Foreword to the *Handbook of Child Psychology and Developmental Science*, Seventh Edition

WILLIAM DAMON

THE *HANDBOOK*'S DEVELOPING TRADITION

Development is one of life's optimistic ideas. It implies not just change but improvement, progress, forward movement, and some sense of positive direction. What constitutes improvement in any human capacity is an open, important, and fascinating question requiring astute theoretical analysis and sound empirical study. So, too, are questions of what accounts for improvement; what enhances it; and what prevents it when it fails to occur. One of the landmark achievements of this edition of the *Handbook of Child Psychology and Developmental Science* is that a full selection of top scholars in the field of human development have offered us state-of-the-science answers to these essential questions.

Compounding the interest of this edition, the concept of development applies to scholarly fields as well as to individuals, and the *Handbook*'s distinguished history, from its inception more than 80 years ago to the present edition, richly reveals the development of a field. Within the field of human development, the *Handbook* has had a long and notable tradition as the field's leading beacon, organizer, and encyclopedia of what's known. This latest *Handbook* edition, overflowing with insights and information that go well beyond the scientific knowledge available in previous editions, is proof of the substantial progress made by the field of human development during its still-short (by scholarly standards) history.

Indeed, the history of developmental science has been inextricably intertwined with the history of the *Handbook*. Like many influential encyclopedias, the *Handbook* influences the field it reports on. Scholars—especially younger ones—look to it to guide their own work. It serves as an indicator and as a generator, a pool of received findings, and a source for generating new insight.

It is impossible to imagine what the field would look like if Carl Murchison had not assembled a ground-breaking collection of essays on the then-almost-unknown topic of child study in his first *Handbook of Child Psychology*. That was 1931, at the dawn of a scholarly history that, like every developmental narrative, has proceeded with a combination of continuity and change. What does this history tell us about where the field of developmental science has been, what it has learned, and where it is going? What does it tell us about what's changed and what has remained the same in the questions that have been asked, in the methods used, and in the theoretical ideas that have been advanced to understand human development?

The First Two Editions

Carl Murchison was a star scholar/impresario who edited the *Psychological Register*, founded important psychological journals, and wrote books on social psychology, politics, and the criminal mind. He compiled an assortment of handbooks, psychology texts, and autobiographies of renowned psychologists, and even ventured a book on psychic phenomena (Sir Arthur Conan Doyle and Harry Houdini were among the contributors). Murchison's initial *Handbook of Child Psychology* was published by a small university press (Clark University) in 1931, when the field itself was still in its infancy. Murchison wrote:

> Experimental psychology has had a much older scientific and academic status [than child psychology], but at the present time it is probable that much less money is being spent for pure research in the field of experimental psychology than is being

> spent in the field of child psychology. In spite of this obvious fact, many experimental psychologists continue to look upon the field of child psychology as a proper field of research for women and for men whose experimental masculinity is not of the maximum. This attitude of patronage is based almost entirely upon a blissful ignorance of what is going on in the tremendously virile field of child behavior. (Murchison, 1931, p. ix)

Murchison's masculine allusion is from another era; it might supply good material for a social history of gender stereotyping. That aside, Murchison was prescient in the task that he undertook and the way that he went about it. At the time this passage was written, developmental psychology was known only in Europe and in a few forward-looking U.S. labs and universities. Nevertheless, Murchison predicted the field's impending ascent: "The time is not far distant, if it is not already here, when nearly all competent psychologists will recognize that one-half of the whole field of psychology is involved in the problem of how the infant becomes an adult psychologically" (Murchison, 1931, p. x).

For this first 1931 *Handbook*, Murchison looked to Europe and to a handful of American research centers for child study—most prominently, Iowa, Minnesota, University of California at Berkeley, Columbia, Stanford, Yale, and Clark—many of which were at the time called *field stations*. Murchison's Europeans included a young "genetic epistemologist" named Jean Piaget, who, in an essay on "Children's Philosophies," cited data from his interviews with 60 Genevan children between the ages of 4 and 12 years. Piaget's chapter would provide U.S. readers with an introduction to his soon-to-be seminal research program on children's conceptions of the world. Another European, Charlotte Bühler, wrote a chapter on young children's social behavior. In her chapter, which still is fresh today, Bühler described intricate play and communication patterns among toddlers—patterns that developmental scientists would not rediscover until the late 1970s. Bühler also anticipated critiques of Piaget that were to be again launched during the sociolinguistics heyday of the 1970s:

> Piaget, in his studies on children's talk and reasoning, emphasizes that their talk is much more egocentric than social . . . that children from three to seven years accompany all their manipulations with talk which actually is not so much intercourse as monologue . . . [but] the special relationship of the child to each of the different members of the household is distinctly reflected in the respective conversations. (Bühler, 1931, p. 138)

Other Europeans include Anna Freud, who wrote on "The Psychoanalysis of the Child," and Kurt Lewin, who wrote on "Environmental Forces in Child Behavior and Development"—both would gain worldwide renown in coming years.

The Americans that Murchison chose were equally notable. Arnold Gesell wrote a nativistic account of his twin studies—an enterprise that remains familiar to us today—and Stanford's Lewis Terman wrote a comprehensive account of everything known about the "gifted child." Harold Jones described the developmental effects of birth order, Mary Cover Jones wrote about children's emotions, Florence Goodenough wrote about children's drawings, and Dorothea McCarthy wrote about language development. Vernon Jones's chapter on "children's morals" focused on the growth of *character*, a notion that was to become mostly lost to the field during the cognitive-developmental revolution, but that has reemerged in the past decade as a primary concern in the study of moral development.

Murchison's vision of child psychology included an examination of cultural differences as well. His *Handbook* presented to the scholarly world a young anthropologist named Margaret Mead, just back from her tours of Samoa and New Guinea. In this early essay, Mead wrote that her motivation in traveling to the South Seas was to discredit the claims that Piaget, Lévy-Bruhl, and other "structuralists" had made regarding what they called *animism* in young children's thinking. (Interestingly, about a third of Piaget's chapter in the same volume was dedicated to showing how Genevan children took years to outgrow their animism.) Mead reported data that she called "amazing": "In not one of the 32,000 drawings (by young 'primitive' children) was there a single case of personalization of animals, material phenomena, or inanimate objects" (Mead, 1931, p. 400). Mead parlayed these data into a tough-minded critique of Western psychology's ethnocentrism, making the point that animism and other beliefs are more likely to be culturally induced than intrinsic to early cognitive development. This is hardly an unfamiliar theme in contemporary psychology. Mead offered a research guide for developmental field workers in strange cultures, complete with methodological and practical advice, such as the following: (1) translate questions into native linguistic categories; (2) do not do controlled experiments; (3) do not try to do research that requires knowing the ages of subjects, which are usually unknowable; and (4) live next door to the children whom you are studying.

Despite the imposing roster of authors that Murchison had assembled for this original *Handbook of Child Psychology*, his achievement did not satisfy him for long. Barely 2 years later, Murchison put out a second edition, of which he wrote: "Within a period of slightly more than 2 years, this first revision bears scarcely any resemblance to the original *Handbook of Child Psychology*. This is due chiefly to the great expansion in the field during the past 3 years and partly to the improved insight of the editor" (Murchison, 1933, p. vii). The tradition that Murchison had brought to life was already developing.

Murchison saw fit to provide the following warning in his second edition: "There has been no attempt to simplify, condense, or to appeal to the immature mind. This volume is prepared specifically for the scholar, and its form is for his maximum convenience" (Murchison, 1933, p. vii). It is clear that Murchison, despite his impresario urges, was willing to sacrifice accessibility and textbook-level sales for scientific value in this instance.

Murchison exaggerated when he wrote that his second edition bore little resemblance to the first. Almost half of the chapters were virtually the same, with minor additions and updating. (For the record, though, despite Murchison's continued use of masculine phraseology, 10 of the 24 authors in the second edition were women.) Some of the authors whose original chapters were dropped were asked to write about new topics. So, for example, Goodenough wrote about mental testing rather than about children's drawings, and Gesell wrote a general chapter on maturational theory that went well beyond his own twin studies.

But Murchison also made certain abrupt changes. He dropped Anna Freud entirely, prompting the marginalization of psychoanalysis within U.S. academic psychology. Leonard Carmichael, later to play a pivotal role in the *Handbook* tradition, made his appearance as author of a major chapter (by far, the longest in the book) on prenatal and perinatal growth. Three other physiologically oriented chapters were added as well: one on neonatal motor behavior, one on visual–manual functions during the first 2 years of life, and one on physiological "appetites" such as hunger, rest, and sex. Combined with the Goodenough and Gesell shifts in focus, these additions gave the 1933 *Handbook* a more biological thrust, in keeping with Murchison's long-standing desire to display the hard-science backbone of the emerging field.

The Early Wiley Editions

Leonard Carmichael was president of Tufts University when he organized Wiley's first edition of the *Handbook*. The switch from a university press to the long-established commercial firm of John Wiley & Sons was commensurate with Carmichael's well-known ambition; and indeed Carmichael's effort was to become influential beyond anything that Murchison might have anticipated. (The switch to Wiley meant that what was to become known as Wiley's first edition was actually the *Handbook*'s third edition—and that what is now called the seventh edition is really the *Handbook*'s ninth.) Carmichael renamed the volume the *Manual of Child Psychology*, in keeping with Carmichael's intention of producing an "advanced scientific manual to bridge the gap between the excellent and varied elementary textbooks in this field and the scientific periodical literature" (Carmichael, 1946, p. vi).

Despite the small title change, there was significant continuity between the Murchison and Carmichael's editions. Carmichael acknowledged this in the prefaces to both of his editions, the 1946 and 1954 *Manuals*:

> Both as editor of the *Manual* and as the author of a special chapter, the writer is indebted . . . [for] extensive excerpts and the use of other materials previously published in the *Handbook of Child Psychology, Revised Edition*. (Carmichael, 1946, p. vi)
>
> Both the *Handbook of Child Psychology* and the *Handbook of Child Psychology, Revised Edition,* were edited by Dr. Carl Murchison. I wish to express here my profound appreciation for the pioneer work done by Dr. Murchison in producing these handbooks and other advanced books in psychology. The *Manual* owes much in spirit and content to the foresight and editorial skill of Dr. Murchison. (Carmichael, 1954, p. v)

The first quote comes from Carmichael's preface to the 1946 edition, the second from his preface to the 1954 edition. It is not known why Carmichael waited until the 1954 edition to add the personal tribute to Carl Murchison. Perhaps a careless typist dropped the laudatory passage from a handwritten version of the 1946 preface and its omission escaped Carmichael's notice. Or perhaps 8 years of further development increased Carmichael's generosity of spirit. It is also possible that Murchison or his family complained. In any case, Carmichael always acknowledged the roots of his *Manual*, if not always their original editor.

Leonard Carmichael took his 1946 *Manual* in the same direction established by Murchison back in 1931 and 1933. First, Carmichael appropriated five Murchison chapters on biological or experimental topics such as physiological growth, scientific methods, and mental testing. Second, he added three new biologically oriented chapters on animal infancy, on physical growth, and on motor and behavioral maturation (a tour de force by Myrtle McGraw that instantly made Gesell's chapter in the same volume obsolete). Third, he commissioned Wayne Dennis to write a chapter that focused exclusively on physiological changes associated with puberty. Fourth, Carmichael dropped

Piaget and Bühler, who, like Anna Freud years earlier, were becoming out of step with then-current experimental trends in U.S. psychology.

The five Murchison chapters on social and cultural influences in development were the ones Carmichael retained: two chapters on environmental forces on the child (by Kurt Lewin and by Harold Jones), Dorothea McCarthy's chapter on children's language, Vernon Jones's chapter on children's morality (now entitled "Character Development—An Objective Approach"), and Margaret Mead's chapter on "primitive" children (now enhanced by several spectacular photos of mothers and children from exotic cultures around the world). Carmichael also stuck with three other psychologically oriented Murchison topics (emotional development, gifted children, and sex differences), but he selected new authors to cover them.

Carmichael's second and final *Manual* in 1954 was very close in structure and content to his 1946 *Manual*. Carmichael again retained the heart of Murchison's original vision, many of Murchison's original authors and chapter topics, and some of the same material that dated all the way back to the 1931 *Handbook*. Not surprisingly, the chapters that were closest to Carmichael's own interests received the most significant updating. As Murchison had done, Carmichael leaned toward the biological and physiological whenever possible. He clearly favored experimental treatments of psychological processes. Yet Carmichael still retained the social, cultural, and psychological analyses by Lewin, Mead, McCarthy, Terman, Harold Jones, and Vernon Jones, even going so far as to add a new chapter on social development by Harold and Gladys Anderson and a new chapter on emotional development by Arthur Jersild.

