electrical resistivity, higher than that of conventional crystalline electrical steels. Because of this, eddy current losses are minimised both at 50 Hz and at higher frequencies. They also have other advantages including flexibility without loss of hardness, high tensile strength and better corrosion resistance than similar crystalline alloys. Properties of typical amorphous alloys are given in Table 20.11.

Table 20.11   AMORPHOUS ALLOYS[2]

Amorphous material	J_s T	Curie temperature °C	Crystal-lisation °C	Electrical resistivity $\mu\Omega\,m$	μ_{max}, d.c. annealed	Coercivity $A\,m^{-1}$	Saturation magneto-striction $\lambda_s \times 10^6$
Iron-based	1.28–1.80	310–415	430–550	1.23–1.37	35–600×10^3	1–1.6	19–35
Nickel–iron-based	0.88	350	410	1.38	8×10^5	0.4	12
Cobalt-based	0.55–0.70	200–365	520–550	1.36–1.42	6–10×10^5	0.15	<1

20.4   High-saturation and constant-permeability alloys

The addition of cobalt to iron increases the saturation intensity. A range of alloys with 24–50% cobalt has saturation up to 10% greater than that of iron. Alloys with around 25% cobalt are used for applications such as magnet pole tips where a combination of good ductility, ease of machining and high-saturation magnetisation are required. The permeability and loss characteristics are however inferior to the 50% cobalt alloy. The 49/49/2 Fe/Co/V alloy called Permendur, to which the vanadium has been added to improve the ductility and also substantially increase the resistivity, is used extensively for stators in lightweight generators.

Recent developments, which have improved its mechanical properties, have extended its use to rotor laminations. Other applications include small-volume transformers, relays, diaphragms, loudspeakers and magnet pole tips. The high cost of cobalt restricts the use of these alloys, but they are widely used in aircraft where weight is at a premium. The properties of the alloys are given in Table 20.12.

Table 20.12   IRON–COBALT ALLOYS[32]

Alloy	Saturation flux density T	Initial permeability	Maximum permeability	Coercive force $A\,m^{-1}$	Remanence T	Resistivity $\mu\Omega\,m$	Curie temperature °C
24% Co	2.35	250	2 000	130	1.5	0.2	925
49/49/2 Co/Fe/V	235	800	7 000	950	1.6	0.4	975