In 1946, when Carmichael had finished his first *Manual*, he had complained that "this book has been a difficult and expensive one to produce, especially under wartime conditions" (Carmichael, 1946, p. vii). But the project had been well worth the effort. The *Manual* quickly became the bible of graduate training and scholarly work in the field, available virtually everywhere that human development was studied. Eight years later, now head of the Smithsonian Institution, Carmichael wrote, in the preface to his 1954 edition: "The favorable reception that the first edition received not only in America but all over the world is indicative of the growing importance of the study of the phenomena of the growth and development of the child" (Carmichael, 1954, p. vii).

The Murchison and Carmichael volumes make fascinating reading, even today. The perennial themes of the field were always there: the nature/nurture debate; the generalizations of universalists opposed by the particularizations of contextualists; the alternating emphases on continuities and discontinuities during ontogenesis; and the standard categories of maturation, learning, locomotor activity, perception, cognition, language, emotion, conduct, morality, and culture—all separated for the sake of analysis, yet, as authors throughout each of the volumes acknowledged, all somehow joined in the dynamic mix of human development.

These things have not changed. Yet much in the early *Handbooks*/*Manuals* is now irrevocably dated. Long lists of children's dietary preferences, sleeping patterns, elimination habits, toys, and somatic types look quaint and pointless through today's lenses. The chapters on children's thought and language were done prior to the great contemporary breakthroughs in neurology and brain/behavior research, and they show it. The chapters on social and emotional development were ignorant of the processes of social influence and self-regulation that soon would be revealed through attribution research and other studies in social psychology. Terms such as *cognitive neuroscience*, *neuronal networks*, *behavior genetics*, *social cognition*, *dynamical systems*, *information processing*, and *developmental psychopathology* were unknown. Margaret Mead's rendition of the primitive child stands as a weak straw in comparison to the wealth of cross-cultural knowledge available in today's "cultural psychology."

Most tellingly, the assortments of odd facts and normative trends were tied together by very little theory throughout the Carmichael chapters. It was as if, in the exhilaration of discovery at the frontiers of a new field, all the facts looked interesting in and of themselves. That is what makes so much of the material seem odd and arbitrary. It is hard to know what to make of the lists of facts, where to place them, which ones were worth keeping track of and which ones are expendable. Not surprisingly, the bulk of the data presented in the Carmichael manuals seems not only outdated by today's standards but, worse, irrelevant.

Carmichael's second and final *Manual* had a long life: Not until 1970 did Wiley bring out a third edition. Carmichael was retired by then, but he still had a keen interest in the book. At his insistence, his own name became part of the title of Wiley's third edition: The edition was called, improbably, *Carmichael's Manual of*

Child Psychology, even though it had a new editor and an entirely new cast of authors and advisors.

Mussen's Transformation

Paul Mussen was editor of the 1970 edition; once again the project flourished. Now a two-volume set, the 1970 third edition swept the social sciences, generating widespread interest in developmental psychology and its related disciplines. Rarely had a scholarly compendium become both so dominant in its own field and so familiar in related disciplines. The volumes became essential sources for graduate students and advanced scholars alike. Publishers referred to Mussen's 1970 *Carmichael's Manual* as the standard against which other scientific handbooks were compared.

By 1970, the importance of theory for understanding human development had become apparent. Looking back on Carmichael's last *Manual*, Mussen wrote: "The 1954 edition of this Manual had only one theoretical chapter, and that was concerned with Lewinian theory which, so far as we can see, has not had a significant lasting impact on developmental psychology" (Mussen, 1970, p. x). The intervening years had seen a turning away from the norm of psychological research once fondly referred to as "dust-bowl empiricism."

The 1970 handbook—still called, as noted above, *Carmichael's Manual*—had an entirely new look. The two-volume set carried only one chapter from the earlier books, Carmichael's updated version of his own long chapter on the "Onset and Early Development of Behavior," which had made its appearance under a different title way back in Murchison's 1933 edition. Otherwise, as Mussen wrote in his preface, "It should be clear from the outset . . . that the present volumes are not, in any sense, a *revision* of the earlier editions; this is a completely new *Manual*" (Mussen, 1970, p. x).

And it was. In comparison to Carmichael's last edition 16 years earlier, the scope, variety, and theoretical depth of the Mussen volumes were astonishing. The field had blossomed, and the new *Manual* showcased many of the new bouquets that were being produced. The biological perspective was still strong, grounded by chapters on physical growth (by J. M. Tanner) and physiological development (by Dorothy Eichorn), and by Carmichael's revised chapter (now made more elegant by some excerpts from Greek philosophy and modern poetry). But two other cousins of biology also were represented, in a chapter on ethology by Eckhard Hess, and a chapter on behavior genetics by Gerald McClearn. These chapters were to define the major directions of biological research in the field for at least the next three decades.

As for theory, Mussen's *Handbook* was thoroughly permeated with it. Much of the theorizing was organized around the approaches that, in 1970, were known as the "three grand systems": (1) Piaget's cognitive-developmentalism, (2) psychoanalysis, and (3) learning theory. Piaget was given the most extensive treatment. He himself reappeared in this *Manual*, authoring a comprehensive (some say definitive) statement of his own theory, which now bore little resemblance to his 1931/1933 catalog of children's intriguing verbal expressions. In addition, chapters by John Flavell, by David Berlyne, by Martin Hoffman, and by William Kessen, Marshall Haith, and Philip Salapatek, all gave major treatments to one or another aspect of Piaget's body of work.

Several other theoretical approaches were represented in the 1970 *Manual* as well. Herbert and Anne Pick explicated Gibsonian theory in a chapter on sensation and perception, Jonas Langer wrote a chapter on Werner's organismic theory, David McNeill wrote a Chomskian account of language development, and Robert LeVine wrote an early version of what was to become "culture theory."

With its increased emphasis on theory, the 1970 *Manual* explored in depth a matter that had been all but neglected in the *Manual*'s previous versions: the mechanisms of change that could account for, to use Murchison's old phrase, "the problem of how the infant becomes an adult psychologically." In the process, old questions such as the relative importance of nature versus nurture were revisited, but with far more sophisticated conceptual and methodological tools.

Beyond theory building, the 1970 *Manual* addressed an array of new topics and featured new contributors: peer interaction (Willard Hartup), attachment (Eleanor Maccoby and John Masters), aggression (Seymour Feshbach), individual differences (Jerome Kagan and Nathan Kogan), and creativity (Michael Wallach). All of these areas of interest are still very much with us.

Wiley's fourth edition, published in 1983, was redesignated to become once again the *Handbook of Child Psychology*. By then, Carmichael had passed away. The set of books, now expanded to four volumes, became widely referred to in the field as "the Mussen handbook."

If the 1970 *Manual* reflected a blossoming of the field's plantings, the 1983 *Handbook* reflected a field whose ground cover had spread beyond any boundaries that could have been previously anticipated. New growth had sprouted in literally dozens of separate locations. A French garden, with its overarching designs and tidy compartments, had turned into an English garden, unruly but often glorious in its profusion. Mussen's two-volume *Carmichael's Manual* had now become the four-volume Mussen *Handbook*, with a page-count increase that came close to tripling the 1970 edition.

The grand old theories were breaking down. Piaget was still represented in 1983 by his 1970 piece, but his influence was on the wane throughout other chapters. Learning theory and psychoanalysis were scarcely mentioned. Yet the early theorizing had left its mark, in vestiges that were apparent in new approaches, and in the evident conceptual sophistication with which authors treated their material. There was no return to dust-bowl empiricism. Instead, a variety of classical and innovative ideas were coexisting: ethology, neurobiology, information processing, attribution theory, cultural approaches, communications theory, behavioral genetics, sensory-perception models, psycholinguistics, sociolinguistics, discontinuous stage theories, and continuous memory theories all took their places, with none quite on center stage. Research topics now ranged from children's play to brain lateralization, from children's family life to the influences of school, day care, and disadvantageous risk factors. There also was coverage of the burgeoning attempts to use developmental theory as a basis for clinical and educational interventions. The interventions usually were described at the end of chapters that had discussed the research relevant to the particular intervention efforts, rather than in whole chapters dedicated specifically to issues of practice.

The Fifth and Sixth Editions

There was a long hiatus between the fourth edition in 1983 and the fifth edition, which was not to appear until 1998. The fifth edition fell to me to organize, and this was not at my own initiative. Two Wiley editors—Herb Reich, a legendary figure in academic publishing, and Kelly Franklin, an up-and-coming innovative star—approached me about reviving the project, which they correctly believed had a vital tradition behind it, but that they also believed was in danger of falling by the wayside. I had been editing the Jossey-Bass series that I founded, *New Directions for Child and Adolescent Development*, and the two Wiley editors believed that if we could impart a "new directions" tone to a new *Handbook* edition, the project could regain its past appeal. I agreed, and I proposed that this next edition be organized in an intuitively simple four-volume design: a theory volume, a volume on cognitive and linguistic development, a volume on social and personality development, and a volume on child psychology in practice. When Wiley accepted my proposal, my first action as general editor was to invite an incredibly talented group of volume editors—Nancy Eisenberg, Deanna Kuhn, Richard Lerner, Anne Renninger, Robert Siegler, and Irving Sigel—to collaborate on the selection and editing of chapters. The edition was to become the result of a partnership among all the editors; and the same team collaborated again to produce the sixth edition of the *Handbook* in 2006, with Richard Lerner assuming an added role as my co-editor-in-chief. The 2006 edition closely followed the model of the 1998 edition, with some important additions, such as chapters on the positive youth development approach, on artistic development, and on religiosity and faith in human development.

Our team approached the 1998 and 2006 editions with the same purpose that Murchison, Carmichael, and Mussen before us had shared: "to provide," as Mussen wrote, "a comprehensive and accurate picture of the current state of knowledge—the major systematic thinking and research—in the most important research areas of the psychology of human development" (Mussen, 1983, p. vii). We assumed that the *Handbook* should be aimed "specifically for the scholar," as Murchison declared, and that it should have the character of an "advanced text," as Carmichael defined it. We expected that our readership would be interdisciplinary, given the tendency of scholars in human development to do work across the fields of psychology, cognitive science, neuroscience, history, linguistics, sociology, anthropology, education, and psychiatry. In Volume 4, we hoped that research-oriented practitioners would be among the scholars for whom the *Handbook* had value.

By the time of the 1998 and 2006 editions of the *Handbook*, powerful theoretical models and approaches—not quite unified theories like the "three grand systems" that had marked earlier editions—were again organizing much of the field's research. There was great variety in these models and approaches, and each was drawing together significant clusters of work. Among the powerful models and approaches prominent in the 1998 and 2006 *Handbooks* were the dynamic system theories, life-span and life-course approaches, cognitive science and neural models, the behavior genetics approach, person–context interaction theories, action theories, culture theory, ecological models, and neo-Piagetian and Vygotskian models. Although some of these models and approaches had been in the making for some time, by the end of the 20th century they had fully come into their own: researchers were drawing on them more directly, taking their implied assumptions and hypotheses seriously, using them with specificity and control, and exploiting all of their implications for practice.

The Present

The seventh Wiley edition of the *Handbook* continues and strengthens the trends toward specific theoretical analyses of multiple developmental processes, even highlighting this focus by including the term "processes" in two of the four volume's titles, a designation new to the *Handbook*'s history. The volumes present a rich mix of classic and contemporary theoretical perspectives, but I believe it is fair to say that the dominant views throughout are marked by an emphasis on the dynamic interplay of all relational developmental systems that co-act across the life span, incorporating the range of biological, perceptual, cognitive, linguistic, emotional, social, cultural, and ecological levels of analysis. At the same time, the chapters together consider a vast array of topics and problems, ranging from sexuality and religiosity to law, medicine, war, poverty, and education. The emerging world of digital experience is also given a fuller treatment than in any previous *Handbook* edition, commensurate with our present-day technological revolution. All this gives this seventh edition of the *Handbook* a timely feel.

The present *Handbook*'s combination of theoretical and methodological sophistication and topical timeliness resolves an old tension evident in the *Handbook*'s prior cycling between theoretical-methodological and problem-centered approaches. My impression is that, rather than leaning in one direction or the other, this *Handbook* manages to be *both* more theoretical-methodological *and* more topical than the previous editions. As a developmental phenomenon, this puts the *Handbook* in a class of organisms that develop toward adaptive complexity rather than toward one or another contrasting polar dimension.

I wonder what Carl Murchison would think of the grown-up child that he spawned before the field of human development had become a mainstream endeavor in research and teaching around the world. Murchison's idiosyncratic assortment of fascinating studies bears little resemblance to the imposing compendium of solidly grounded knowledge in the present *Handbook*. Yet each step along the 83-year way followed directly from what had gone before, with only occasional departures or additions that may have seemed more like gradual revisions at the time. Over the long haul, the change in the *Handbook* has been dramatic, but the change process itself has been marked by substantial continuities. If Murchison were to come back to life today, he may be astonished by the size and reach of his child, but I believe he would recognize it—and proudly so.

Preface

Across its editions, the title of this handbook has changed, now, five times: *A Handbook of Child Psychology*; *Manual of Child Psychology*; *Carmichael's Manual of Child Psychology*; *Handbook of Child Psychology*; and *Handbook of Child Psychology and Developmental Science*. As well, the field of scholarship represented in the *Handbook* has also been labeled differently: child psychology, child development, developmental psychology, and, today, developmental science. The rationales for the use of these labels involve historically changing ontological and epistemological assumptions.

During the latter years of the 19th century and for much of the past two thirds of the 20th century, and perhaps especially in the United States and Western Europe, the study of human development was a visible subfield of psychology (see Cairns & Cairns, 2006, for a review; see also Damon, in the Foreword to this edition of the *Handbook*). In this literature, and its antecedents in philosophy (see Baltes, 1983; Overton, 2006 for reviews), development was envisioned to be a life-span phenomenon (e.g., Erikson, 1959; Hall, 1904, 1922). However, the majority of the scholarship about human development in the United States and Western Europe was focused on the early years of life (infancy and childhood) (e.g., Binet & Simon, 1905a, 1905b; Gesell, 1929; Piaget, 1923; Preyer, 1882; Terman, 1925).

As a consequence, across this historical period, child psychology emerged as a specific subarea of psychology, spurred on by the research of scientists studying this age period; by the founding of several university centers and institutes devoted to the study of children (e.g., in Iowa, involving scholars such as Boyd R. McCandless; and in Minnesota, involving scholars such as Dale B. Harris); and by the work in the field of home economics, which was focused on children (and families), that was occurring within land-grant universities in the United States (Cairns & Cairns, 2006; Lerner & Simon, 1998). At the same time, many of the contributors to child psychology also created a purportedly multidisciplinary instantiation of scholarship devoted to the study of children, that is, child *development*. In 1933, the Society for Research in Child Development (SRCD) was founded to promote such a multidisciplinary approach to the study of children (and to the application of child development research) but, in actuality, SRCD was from its outset and remains today dominated by scholars whose training is in psychology. It is not surprising, then, that, whether labeled child psychology or child development, the study of the early portion of the life span was approached in very similar ways by scholars studying children.

At its inception, the child development (or child psychology) field was framed by Cartesian-split conceptions of change across ontogeny and by reductionist accounts of the bases of human development (Overton, 2013a, 2013b; Overton & Müller, 2013). The core conceptual issues of child development were the nature-nurture, the continuity-discontinuity, and the stability-instability controversies (Lerner, 2002), and "solutions" to these debates involved, for instance, reducing development to being a phenomenon explained by either nature variables (genes or maturation; e.g., Hamburger, 1957) or by operant or respondent stimulus-response connections (e.g., Bijou & Baer, 1961). This split, reductionist ontology about development meant that the epistemological route to learning about the basis of development was to identify the essential (nature *or* nurture) explanatory variable(s). Accordingly, the study of development was also marked by variable-centered analyses, as exemplified by the tables of contents of the editions of this *Handbook* published during this period (e.g., Carmichael, 1946, 1954; Murchison, 1931, 1933; Mussen, 1970, 1983; see also Damon, in the Foreword to this edition), as well as by the tables of contents of other major compendiums published during this period (e.g., Reese & Lipsitt, 1970; Stevenson, 1963).

However, as early as 1970, Mussen, the editor of the third edition of the *Handbook* published by Wiley, pointed to the potential meaning of a growing interest among some scientists to move away from a reductionist approach, involving descriptions of the variables purportedly accounting for ontogenetic structure and function, and toward an approach that viewed development as involving interrelations among variables (from multiple levels of organization). Mussen (1970) said that "the major contemporary empirical and theoretical emphases in the field of developmental psychology . . . seem to be on *explanations* of the psychological changes that occur, the mechanisms and processes accounting for growth and development" (p. vii). By pointing to the interest in change processes, Mussen was implying that we needed something more to explain the process of development, unless we believed that nature or nurture variables explained themselves in structure or function.

That "something more" was already emerging within the study of development—for instance, at a series of conferences held at the University of West Virginia in the late 1960s and early 1970s about the nature and implications of a life-span view of human development (e.g., Baltes & Schaie, 1974; Nesselroade & Reese, 1973; Schaie, 1970). These West Virginia University conferences, the edited books that derived from them, and the associated articles published in both theoretically oriented journals (e.g., *Human Development*, *Developmental Review*) and empirically oriented journals (e.g., *Child Development*, *Developmental Psychology*, *International Journal of Behavioral Development*, and *Journal of Research on Adolescence*) discussed the philosophical, theoretical, and methodological problems associated with split/reductionist accounts of development. In addition, they introduced ideas about the potential for plasticity (i.e., the potential for systematic change) in development across life, and pointed to the role of potentially mutually influential relations between individuals and their normative age- and history-graded experiences and, as well, their non-normative experiences, in instantiating this plasticity. Finally, they underscored the fundamental necessity of studying intraindividual changes (and interindividual differences in intraindividual changes) involved in these individual-context relations in order to describe, explain, and optimize the course of human development. These ideas would act synergistically with growing scholarship in Europe that provided theory and data fostering a "reversal" of focus for developmental inquiry—from variable-centered to person-centered approaches to human development (e.g., Magnusson, 1999). These ideas were also synergistic with work in sociology that demonstrated that the course of life was shaped by historical events that one encountered at particular times and in particular places (Elder, 1974).

When taken together, the dimensions of human development scholarship that crystallized and coalesced between the 1970s and 1990s pointed to the vacuity of split/reductionist models (and their attendant methodologies). In turn, these ideas underscored the importance of time and place, person–context relations, plasticity, and the need for a focus on longitudinal (change-sensitive) methods to study intraindividual change across life and, as well, the diverse life paths of these intraindividual changes. These ideas, when considered together, presented a major challenge to the then-dominant metatheoretical and theoretical ideas in the field. Indeed, the new ideas about human development that found an impetus at the West Virginia University conferences grew in influence across the field and together, across the last three decades of the 20th century, created a Kuhn-like (Kuhn, 1962) paradigm shift (Overton, 2013a, 2013b; Overton & Lerner, 2012).

The shift in conceptual and empirical foci attendant to this paradigm shift was multifaceted. As I noted, Mussen (1970) observed that the field had been primarily descriptive and normative (Mussen, 1970), with the norms usually generated by studying only a small portion of humanity (i.e., European American middle-class children in the main; Hagen, Paul, Gibb, & Wolters, 1990). In addition, the "paradigm" framing this research was as likely (if not more likely) to use cross-sectional research to study development as it was to employ longitudinal methods. The use of cross-sectional designs (and data analysis methods, e.g., R-technique analyses; e.g., see Cattell, 1966, and for more current versions of these ideas see Molenaar & Nesselroade, 2014; Nesselroade & Molenaar, 2010) was predicated on the assumption of the applicability of the ergodic theorem (e.g., Molenaar, 2007; Molenaar & Nesselroade, 2014). The ergodic theorem holds that data sets are marked by: (a) homogeneity across individuals in a three-dimensional matrix that involves persons, variables, and time; and (b) stationarity of individuals' scores on variables across time (Molenaar, 2007).

In contrast, the approach to the study of human development that was evidenced by the life-span and life-course perspectives involved research that documented the presence of systematic variation in trajectories of intraindividual change, both within and across people. As such, the assumptions of homogeneity and stationarity of the ergodic theorem were rejected and developmental scientists placed greater importance on not only person-centered research but, as well, change-sensitive methodologies for both descriptive and explanatory efforts (Molenaar, 2007, 2010). What was distinctive about this research, however, was that it was both derived from and promoted diverse attempts to create theoretical models of human development associated with an emergent, relational paradigm (Overton, 2013a, 2013b; Overton & Müller, 2013), a conception that focused on the individual and on the course of his or her trajectories of reciprocal bidirectional relations with the multiple levels of the ecology of human development (represented as individual ←→ context relations). Examples were the bioecological model of Bronfenbrenner (e.g., 1979), the dialectical model of Riegel (e.g., 1975), the developmental contextual approach of Lerner (1982), the developmental systems concepts of Gottlieb (1997, 1998) and of Ford and Lerner (1992), the model of individual development proposed by Magnusson (1999), and the embodiment model presented by Overton (1994, 1997).

In short, these "strands" of theory merged in the 1970s, 1980s, and 1990s and shifted the predominant developmental "paradigm" away from reductionism, Cartesian-split conceptions, and methods predicated on ergodicity, and created a focus on models emphasizing the mutually influential relations between individuals and their contexts, on person ←→ context relations (Cairns & Cairns, 2006; Lerner, 2006). Such models involved the belief that time and place matter in regard to shaping the course of life (Bronfenbrenner, 2005; Elder, 1998; Elder & Shanahan, 2006), and emphasized that the scientific study of human development needed to study both the individual and the diversity of people in order to understand human development.

In sum, the relational paradigm that framed conceptions of the bases of human development was associated with the generation of several, relational developmental systems models of human development (Lerner, 2006; Lerner & Overton, 2008; Overton, 2013a, 2013b; Overton & Müller, 2013), conceptions that were used to guide the study of individuals, contexts, and their dynamic interrelations across the life span. Table P.1 presents the defining features of such models.

This multilevel and multidisciplinary approach to studying human development was the basis of the view that the field was best represented by the term developmental science. In turn, given this synergistic history of the links among theory, method, and research, it is not surprising that, at this writing, relational developmental systems theories are at the forefront of the study of human development (e.g., Lerner, 2012; Lerner & Benson, 2013a, 2013b; Overton & Lerner, 2012). Indeed, the fifth edition of the Wiley *Handbook* (Damon, 1998) had pointed to the growing prominence of such approaches to the study of human development and, in turn, the sixth edition (Damon & Lerner, 2006) noted that models derived from relational developmental systems thinking, and from a relational meta-model more generally, had become the predominant conceptual lens for the cutting-edge theory and methodological innovations guiding research in human development across the life span.

In the present seventh edition of the Wiley *Handbook,* this pathway of scholarly progression is continued. Key examples of relational developmental systems models are found across all four volumes of this seventh edition of the *Handbook*. Moreover, accompanying the use of these models are new methodologies to study individuals, to therefore capture the nonergodic character of human development and, as well, to study the developmental system within which individual ←→ context relations are embedded. Examples of these methods are also a prominent contribution of chapters in this edition of the *Handbook*.

Another key feature of the chapters in this edition of the *Handbook* is the applied use of relational developmental systems theoretical models. Based on ideas about the relative plasticity of individual ←→ context relations, this use of theory overcomes yet another traditional split within the study of human development—between theory-predicated explanations of human development and applications aimed at enhancing human development (Baltes, Reese, & Nesselroade, 1977; Lerner, 2002, 2012). For instance, to test explanations of developmental change, scholars need to institute or evaluate actions that are aimed at altering the bidirectional relations theoretically expected to produce changes in behavior and development. These actions must necessarily be embedded in the actual ecology of human development in order to have generalizability to the lived experiences of individuals (Lerner & Callina, 2014) and, as such, they constitute intervention (applied) research; at the same time, such research tests basic explanatory processes of human development. As such, in contemporary developmental science any splits between basic and applied research are regarded as anachronistic representations of the reductionist, Cartesian approaches of earlier eras.

TABLE P.1 Defining Features of the Relational Developmental Systems Paradigm

Relational Metatheory
Predicated on a philosophical perspective that transcends Cartesian dualism and atomism, theories derived from the relational developmental systems paradigm are framed by a relational metatheory for human development. This focus includes an emphasis on process and a rejection of all splits between components of the ecology of human development (e.g., between nature- and nurture-based variables, between continuity and discontinuity, and between stability and instability). Holistic syntheses replace dichotomies, as well as reductionist partitions of the developing relational system, through the integration of three relational moments of analysis: the identity of opposites, the opposites of identity, and the syntheses of wholes. Deriving from the relational metatheory, relational developmental systems posit the organism as an inherently active, self-creating, self-organizing, and self-regulating nonlinear complex adaptive system, which develops through embodied activities and actions, as they co-act with a lived world of physical and sociocultural objects.

The Integration of Levels of Organization
Relational thinking, with the rejection of Cartesian splits, is associated with the idea that all levels of organization within the ecology of human development are integrated or fused. These levels range from the biological and physiological through the cultural and historical.

Developmental Regulation Across Ontogeny Involves Mutually Influential Individual ←→ Context Relations
As a consequence of the integration of levels, the regulation of development occurs through mutually influential connections among all levels of the developing relational system, ranging from genes and cell physiology through individual mental and behavioral functioning to society, culture, the designed and natural ecology, and, ultimately, history. These mutually influential relations may be represented generically as Level 1 ←→ Level 2 (e.g., Family ←→ Community), and in the case of ontogeny may be represented as individual ←→ context.

Integrated Actions, Individual ←→ Context Relations, Are the Basic Unit of Analysis Within Human Development

The character of developmental regulation means that the integration of actions—of the individual on the context and of the multiple levels of the context on the individual (individual ←→ context)—constitute the fundamental unit of analysis in the study of the basic process of human development.

Temporality and Plasticity in Human Development
As a consequence of the fusion of the historical level of analysis—and therefore temporality—in the levels of organization comprising the ecology of human development, the developing relational system is characterized by the potential for systematic change, by plasticity. Observed trajectories of intraindividual change may vary across time and place as a consequence of such plasticity.

Relative Plasticity
Developmental regulation may both facilitate and constrain opportunities for change. Thus, change in individual ←→ context relations is not limitless, and the magnitude of plasticity (the probability of change in a developmental trajectory occurring in relation to variation in contextual conditions) may vary across the life span and history. Nevertheless, the potential for plasticity at both individual and contextual levels constitutes a fundamental strength of all human development.

Intraindividual Change, Interindividual Differences in Intraindividual Change, and the Fundamental Substantive Significance of Diversity
The combinations of variables across the integrated levels of organization within the developmental system that provide the basis of the developmental process will vary at least in part across individuals and groups. This diversity is systematic and lawfully produced by idiographic, group differential, and generic (nomothetic) phenomena. The range of interindividual differences in intraindividual change observed at any point in time is evidence of the plasticity of the developmental system, and gives the study of diversity fundamental substantive significance for the description, explanation, and optimization of human development.

Interdisciplinarity and the Need for Change-Sensitive Methodologies
The integrated levels of organization comprising the developmental system require collaborative analyses by scholars from multiple disciplines. Interdisciplinary knowledge is a central goal. The temporal embeddedness and resulting plasticity of the developing system requires that research designs, methods of observation and measurement, and procedures for data analysis be change- and process-sensitive and able to integrate trajectories of change at multiple levels of analysis.

Optimism, the Application of Developmental Science, and the Promotion of Positive Human Development
The potential for and instantiations of plasticity legitimate an optimistic and proactive search for characteristics of individuals and of their ecologies that, together, can be arrayed to promote positive human development across life. Through the application of developmental science in planned attempts (interventions) to enhance (e.g., through social policies or community-based programs) the character of humans' developmental trajectories, the promotion of positive human development may be achieved by aligning the strengths (operationalized as the potentials for positive change) of individuals and contexts.

Source: Based on Lerner (2006) and Overton (2013a, 2013b).

In short, the application of developmental science (optimization) is a co-equal partner with description and explanation within developmental science as it now exists. Once again, the chapters in this edition of the *Handbook* provide rich illustrations of the integrated foci of developmental scholarship on the description, explanation, and optimization of human development across the life span.

Together, the metatheoretical, theoretical, methodological, and applied features of contemporary developmental science that are represented across the four volumes of this seventh edition of the *Handbook* allow this reference work to continue its history of marking the best scholarship in our field and of specifying the key directions for scientific progress. These contributions of the *Handbook* emerge from the intellectual abilities and wisdom of the volume editors and the authors of the chapters involved in this edition. I am enormously indebted to Willis F. Overton and Peter C. M. Molenaar, editors of Volume 1, Lynn S. Liben and Ulrich Müller, editors of Volume 2, Michael E. Lamb, editor of Volume 3, and Marc H. Bornstein and Tama Leventhal, editors of Volume 4, for their broad and deeply erudite scholarship, vision, and leadership. Their knowledge and skills created and shaped the volumes they edited.

The volume editors and I are also profoundly grateful to the authors of the chapters in this edition. Their singular levels of expertise and mastery of their areas of scholarship are richly and compellingly conveyed in this edition. The work of these colleagues represents the best scholarship in developmental science, and we are deeply grateful for their truly field-defining contributions to this edition.

I wish to express particular gratitude to William Damon, for his thoughtful, illuminating, and generous Foreword to this edition of the *Handbook*. Professor Damon was the editor of the fifth and sixth editions of the *Handbook* and, as well, for five decades he has been a visionary intellectual leader of the field that we now term developmental science. He stands as a model of scholarly excellence, erudition, and wisdom, and I am deeply grateful to have his ideas frame the volumes in this edition.

In addition, as scholars contributing to reference works of the scope of the *Handbook* realize, their work cannot be crystallized, completed, or disseminated without the efforts of the professional editors and publishers who work with them. The editors and authors of the seventh edition have been exceedingly fortunate to have had superb support and, as well, collegial guidance, from our editors in the Institute for Applied Research in Youth Development at Tufts and at John Wiley & Sons.

Jarrett M. Lerner, the managing editor in the Institute at Tufts, was involved with the seventh edition since its inception. He has organized and advanced every facet of the editorial and production process. His professionalism, knowledge, organizational capacities, efficiency, commitment, and indefatigable, positive spirit were vital to the existence, and to any archival contributions, of this edition.

In addition, Patricia A. Rossi, the executive editor for psychology at Wiley, was a masterful and wise guide and catalyst for the seventh edition, again from its inception. Her deep knowledge of the scholarly qualities that are required to produce a reference work that will set the standard of excellence for its field, and her enthusiasm and unflagging commitment to enabling editors and authors to attain this standard, were essential contributions to the development and completion of this edition. She and her colleagues at Wiley, who enacted a superbly organized, efficient, and invariantly high-quality production process, have enabled the scholarship of the authors and editors to be superbly presented to our readership.

Across the several years that I have worked on this edition of the *Handbook,* I have been blessed by having support, stimulation, and feedback from my colleagues in the Eliot-Pearson Department of Child Study and Human Development, and from my colleagues, staff, and students at the Institute for Applied Research in Youth Development, both at Tufts University. I am grateful for their inspiration and collaboration. I am also extremely fortunate to have had support for my scholarly work provided by the John Templeton Foundation, the Thrive Foundation for Youth, the Poses Family Foundation, the National 4-H Council, the Altria Group, Inc., the Bertelsmann Foundation, the National Science Foundation, the Gary and Joan Bergstrom family, and several individuals who have made private donations to the Institute to support its research. I thank them for their faith in me and for honoring me with their support. My family has been a vital resource of emotional and intellectual support—encouraging me when things seemed overwhelming and grounding me when, on rare occasions, things seemed to be going exceedingly well. My wife, Jacqueline Lerner, merits special recognition—as my life partner, as my chief scholarly collaborator, and my muse. I would have accomplished nothing in my career or my life without her.

Finally, the volume editors and I want to thank the colleagues and students who will read the chapters in this edition of the *Handbook* and who, we hope, will gain from the work presented across its four volumes. Many of these colleagues will find their contributions to developmental science represented in the pages of this edition. We thank them for these contributions. As well, we are grateful to them for another reason. Many of these colleagues will also be training the next generation of developmental scientists, young scholars whom we hope will be inspired by this edition of the *Handbook* to undertake scholarship that will make subsequent editions even better and more useful.

We wish these younger scientists well in this intellectual journey. As such, with the hope that their scientific aspirations will be realized, we dedicate this seventh edition of the *Handbook of Child Psychology and Developmental Science* to them.

Volume 1 Preface

The chapters in this volume document conceptual and methodological advances both in theory and in empirical tools of design and analysis that enable developmental processes and the mutually co-acting relations between individual and context to be better understood and better investigated. The chapters also demonstrate that a paradigm shift has occurred within developmental science. The shift has been from a Cartesian-Split-Mechanistic scientific research paradigm to a Process-Relational and Relational-Developmental-Systems scientific research paradigm. The new paradigm forms the conceptual framework for various relational developmental systems models and theories of the development of living organisms broadly and human development specifically. The shift has also opened the path for the construction of important methodological innovations. Indeed, the use of relational developmental systems models in research employing these methodological innovations has advanced knowledge of the holistic, self-creating (enactive), self-organizing, embodied development of the person in individual ←→ context relations, which constitutes the fundamental processes of human development.

We believe that the scholarship within this volume and, as well, across the four volumes of this edition, attest to the fact that we are in the midst of a very exciting period within the development of developmental science. The paradigm shift that we are witnessing involves increasingly greater understanding of how to think about and how to describe, explain, and optimize the course of human life for diverse individuals living within diverse contexts. The years ahead in developmental science hold great promise for profound advances in knowledge about the bases, and evidence for enhancing, human development across the life span.

We are very grateful for the collaborations we have had across the years we have devoted to editing this volume. Most important, we are grateful for the scholarly excellence and unflagging spirit of collegiality of the contributors to this volume. Their commitment to producing the best in developmental science and their goodwill and persistence in accommodating requests for revision enabled us to collaboratively produce a volume that both enhances the seventh edition of this *Handbook* and advances developmental science.

We are also grateful to Richard M. Lerner, the editor-in-chief of this edition and, as well, the remarkably skilled, adept, and productive leader of Rich's editorial staff at Tufts University, Jarrett Lerner. Their work helped transform our goals for this volume into reality.

CHAPTER 1

Concepts, Theory, and Method in Developmental Science

A View of the Issues

WILLIS F. OVERTON and PETER C. M. MOLENAAR

THE PLAN OF THIS VOLUME 3
CONCLUSIONS 8
REFERENCES 8

The study of the development of living organisms generally, and humans, in particular, has itself developed and significantly so, as compared to past editions of this *Handbook*. For example, across just these early years of the 21st century, scholarship in developmental science has involved several important philosophical, theoretical, and methodological changes and, together, these changes constitute a paradigm shift for the field (Overton & Lerner, 2012).

The outcome of this paradigm shift involves the reanalysis and rethinking of a number of issues in the field, followed by the generation of new data, and new powerful methodological tools. One of the issues affected by the paradigm shift is the hoary nature–nurture debate (i.e., the issue of inheritance). Here, advances in epigenetics and a broader understanding of the genome itself have made the route from genotype to phenotype complex to the point that the classic Cartesian position, which claims that who we are and what we become to be is a simple additive function of gene × environment interactions has become highly untenable (see Bateson, Chapter 6, this *Handbook*, this volume; Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume; Overton, Chapter 2, this *Handbook*, this volume). A second broad issue affected by the paradigm shift entails the relation of evolution and ontogenetic development (see Bateson, Chapter 6, this *Handbook*, this volume; Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume; Overton, Chapter 2, this *Handbook*, this volume). Here, the field is rapidly moving away from implications of the classic *Modern Synthesis* (i.e., the integration of Mendelian genetics with neo-Darwinian variation and natural selection), which splits evolution off from individual ontogenetic development.

This view of evolution is rapidly being replaced with a position in which individual ontogenetic development is understood to be an integral part of the fabric of evolution. A third issue affected by the paradigm shift concerns cognition and cognitive development. Here the standard Cartesian-framed analysis had held that mental processes are exclusively located in the brain. This position has increasingly been challenged by the view that mental processes extend out into the body as embodied action, and into the technological and cultural worlds (see Marshall, Chapter 7, this *Handbook*, this volume; Mascolo & Fischer, Chapter 4, this *Handbook*, this volume; Overton, Chapter 2, this *Handbook*, this volume). One final example of the impact of the paradigm shift appears in the area of sociocultural development. In this area rethinking has resulted in a distinctive movement away from positions that at one time identified individual development and culture as separate and distinct, if interacting, entities, and toward a position that recognizes their coconstruction, codetermination, and codevelopment (see Mistry & Dutta, Chapter 10, this *Handbook*, this volume).

All the above and other changes that have occurred in developmental science over the past decade or so have been framed by fundamental philosophical and theoretical thinking about the nature of living organisms, the nature of development, and the nature of science, as well as by methodological innovations that have revolutionized the ability of developmental scientists to study developmental change and the mutually influential relations between organism and context that constitute the basic process of intraindividual change across the life span. In regard to the philosophical and theoretical bases of this paradigm shift, it is clear that, whether studying infancy, childhood, adolescence, or the adult and late-adult phases of the life span, contemporary scholarship in developmental science aims to articulate and understand the coacting relational processes that operate between individuals and their contexts (i.e., reciprocally bidirectional, synergistic, or fused relational processes) that serve as the ground for individual action and development. Contemporary developmental scientists focus on systematic and successive alterations in the course of these relations, and focus on the integration of multiple processes of individual functioning (e.g., cognitive, emotional, motivational) and multiple levels of the ecology of human development, ranging from the biological through the sociocultural and historical levels, including designed and natural environments.

Contemporary developmental science recognizes that scientific advances entail the need for new conceptual systems, new theories, and new methods capable of coherently accounting for the highly complex nature of the processes of individual functioning and development. New theories and methods are themselves rooted in novel conceptual systems. Accordingly, the cutting edge of developmental science has increasingly recognized the inadequacies of the classic Cartesian-Split-Mechanistic research paradigm and the theories and methods this paradigm has generated. As an alternative, developmental science has been developing new theories and new methods rooted in an alternative Process-Relational and Relational-Developmental-Systems research paradigm (see Overton, Chapter 2, this *Handbook*, this volume). Lerner, in the Preface to this edition, delineates many features of relational developmental systems theories and their conceptual metatheoretical roots (see Table P.1 in the Preface to this edition of the *Handbook*, and Overton, Chapter 2, this *Handbook*, this volume).

The study of the development of living organisms, including humans, has evolved from a field dominated by dichotomous either/or approaches (e.g., either psychogenic explanation or biogenic explanation) to an interdisciplinary approach to the life span that recognizes the scientific value of integrating multiple perspectives—biological, psychological, sociocultural, historical—into a synthetic, holistic, complex, coactional system. Cartesian reductionistic accounts that treat the complex organism ←→ context system as an additive aggregate of simple elements have been rejected by scientists who approach research within the context of relational developmental systems theories (see, e.g., Lerner, Lerner, Bowers, & Geldhof, Chapter 16, this *Handbook*, this volume; Mascolo & Fischer, Chapter 4, this *Handbook*, this volume; Turiel, Chapter 13, this *Handbook*, this volume). The Cartesian-Split-Mechanistic research paradigm splits as dichotomous competing alternatives perspectives on issues that have traditionally been central to developmental inquiry such as those discussed above. Today, such splits are rejected by developmental scientists who operate within a Process-Relational and Relational-Developmental-Systems research paradigm. The various relational developmental system theories and methods framed by this paradigm convert all such splits into relationally joined integrations of developmental processes as they operate at all levels of organization across the life span. Thus, the conceptual emphasis of various relational developmental systems theories is placed on the nature of mutually coacting relations between individuals and contexts, represented as individual ←→ context relations.

As discussed by Overton (Chapter 2, this *Handbook*, this volume), all levels of the relational developmental system are integrated within relational developmental systems theories, ranging from variables involved in biological/physiological processes, through behavioral and social relationship processes, through physical ecological, cultural, and historical processes. The embeddedness of all levels within history imbues a *temporality* into individual ←→ context relations, and means that there is a potential for *relative plasticity*, for organized and systematic change in these relations, across person, time, and place (see Elder, Shanahan, & Jennings, Chapter 2, this *Handbook*, Volume 4). Accordingly, relational developmental systems theories focus on the "rules," the processes that govern developmental change and exchanges between individuals and their contexts. Brandtstädter (1998) termed these *developmental regulations*, and noted that when developmental regulations involve mutually beneficial individual ←→ context relations, they constitute *adaptive* developmental regulations.

The possibility of adaptive developmental relations between individuals and their contexts and the potential plasticity of human development are the distinctive features of this approach to human development. These features of developmental theory raise, however, important methodological issues. That is, three core features of Relational-Developmental-Systems models provide a rationale for making a set of methodological choices that differ in study design, measurement, sampling, and data analytic techniques, from selections made by researchers using split, dichotomous, or reductionist approaches to developmental science (see Molenaar, Lerner, & Newell, 2014; Molenaar & Nesselroade, Chapter 17, this *Handbook*, this volume;

Nesselroade & Molenaar, 2010; Ram & Grimm, Chapter 20, this *Handbook*, this volume; von Eye, Bergman, & Hsieh, Chapter 21, this *Handbook*, this volume). These three features of relational developmental systems are:

1. The conceptualization of development as the result of multiple coacting influences, which are context sensitive and contingent. This implies that development is inherently subject-specific and stochastic (probabilistic or random).
2. Development is understood to be a constructive process in which nonlinear epigenetic influences play central roles (see Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume). The most successful class of mathematical-biological models explaining such epigenetic influences are the so-called nonlinear reaction-diffusion models. These are nonlinear dynamic models generating emergent qualitative developmental changes that are not caused by genetic or environmental influences but instead are the result of dynamic self-organization. Such nonlinear epigenetic influences create substantial subject-specific variation which reinforces the subject-specific effects due to contingent contextual influences.
3. There is a focus on the potential for change evolving at multiple time scales and at multiple levels. This implies that dynamic systems models inspired will include time-varying parameters located at different levels and changing with different rates.

Along with these methodological implications, the emphasis on how the individual acts within the context, to contribute to the plastic relations with it, fosters an interest in individual agency (see Sokol, Hammond, Kuebli, & Sweetman, Chapter 8, this *Handbook*, this volume) or on intentional self-regulation (see McClelland, Geldhof, Cameron, & Wanless, Chapter 14, this *Handbook*, this volume), and this focus is best instantiated by person-centered (as compared to variable-centered) approaches to the study of human development (see von Eye, Bergman, & Hsieh, Chapter 21, this *Handbook*, this volume) and thus, to individual difference (diversity) oriented developmental scholarship (Molenaar & Nesselroade, Chapter 17, this *Handbook*, this volume).

In addition, the person-centered focus, as well as the emphases on relative plasticity and on mutually influential person ←→ context relations, has resulted in relational-developmental-systems theories being used as a frame for modeling the changing structure of ontogenetic trajectories, and has resulted in the view that developmental science is a nonergodic field (Molenaar & Nesselroade, Chapter 17, this *Handbook*, this volume). The ergodic theorem holds that data sets are marked by (a) homogeneity across individuals in a three-dimensional matrix that involves persons, variables, and time and (b) stationarity of individuals' scores on variables across time. Framed by the Process-Relational and Relational-Developmental-Systems research paradigm, however, developmental scientists argue that there is variation across individuals both within time and within individuals across time in their trajectories of individual ←→ context relations (i.e., across time differences). In other words, people differ in their paths across the life span. Because of this, the assumptions of homogeneity and stationarity of the ergodic theorem are rejected in contemporary developmental science. As a consequence of nonergodicity, developmental scientists emphasize the fundamental value of both person-centered and change-sensitive methods.

The chapters in this volume collectively document the paradigm shift to a process-relational and relational-developmental-systems research paradigm that has emerged in developmental science. All chapters focus on the implications for scholarship in different substantive areas of developmental science of process-relational and relational developmental systems thinking. The chapters in this volume also present and discuss contemporary research and new data analytic methods that have emerged within this new paradigm, and reflect the paradigm's focus on concepts of *process and system* with the aim of describing, explaining, and optimizing intraindividual changes and interindividual differences in intraindividual change across the life span (see Lerner, Preface to this edition). The dual and integrated contributions of this volume—to instantiating a paradigm shift by advancing both theory and method in developmental science—are exemplified within the chapters in this volume. A brief summary of each of these chapters describes these contributions.

THE PLAN OF THIS VOLUME

In Chapter 2, Overton compares and contrasts the classic Cartesian-Split-Mechanistic scientific research paradigm with the contemporary process-relational and relational-developmental-systems scientific research paradigm. In this presentation, he discusses the scientific advantages of a holistic approach that treats *endogenous activity, change, becoming, process, necessary organization*, and *relations* as fundamental categories in constructing relational developmental systems theories and research methods. Overton goes on to demonstrate how these fundamental categories lead to a characterization of the organism as an *inherently active, self-creating (autopoetic, enactive), self-organizing, and self-regulating, relatively plastic, nonlinear complex adaptive system*. The system's development occurs through its own *embodied activities and actions* operating *coactively* in a lived world of physical and sociocultural objects, according to the principle of *probabilistic epigenesis*. This development leads, through positive and negative feedback loops created by the system's organized action, to increasing system differentiation, integration, and complexity, directed toward adaptive ends.

In the next chapter, Witherington, explicitly operating within a process-relational context, discusses dynamic systems in developmental science, noting that in its mathematical, methodological, and conceptual grounding, the dynamic systems approach to development offers a unique, relationally focused model for understanding developmental process. Proponents of the dynamic systems approach, however, are metatheoretically divided with respect to what constitutes the very nature of explanation in developmental science, resulting in two distinct ontological frameworks within the approach: a relational inclusive, pluralistic framework, and a split exclusive, monistic framework. The author explains that the purpose of this chapter is to articulate the metatheoretical divide that currently exists within the dynamic systems approach and to address the implications of this divide for realization of the approach's potential as a part of the Process-Relational and Relational-Developmental-Systems paradigm. The chapter begins with an overview of historical influences on the dynamic systems approach to development, specifically targeting the multidisciplinary frameworks of von Bertalanffy's *general systems theory* and *nonlinear dynamical systems theory*. Alternate ways of marrying these multidisciplinary influences are discussed and used to anchor the chapter's delineation of the dynamic systems approach to development through its ontologically distinct variants. The chapter ends by framing metatheoretical division within the dynamic systems approach in terms of the Relational-Developmental-Systems and Cartesian-Split-Mechanistic paradigms.

The following chapter by Mascolo and Fischer represents one the most comprehensive illustrations of a relational developmental systems theory in the contemporary field of developmental science. The theory spans the development of cognitive, affective, and action systems from infancy through adulthood. Flowing from this *dynamic systems* and *skill* theory, along with the associated empirical research the theory has generated, the authors find that qualitatively new abilities emerge naturally in learning and development, transitioning from one form of action or representation to another, and they argue that "humans are self-creating, self-organizing, and self-regulating systems grounded in meaning through the action of our bodies and our cultures." Throughout the chapter, they repeatedly demonstrate empirically that development involves dynamic transformations in the structure-function of behavior.

Relational-Developmental-Systems incorporates a variety of systems perspectives. In their chapter on biology, development, and human systems, Lickliter and Honeycutt take a psychobiological systems perspective, and discuss the interwoven genetic, epigenetic, developmental, ecological, and evolutionary components of contemporary biology as they contribute to our understanding of developmental processes. As is the case with all the sciences, progress in biology depends on advances in theory building, empirical research, and modeling. Development, as one of the central processes of biology, has been the focus of both empirical and theoretical attention for centuries. Research techniques and methods used in biology to study development have evolved dramatically over the past several decades, generating a wealth of detailed empirical data. Metatheoretical frameworks, theories, and modeling have likewise advanced, calling into question established interpretations and assumptions about development, including the relation between genotype and phenotype, the nature and extent of heredity, the links between development and evolution, and the biological bases of behavior and cognition. The authors review the history and current status of biology's perspective on development and discuss the broader implications of this view understanding human development.

In the next chapter, Bateson presents an ethological perspective on how developmental processes become integrated, and he points to the contributions that ethology has made to an understanding of human development and evolution along with how these contributions are being integrated with modern studies of epigenetics. He notes that ethologists have focused on behavior that is characteristic of the species and adapted to its biological requirements. Studies of development have brought ethologists together with those working in many other fields of biology, psychology, psychiatry, and epigenetics. Contemporary ethology maintains a distinctiveness in taking an active view of the organism and focusing on biological function. Bateson points out that the old static view divided behavior into the innate and the acquired and—much in keeping with a Process-Relational and Relational-Developmental-Systems paradigm—the innate versus acquired position has been replaced by a much more dynamic systems view of underlying processes. Attention is now focused on how an individual develops and the interplay between the processes generating the robust features of an individual's behavior and the many processes involved in plasticity. Individuals make choices and control their environment. Their adaptability is crucial. All these activities have an impact on the evolution of their descendants.

Marshall's chapter on neuroscience, embodiment, and development focuses on the problem of the relation of contemporary neuroscience, psychology, and human development. He describes the separatist perspective that neuroscience is unrelated to psychology and human development, and the reductionist view of behavior reduced to brain function. Marshall argues for a more relational understanding based on the concept of *embodied action* and *embodied development*. This concept, Marshall argues, must be an essential feature of any theory of developmental cognitive neuroscience. The argument is made that embodiment has the potential to reframe the ways in which neuroscience data are considered in relation to other kinds of data. However, key developmental features of this reframing are currently underspecified, and Marshall argues that a Relational-Developmental-Systems perspective provides a productive path to integration. The implications of this approach for forging a new biologically grounded perspective for developmental science are profound, and Marshall discusses these in detail.

The chapter by Sokol, Hammond, Kuebli, and Sweetman considers the development of agency as a relational developmental conception that makes clear that the most basic form of agency is already present in the dynamic, self-organizing activities of living systems. The authors discuss how from the earliest point in the development of persons, agency manifests in different forms and grows through the interrelations of various biopsychosocial processes. These processes can be organized into the general levels, including the levels of biophysical agency, psychosocial agency, and sociocultural agency. The authors further describe how the most flexible and richest forms of agency seen in adulthood build from developmental processes evidenced throughout the life span: infants' sensorimotor and perceptual functioning, toddlers' symbolic representational and linguistic functioning, the child's self-regulatory functioning, and adolescents' and young adults' moral functioning.

The dialectic and transactional coactions are constitutive features of the Process-Relational and Relational-Developmental-Systems paradigm. In their chapter, Kuczynski and De Mol employ these concepts to describe contemporary dialectical models of socialization. They argue that dialectics draws attention to ideas of context, change, and nonlinear synthesis, which are best fitted to model the lived experiences of socialization processes. The authors note that despite contemporary acceptance that children are active agents in their own socialization, the influences between parents and children are still often viewed as unidirectional. They argue that a most important advance in the area of socialization has been the move to relationally bidirectional (←→) models and to recognize the complex causal structure of the socialization process. The chapter describes *social relational theory* as a framework for translating four assumptions of a dialectical ontology—*holism, agency, contradiction*, and *synthesis*—to reformulate major transactional processes in parent-child relations and socialization. The chapter concludes with a discussion of applied and methodological implications of social relational theory.

The chapter by Mistry and Dutta discusses conceptual and methodological advances that have been made toward an integration of human development and culture. Beginning as separate and separated fields of inquiry, cross-cultural psychology, cultural psychology, and human development achieved several steps toward integration beginning in the late 20th century and continuing into the 21st century. These are described along with the contemporary trend toward a relational integrative approach. In this analysis the authors point to parallels between contemporary sociohistorical perspectives and relational development science perspectives. In particular, they call attention to four key convergences: (1) the relation of person and culture as embodied or mutually constitutive, (2) the integration of meaning-making as part of context, (3) action and epigenesis as the source and process of developmental change, and (4) the simultaneous focus on both idiographic and nomothetic levels of analysis.

In the next chapter, Lewis discusses the development of emotions and the importance of the emergence of consciousness in the child's emotional development. This discussion begins from the Relational-Developmental-Systems premise that both emotional development and the child's growing knowledge of the world entail the active reciprocal bidirectional (←→) coactions among biological and environmental systems. Lewis argues that the first signs of what will be emotions are found in the newborn's adaptive patterns of action, which developed in utero in the context of an evolutionary background and according to processes of *probabilistic epigenesis*. These action patterns, which have been termed by others as *primary emotions* (anger, contempt, fear, disgust, happiness, sadness, and surprise) engage the child's social and object worlds; shape these worlds, and are shaped by them. However, it is not until the child has the capacity to think and think about him- or herself that these action patterns become *emotions*. Thus, the development of consciousness as self-reflective thought, as evidenced by *self-referential behavior*, becomes a constitutive feature of the development of emotions.

The development of personal and cultural identities is discussed in the next chapter by Chandler and Dunlop. The authors present their chapter in the context of a discussion of dualisms in general and, more particularly, those Cartesian dichotomies of thought that set selves apart from society, and conceptually isolate individuals from their communities. Because these familiar cleavages between persons and collectives can only be understood in the context of centuries of commitments to Cartesian substance dualisms more generally, the chapter begins with an introductory detour through earlier crash sites of contested claims about the alleged vices and virtues of dualistic thought more generally. They explain that it is obviously not enough to simply document common isolationist tactics. Rather, they argue that a promising first step out of this doctrinaire dilemma involves the use of common concepts that already exist at the margins of the problem. The concepts of personal and cultural continuity are offered up as provisional examples of such shared constructs, and are enlisted in the service in a post-Durkheimian account of differential suicide rates in indigenous and nonindigenous cultures.

The chapter by Turiel represents another comprehensive relational developmental systems theory. This chapter, while focusing on moral development presents the author's social domain theory, a *constructivist-relational* approach, which has led to many empirical demonstrations showing that judgments in the moral domain begin at a very early age and are distinct from the formation of other social and personal domains of judgment. A key feature of Turiel's work is the insistence that differentiations that children, adolescents, and adults make among the domains (moral, social, personal) reflect *relational* processes of thought and emotions as well as flexibility of thought. The emphasis throughout is that this relational position means that although thought and emotion can be looked at from one point of view or another, the two processes cannot be dichotomized as separate disconnected processes.

McClelland, Geldhof, Cameron, and Wanless examine the development of self-regulation, especially intentional self-regulation, in the context of the Relational-Developmental-Systems paradigm and action theory, which is a highly prominent theory within the Relational-Developmental-Systems perspective. The authors define the *concept* of self-regulation as referring to taking in information, weighing choices and consequences, and making adaptive choice(s) to attain a particular goal. They note that self-regulation has received heightened attention as a key process, which predicts a variety of developmental outcomes across the life span. However, beyond the general agreed-upon definition, there are a number of debates about the scientific *constructs* that represent self-regulation. The authors discuss the various key conceptual and methodological issues surrounding self-regulation and conclude that the term *self-regulation* is itself an oversimplification. They argue that individuals constantly regulate their behavior in reaction to, and with support from, the opportunities and constraints afforded by their environment. Consequently, optimal self-regulation requires orchestrating a diverse set of self-regulatory skills and abilities. Thus, similar to the conceptual shift away from deficit models, which describe where children are lacking in comparison to other children, is an acknowledgment that people develop the most adaptive regulatory strategies for a given context. The authors say that, in other words, it is not as accurate to say a child "has" or "lacks" self-regulation, but to instead to describe the nature of his or her self-regulatory behaviors and the conditions under which he or she self-regulates in ways that optimize development. The chapter concludes with a discussion of the next steps needed for studying self-regulation in context, improving intervention efforts, and advancing analytical and measurement methods.

In the next chapter, Cummings and Valentino begin their presentation of developmental psychopathology with a consideration of the definition of the field, the gaps it addresses in the study of child psychopathology, theoretical assumptions about the nature of human development, and its relation with other disciplines. The authors demonstrate the close association with a Relational-Developmental-Systems perspective in the key conceptual components of developmental psychopathology they examine. Like relational developmental systems, these components include a holistic approach, an emphasis on plasticity, and a dynamic, process-oriented perspective on both normal development and developmental psychopathology. The notions of developmental pathways, resilience, and the consideration of both risk and protective factors are all important components in the study of developmental psychopathology. In discussing *holism*, Cummings and Valentino introduce the concept of *floating holism* to emphasize the already well-accepted fact that holism does not preclude analysis, but encourages systematic analyses. The authors also emphasize that the evaluation of what is considered disordered or adaptive must take into account the context in which the pattern occurs; for instance, the family and community. The implications for prevention, intervention, diagnosis, and classification are also discussed. The authors close with a consideration of new directions and emerging themes in the field.

Lerner, Lerner, Bowers, and Geldhof's chapter presents a relational developmental systems model of positive youth development. The authors explain that interests in the strengths of youth, the plasticity of human development, and the concept of resilience coalesced in the 1990s to foster the development of the concept of positive youth development (PYD). As discussed by Hamilton (1999), the concept of PYD was understood in at least three interrelated but nevertheless different ways: (1) as a developmental process; (2) as a philosophy or approach to youth programming; and (3) as instances of youth programs and organizations focused on fostering the healthy or positive development of youth. The authors use concepts drawn from the Process-Relational and Relational-Developmental-Systems paradigm and the tripartite conception of PYD suggested by Hamilton as frames to review the literature on (a) the different theoretical models of the PYD developmental process; (b) philosophical ideas about, or conceptual approaches to, the nature of youth programming with a special emphasis on the model of PYD with the most extensive empirical support, the Five Cs Model of PYD; and (c) key instances of programs aimed at promoting PYD. The authors also discuss the conceptual and practical problems in integrating these three facets of PYD scholarship. This chapter concludes by explaining why understanding complex development requires multimethod integration as well as an integration of ideographic and nomothetic perspectives.

Turning to the methodological innovations that have emerged to enable ideas derived from relational-developmental systems theories to be tested, Molenaar and Nesselroade present an overview of new powerful approaches to statistical dynamic systems analysis. They begin their chapter with a heuristic description of a general mathematical theory—ergodic theory—that as mentioned earlier in this introduction implies that the study of developmental processes requires a fundamental change in methodology in which the focus is on analysis of intraindividual variation (time series analysis). A canonical multivariate time series model—the dynamic factor model—is introduced to organize the ensuing presentation of statistical methods for the analysis of intraindividual variation. Special emphasis is given to new methods for inferring valid nomothetic dynamic systems models of heterogeneous developmental processes. The chapter closes with an in-depth description of successful nonlinear dynamic systems approaches to the study of *stagewise* developmental processes.

In the next chapter, on neuroscientific methods with children, de Haan notes that neuroscientific methods can be used to capture the structural and functional changes happening in the human nervous system as it develops throughout infancy, childhood, and adolescence. This chapter provides an introductory overview of the noninvasive neuroscientific methods used in developmental research involving humans. It covers measurement of both the central and the autonomic nervous systems, considers the relative strengths and weaknesses of the methods, and provides examples illustrating their use. Special emphasis is given to general issues in measurement, methods for measuring brain structure and function (in particular an extensive overview of techniques based on magnetic resonance imaging [MRI]), and methods for studying genetics. The chapter concludes with a discussion of challenges that neuroscientific methods with children need to address and the role they will play in future research.

Qualitative and mixed methods models are discussed by Tolan and Deutsch. They note that mixed methods are increasingly recognized as advantageous and particularly informative for developmental science research. Initially and typically referring to the combination of quantitative and qualitative methods within or across studies, the approach can be considered more general than that, referring to the juxtaposition of different analytic methods to increase how informative a study or set of studies can be. This approach recognizes that different methods, within and across quantitative and qualitative types, each have different assumptions and capabilities. Multiple methods help to overcome limitations that occur with any single analytic method and bolster clarity and robustness of understanding. The chapter outlines the theoretical, design, and practical issues in use of mixed methods in developmental science. The key constructs, epistemological framework, theoretical considerations, approaches to different qualitative and quantitative methods and different arrangements in mixing methods are described. Limitations, critical and emerging issues, and exemplars of mixed methods applications are provided.

Ram and Grimm present a review of latent growth curve models and longitudinal factor models and consider how these models can be applied to individual-level and sample-level inquiry to examine intraindividual change and interindividual differences in change. They begin by presenting a taxonomy of change processes, and tether a selection of contemporary models to that taxonomy. Next an extensive list of increasingly complex growth curve models is described, culminating in a number of innovative nonlinear growth curve models (exponential, sigmoid, sinusoidal). This is followed by an insightful theoretical discussion of the relations between growth curve models, latent change models and dynamic systems theory. The chapter continues with the presentation of factor analytic methods, including P-technique, dynamic factor analysis, and latent Markov modeling. Ram and Grimm finish their chapter with emphasizing the need to embrace nonlinearity to capture the intricacies of developmental processes—including the use of differential equations for representing this nonlinearity—as well as the need to measure more frequently (intensive longitudinal designs).

In the next chapter, von Eye, Bergman, and Hsieh discuss person-oriented methodological approaches. They explain that person-oriented approaches to social and behavioral developmental sciences proceed from the fact that aggregate-level descriptions of constancy and change usually fail to represent individuals. Protagonists of a person-oriented approach, including relational developmental systems theories, therefore, have presented tenets stating that development can be person-specific and that psychometric instruments must possess dimensional identity to be applicable over time, and to enable researchers to perform comparisons of individuals or groups of individuals. Protagonists of idiographic psychology have shown that cross-sectional information can be used as substitute for longitudinal information only under conditions that are atypical of developmental processes. In the first part of this chapter, the authors present the main lines of person-oriented and idiographic research, and compare these approaches with differential psychology. In the second part of the chapter, the authors discuss methods of analysis that are suitable for person-oriented research. These methods include, but are not restricted to, hierarchical linear modeling, time series analysis, longitudinal factor analysis, configural frequency analysis (CFA), and item response theory (IRT). Examples with empirical data are given for CFA and IRT. In the discussion, perspectives of the research planner, the data analyst, and the applied developmental scientist are taken.

CONCLUSIONS

As documented by the contributions to this volume, philosophy, theory, and method in developmental science are converging on concepts and empirical tools of design and analysis that enable the mutually influential relations between an individual and his or her context to be better understood and better investigated. The paradigm shift represented by Process-Relational and Relational-Developmental-Systems research paradigm to frame Relational-Developmental-Systems models and theories of human development has advanced sufficiently to enable ideas pertinent to such theories to be aligned with methods elucidating the holistic, embodied development of the individual ←→ context relations constituting the basic process of human development.

The scholarship within this volume and, as well, across the four volumes of this edition, attest to the fact that the field of development of developmental science is in the midst of an exciting period. The paradigm shift involves increasingly greater understanding of how to think about and how to describe, explain, and optimize the course of human life for diverse individuals living within diverse contexts. As documented by the chapters in this volume, the years ahead hold great promise for important, and perhaps profound, advances in knowledge about the bases, and evidence for enhancing, human development across the life span.

CONCLUSIONS 56
REFERENCES 56

Developmental science is an interdisciplinary scientific field dedicated to understanding and explaining developmental processes, and optimizing the adaptive development of the individual (Lerner, 2012a). The focus of developmental science is on the development of the individual or intraindividual change. Individual differences are explored in the context of this intraindividual change. Like any science, developmental science operates within a broad system of assumptions, principles, or rules. Or stated inversely, developmental science does not operate according to brute induction. The broad system that frames developmental science, as well as any field of science, is usually referred to as a scientific paradigm (Kuhn, 1962, 1970, 1977) or a scientific research program (Lakatos, 1978a,1978b). This chapter will explore paradigmatic issues, some of which are consistent with, and some which are inconsistent with, the aims of developmental science. A good deal of what I present covers territory that represents many years of analysis and reflection on the nature of developmental processes (e.g., Overton, 2013a, 2013b; Reese & Overton, 1970). This chapter represents an extension of earlier chapters that were written for the fifth and sixth editions of the *Handbook of Child Psychology* (Overton, 1998, 2006). The broad aim in this chapter

I would like to express my thanks and appreciation to Rich Lerner for his enormous support during the writing of this chapter and the editing of this volume; to David Witherington for his extremely helpful feedback on the chapter; and to Jen Agans for her outstanding graphic support work on the chapter.

is to work toward bringing greater conceptual clarity to the field. This, in the belief that only through establishing coherent sets of concepts can we continue to move forward toward the goals of describing, explaining, and optimizing human development. The work of conceptual clarification often flies in the face of an earlier description, given by Horgan (2001) of a reality that developmental scientists generally face: "Our training and core practices concern research methods; the discipline is . . . deeply skeptical of . . . [conceptual clarification]. We emphasize methods for the verification of hypotheses and minimize the analysis of the concepts entailed by the hypotheses" (p. 27). However, the work of conceptual clarification is consistent with Horgan's further comment that "All the empiricism in the world can't salvage a bad idea" (p. 27). And, conceptual clarification also stands as an antidote to Wittgenstein's (1958/1953) cynical conclusion that "in psychology there are empirical methods and conceptual confusions" (p. xiv).

Ongoing conceptual work is a necessary feature of any science. In this context it is important to note that since the last edition of this *Handbook* published in 2006, there has been both an increasing recognition of the need for a clearly articulated coherent conceptual system to contextualize our field, and a significant increase in efforts to provide this conceptual framework. Evidence of the accomplished conceptual work is found in each of the chapters of this volume. Evidence of the need for further conceptual reflection is found in several contemporary trends in subareas of developmental science, and here four are presented as examples; these include new understandings of (1) the nature of inheritance (i.e., the old nature-nurture debate), (2) the nature of evolution, and its relation to human development, (3) the nature of cognition and cognitive development, and (4) the relation of culture and individual development.

Concerning the issue of inheritance, advances in epigenetics and a broader understanding of the genome itself have made the route from genotype to phenotype complex to the point that the classic model, asserting that who we are and what we become to be a simple additive function of gene × environment interactions, has become completely untenable (see, e.g., Charney, 2012; Gottlieb, 2000, 2003; Gottlieb, Wahlsten, & Lickliter, 2006; Greenberg, 2011; Ho, 2012; Joseph, 2010; Keller, 2010; Lerner, 2012b; Lickliter & Honeycutt, 2010, Chapter 5, this *Handbook*, this volume; Meaney, 2010; Moore, 2001; Partridge, 2005, 2011; Slavich & Cole, 2013; Wahlsten, 2012).

In her reexamination of this inheritance issue, or nature-nurture debate, Keller (2010) emphasizes the conceptual issues, as she finds a "*morass of linguistic and conceptual vegetation* grown together in ways that seem to defy untangling" (p. 9; emphasis added), and concludes:

> Daily, we are discovering new and extraordinarily ingenious ways in which noncoding DNA sequences participate in the mammoth projects of regulating the spatially and temporally specific transcription of DNA, the construction and translation of messenger RNA and the positioning, conformation, and activity of proteins. Early concepts of the gene were predicated on the assumption of a relatively simple transformation from genotype to phenotype, but now we are beginning to understand just how enormously complex that process is. *Such findings not only require us to rethink basic assumptions in biology, they also create the opportunity for such reconceptualizations*. (p. 78; emphasis added)

Similarly, Charney (2012) expresses the need for conceptual reflection in an exceptionally valuable review and analysis of the significant new empirical findings in genetics and epigenetics. Charney argues that although the new evidence creates virtually insurmountable obstacles for population (quantitative) behavior genetics, and while the evidence moves genetics into a postgenomic era, it does not itself yet constitute a paradigm because, "the post-genomic perspective has *not yet coalesced around a core set of principles or assumptions* characteristic of a paradigm" (2012, p. 332; emphasis added).

With respect to the relation between evolution and individual development and the need for new concepts, in this area of developmental science is rapidly moving away from two related positions. The first, a position held by contemporary evolutionary psychologists, is that "human nature, in the sense of the cognitive and emotional inventory of our species, has been constant over . . . [a] ten-thousand year window . . . a standard assumption in evolutionary psychology" (Pinker, 2011, p. 612). The second retreating position is the now 70-plus-year-old so-called "modern synthesis" (i.e., the integration of Mendelian genetics with neo-Darwinian variation and natural selection). In both cases individual development was taken to be controlled by evolutionary forces, but individual development was understood as playing no constitutive role in evolution. Today overwhelming evidence points to the fact that individual development is an integral part of the fabric of evolution (e.g., Bateson, Chapter 6, this *Handbook*, this volume; Bateson & Gluckman, 2011; Gilbert & Epel, 2009; Gottlieb, 2002; Ho, 2010; Jablonka & Lamb, 2005; Jablonka & Raz, 2009; Laubichler, 2010; Lerner & Overton, 2014; Lickliter & Schneider, 2006; Pigliucci & Müller, 2010b; Robert, 2004; West-Eberhard, 2003).

For present purposes the most important feature of this advance of integrating individual development and evolution is the simultaneous recognition of the need for a new conceptual framework. This sentiment is captured in the title of a chapter—"Rethinking Epigenesis and Evolution in the Light of Developmental Science"—written by Lickliter and Honeycutt (2010). Further, West-Eberhard (2003), one of the major figures in this advance, argues that "the *need for a conceptual framework* for the study of organization lies at the heart of unsolved problems in both ontogeny and phylogeny" (p. 16; emphasis added).

Cognition and cognitive development represents a third example of an area that has increasingly recognized the need for a new coherent conceptual framework. In this area, for example, the standard model, which Rowlands (2010) refers to as "*Cartesian cognitive science*" (p. 2), has involved the claim that mental processes are exclusively located in the brain (e.g., Adams & Aizawa, 2010). This model is increasingly being challenged by "a non-Cartesian vision of mental processes" (Rowlands, 2010, p. 25; see also Carpendale, Atwood, & Kettner, 2013), in which embodied processes, the environment, and culture all enter as constitutive features of mind (see, e.g., Marshall, Chapter 7, this *Handbook*, this volume; Menary, 2010; Mistry & Dutta, Chapter 10, this *Handbook*, this volume; Overton, 2013a; Stewart, Gapenne, & Di Paolo, 2010). However, Rowlands (2010) points to the need for further conceptual reflection on this non-Cartesian vision as he says, it would be "premature to describe this cluster of theories as a new science . . . because the new science, as yet, has *no clear conceptual foundation*" (p. 25).

A final example of an area in which a new conceptual framework is emerging is that of culture and individual development. In this area there appears to be a clear conceptual movement away from positions that treat individual development and culture as separate and distinct, if interacting, entities, and toward concepts that recognize coconstruction, codetermination, and codevelopment of person and culture (e.g., Eckensberger, 2003; Goodnow & Lawrence, Chapter 19, this *Handbook*, Volume 4; Mistry, Contreras, & Dutta, 2012).

The primary thesis of this chapter is that a good deal of the called-for "reconceptualization" and the development of a new conceptual framework—a Process-Relational and Relational-Developmental-Systems paradigm—has already been undertaken in developmental science and elsewhere. Mascolo and Fischer (Chapter 4, this *Handbook*, this volume) note that in recent decades, "there has been what might be called a *relational turn* in many areas of the social sciences" (p. 115). One example of this relational turn in the social sciences is offered by the anthropologist Tim Ingold (2004).

> What I offer is . . . not a recycling of tired preconceptions but a genuinely new way of thinking about human beings and their place in the world, centered on processes of development and the dynamic properties of relational fields, that not only promises a new reintegration of social and biological anthropology, but also sets a radical evolutionary agenda for the twenty-first century. It will, I hope, inaugurate the coming-of-age of anthropology as a *science of engagement in a relational world*. (p. 220)

Other social science examples are found in sociology (Emirbayer, 1997) and cultural psychology (Straub, 2006). This relational turn has not, however, been limited to the social sciences. Gilbert and Epel (2009) in presenting ecological developmental biology (eco-devo) describe several "revolutions" occurring in biology, including a new relational orientation: "Rather than analyzing independent 'things' a new focus of developmental biology concerns '*relationships*.' Nothing, it seems, exists except as part of a network of interactions" (p. xiii; emphasis added).

The theoretical physicist Lee Smolin (1997, 2013) refers to our living in a "relational world" and has sketched the beginning of a relational cosmology in physics, arguing "If we insist on reciprocal action and rule out fixed-background structures, what we are saying is that every entity in the universe evolves dynamically, in interaction with everything else. This is the essence of the philosophy of relationalism" (p. 117). And "In a relational world . . . things are defined by their relationships. Individuals exist . . . but their possibilities are determined by the network of relationships. Individuals encounter and perceive one another through the links that connect them within the network, and the networks are dynamic and ever evolving" (p. xxviii). Smolin terms this "the relational revolution" (p. xxviii).

Latour (1993, 2004), in the field of science studies, contributes to this relational revolution through his detailed proposals of how to move away from the extremes of Cartesian splits to a center or *middle kingdom* position where entities and ideas are represented, not as pure forms of matter, but as forms of process that flow across fuzzy boundaries. This movement is one toward what Latour terms *relationism*, a metatheoretical space where foundations are groundings, not bedrocks of certainty, and analysis is about creating categories, not about cutting nature at its joints.

Like any revolution, the birth of the relational revolution finds its origins deep in the history of humankind's thought about the nature of the universe, nature, and science, and this history includes, among others, centrally, the writings of Heraclitus, Leibniz, Kant, Schelling, Frichte, Hegel, James, Dewey, Pierce, Bergson, and Whitehead. In this chapter I elaborate and analyze in finer detail the central features and historical origins of the contemporary base of the relational turn—the Process-Relational and Relational-Developmental-Systems scientific paradigm.

In broad outline the rethinking leading to the relational turn has entailed reanalyses of the hitherto dominant Cartesian-Split-Mechanistic scientific paradigm along with arguments for the replacement of this paradigm with a Process-Relational[1] scientific paradigm that incorporates Relational-Developmental-Systems as a central component (see, e.g., Lerner, 2006; Lerner & Benson, 2013; Lerner & Overton, 2008, 2014; Overton 1998, 2006, 2010, 2013a, 2013b, 2014; Overton & Lerner, 2012; Overton & Lerner, 2014; Overton & Müller, 2012). In schematic form, the ontological and epistemological categories of this new paradigm include:

- *Holism* (compared to Cartesian *Atomism*).
- The inherent *Activity* of nature (compared to Cartesian *Fixity*).
- *Change* and *Becoming* as features of nature (compared to Cartesian Stasis and Being).
- Nature as *Process* (compared to Cartesian Nature as *Substance*).
- The *Necessary Organization* of nature (compared to Cartesian *Uniformity*).
- A *Pluralistic Universe* (compared to a Cartesian *Dualism*).
- *Constructivism* (compared to Cartesian *Realism*)
- Relational understanding (compared to Cartesian Either/or Split understanding).
- Multiple perspectives (compared to Cartesian Dualistic split Objectivism versus Subjectivism).
- Multiple forms of explanation (compared to Cartesian-Mechanistic Efficient/material causal explanation).

[1]In earlier writings (e.g., Overton, 2013a, 2013b) this paradigm was termed *Relationism*. However, *Process-Relational* better captures the ontological as well as the epistemological groundings of this metatheory.

Deriving from the ontological and epistemological Process-Relational categories, again in broad strokes, Relational-Developmental-Systems characterizes the living organism as an *inherently active, self-creating (autopoetic, enactive), self-organizing, and self-regulating, relatively plastic, nonlinear complex adaptive system*. The system's development takes place through its own *embodied activities and actions* operating *coactively* in a lived world of physical and sociocultural objects, according to the principle of *probabilistic epigenesis*. This development leads, through positive and negative feedback loops created by the system's organized action, to increasing system differentiation, integration, and complexity, directed towards adaptive ends.

In this chapter I first discuss the conceptual context, and how the concepts of any scientific paradigm form a nested system of interrelated concepts. This discussion is followed by a presentation of the nature and history of the Cartesian-Split-Mechanistic paradigm, along with the description of a more circumscribed sets of concepts that are nested within this metatheory, termed *metatheories of a middle range*. At that point in the chapter, attention is turned to a focus on the description and analysis of the Process-Relational paradigm including Relational-Developmental-Systems and closely related metatheories of a middle range.

CONCEPTUAL CONTEXTS

In any area of developmental science, as well as science in general, *context*, whether viewed as constitutive or causal, is a necessary, central, and enduring feature in the understanding of phenomena. For developmental scientists, the living system is the fundamental example, from the molecular, to the cellular, organ, person, and societal level of the functioning and development, each higher level forms the context for all lower levels and, in a relational reciprocal bidirectional fashion (←→), each lower level forms the context for all higher levels. As context, each level operates to both constrain and guide other levels. At this time, particularly in developmental science, there is scarcely anyone who would disagree with this assessment; it is virtually commonplace. What is less often recognized, however, is that the same necessity, centrality, and enduring quality of context extends beyond the empirical target phenomena of scientific investigation to conceptual systems.

Recognition of the nature and role of context in scientific conceptual systems has been hampered by two anachronistic narratives about scientific concepts that continue to exert a shadowy influence on many developmental scientists. In one narrative, that of the early 20th-century neopositivists, scientific concepts were represented as the simple outcome of an entirely bottom-up process, moving through brute induction from pristine particular observations to universal "empirical generalizations." The second shopworn narrative, told by mid-20th-century postpositivists (e.g., Popper, 1959, 1963, 1970), maintained that scientific concepts are merely human conjectures open to refutation via experimental testing. In neither narrative are concepts and conceptual systems considered as contextual in a constitutive sense.

Scientific Research Paradigms and Programs: Metatheory, Theory, Observation

In contemporary scientific epistemology (e.g., Godfrey-Smith, 2003; Lakatos, 1978a, 1978b; Laudan, 1977, 1984) concepts and conceptual systems do function as necessary, central, and enduring contexts for any broad scientific research program (Lakatos 1978a, 1978b) or scientific paradigm (Kuhn 1962, 1970, 1977). Further, and importantly, conceptual systems are understood to be interwoven in a nested fashion. This idea is most clearly described as a hierarchical set. Because all concepts are, by their very nature, abstract, the hierarchy is defined and arranged according to their scope, or the territory each set encompass, and the set's immediacy to everyday experience.

Taken as a whole the conceptual sets constitute the *conceptual framework* of a research paradigm. The most general sets are composed of *background concepts,* which are so termed because, although they establish the framing context for the whole paradigm, they seldom *explicitly* enter into the discourse of any specific set of investigations. These background concepts are generally termed *metatheoretical* or, when described as coherent sets, *metatheories*. They transcend (i.e., *meta*) theoretical concepts and theories in the sense that they constitute the conceptual context within which theoretical concepts and theories are constructed. Metatheories ground, constrain, and sustain theoretical and observational concepts. They perform the same general function with respect to methods, and in this case are termed *metamethods*. *Methodology* is a more familiar term for metamethods, but only when understood in its broad sense as a set of principles that guide the construction of methods (Asendorpf & Valsiner, 1992; Overton, 1998, 2006), and not as methods per se. In general, metatheory and methodology provide a rich source of concepts out of which theories and methods are constructed, and they provide guidelines that assist in avoiding conceptual confusions and inappropriate methods.

The Cycle of Scientific Discourse

An elaboration of the nature and role of metatheory in science, and specific metatheories (including methodology) in developmental science, entails a recognition of the cyclical nature of scientific discourse as it moves between the levels of observational and metatheoretical discourse (see Figure 2.1).

The most immediate and circumscribed area of scientific discourse is the *observational*. This set of concepts is one's current commonsense means of discussing and understanding the nature of objects and events in the world. There is uniform agreement across a wide spectrum of philosophical systems that commonsense observational concepts constitute the base of the structure of scientific discourse (Nagel, 1967, 1979; Pepper, 1942; Wartofsky, 1968; Whitehead, 1925). "The topic of every science is an abstraction from the full concrete happenings of nature" (Whitehead, 1938/1966, p. 143). These commonsense concepts are not the pristine observations of neopositivist methodology; rather they are folk beliefs and distinctions that surround us in everyday life. That "some people are smart" and "other people are more or less smart" is commonsense discourse; "IQ" is not. That "people control their behavior in various ways" is commonsense discourse; "self-regulation" is not. That "people and other animals change over time" is commonsense discourse; "ontogenetic development" is not.

Although the observational, commonsense, or folk set of discourse concepts has a sense of immediacy and

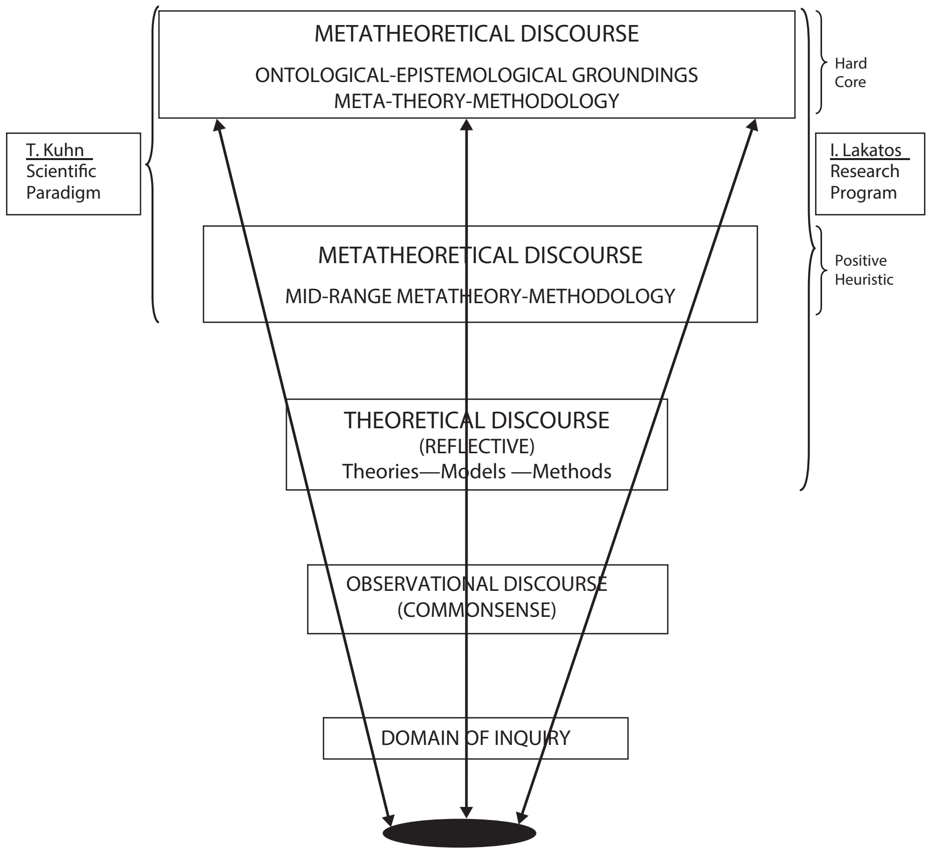

Figure 2.1 Conceptual context of a scientific research paradigm.

concreteness, science—often defined as the reflective criticism of common sense (Wartofsky, 1968)—requires movement to a level of critical reflection on this commonsense understanding. *Reflective* discourse itself entails several increasingly general sets (see Figure 2.1). The first reflective set entails *theoretical* discourse. Here, discourse is about organizing and reformulating observational understandings in a broader and more coherent fashion. At this level, concepts are *about* the observational set of discourse. Theoretical concepts include theories, models, hypotheses, and they range from informal hunches to highly refined concepts concerning the nature of, and relations among, objects and events. For example, classical developmental theories such as Piaget's (1967) and Werner's (1957, 1958; Werner & Kaplan, 1963), as well as contemporary theories such as Mascolo and Fischer's (2010, Chapter 4, this *Handbook*, this volume), Turiel's (Chapter 13, this *Handbook*, this volume) and Witherington's (2011, Chapter 3, this *Handbook*, this volume) contain theoretical principle (e.g., *stage, tier, level of organization*) that represent developmental change as involving both continuous and discontinuous (i.e., transformational) features. Skinnerian, social learning, and information processing theories, on the other hand, all contain theoretical concepts, which represent developmental change as strictly continuous and additive. Each of the theoretical models in turn is, or should be, associated with statistical methods that most faithfully measure the form of change represented by the model. Chapters by Molenaar and Nesselroade (Chapter 17, this *Handbook*, this volume), by Ram and Grimm (Chapter 20, this *Handbook*, this volume), and by von Eye, Bergman, and Hsieh (Chapter 21, this *Handbook*, this volume), all present contemporary methods designed to measure both discontinuous and additive change, while earlier statistical methods, including ANOVA-based methods were limited to the measurement of additive change.

The next more general set of reflective discourse concepts is the metatheoretical (see Figure 2.1). Here discourse is *about* theoretical and observational concepts. A *metatheory* is defined as a coherent set of rules or principles. The rules describe and prescribe what is acceptable and unacceptable, meaningful and meaningless as theory—the means of conceptual exploration of any scientific domain—and these rules place constraints on theoretical and observational discourse. Consider an extremely simple metatheoretical rule: "the living organism is an input-output machine." Such a machine does not *do* anything unless external energy is applied to it. We can invent a theoretical concept *stimulus* for the energy applied as input and a concept *response* for movements of the device constituting output. Then we can "observe" what kinds of things in the world count as stimuli and what kinds of movements of the device would count as responses, and go on to investigate "causal" relations among stimuli and responses. As Searle (1992) points out, we can and do become "captives of a . . . set of verbal categories" (p. 31), to the point, in this example, of believing that the world is actually composed of stimuli and responses. Within this metatheoretical rule we might also come to extend the theory so that stimuli and responses are not simply forces and movements *outside* the device, but *inside* the device as well. In this case, we might consider an outside *S* (Stimulus) producing an inside the device *r* (internal response) leading to an inside *s* (internal stimulus) leading to another *r* and another *s* . . . until an ultimate *R* is produced. And we might then invent a new theoretical terms for the internal sets of *s* and *r* (i.e., *mediators*). One thing is clear; the simple metatheoretical rule has an impact on both the theory and the observations. Now, we can change the metatheoretical rule to another simple one, "the living organism is an inherently active system." With this change *stimulus* becomes not just obsolete, but theoretically meaningless, as does *responses*, because the latter were the product of stimuli. Other theoretical concepts that also immediately become meaningless under this new rule include *mediator, elicit, evoke, reinforce*, and *reinforcement*. Thus, a second thing becomes clear—the metatheoretical rule determines what will be theoretically meaningful and meaningless.

Reflective metatheoretical discourse can be analyzed into subsets according to scope and the character of the metatheoretical principles. At the pinnacle of greatest generality are metatheories that are so broad as to subsume a universe of content. This set is one of *worldviews* (see Figure 2.1). Like other metatheories, worldviews are composed of coherent sets of rules or principles, but in this set the principles are *epistemological* (i.e., pertaining to sources and justification of knowledge) and *ontological* (i.e., pertaining to fundamental categories of Reality) in nature.[2] In essence, a worldview is a framework that presents a vision of the nature of the world (e.g., are stasis or change, substance or process, asserted as the fundamental categories of the world?) and the nature of how we know that world (e.g., is knowledge the reflection of a mind-independent reality, or do minds actively participate in the constitution—construction—of the world as known?).

Nested within worldviews, but more general than theories, discourse involves *metatheories of a middle range* (see Figure 2.1). These conceptual systems are less general than worldviews, and entail principles that are identifiably more specific to the observational domains of interest. For example, nested within one particular worldview a middle-range metatheory represents the human organism as an *active agent* or as a *dynamic system*, while nested within another worldview a middle-range metatheory represents the organism as an *input-output computational recording device*.

The described structure of scientific discourse from commonsense observations to worldviews and back again represents the structure of what Lakatos (1978a, 1978b) referred to as a *scientific research program* (see also Laudan, 1977). The two metatheoretical sets reflect what Lakatos referred to as the program's *hard core* (worldview) and *positive heuristic* (middle-level metatheory), whereas the two metatheoretical sets also reflect Kuhn's (1962, 1970, 1977; see also Overton, 2013a, 2013b) concept of a *scientific paradigm*, (see Figure 2.1; and see Figure 2.2 for levels of discourse with specific examples).

THE CARTESIAN-SPLIT-MECHANISTIC WORLDVIEW AND SPLIT-MECHANISTIC MIDDLE-RANGE METATHEORIES AS SCIENTIFIC PARADIGM

As suggested earlier, the dominant paradigm or scientific research program has been until recently framed by the Cartesian, or, more accurately, the Cartesian-Split-Mechanistic worldview. Lakatos (1978a) has referred to

[2] Putnam (1987) introduced the convention of identifying the ontological Real—defined as that which is not dependent on something else (i.e., that which cannot be reduced to something else)—with a capital "R," thus differentiating it from commonsense reality (i.e., the reality of the manifest world of objects and events). This convention is followed in this chapter.

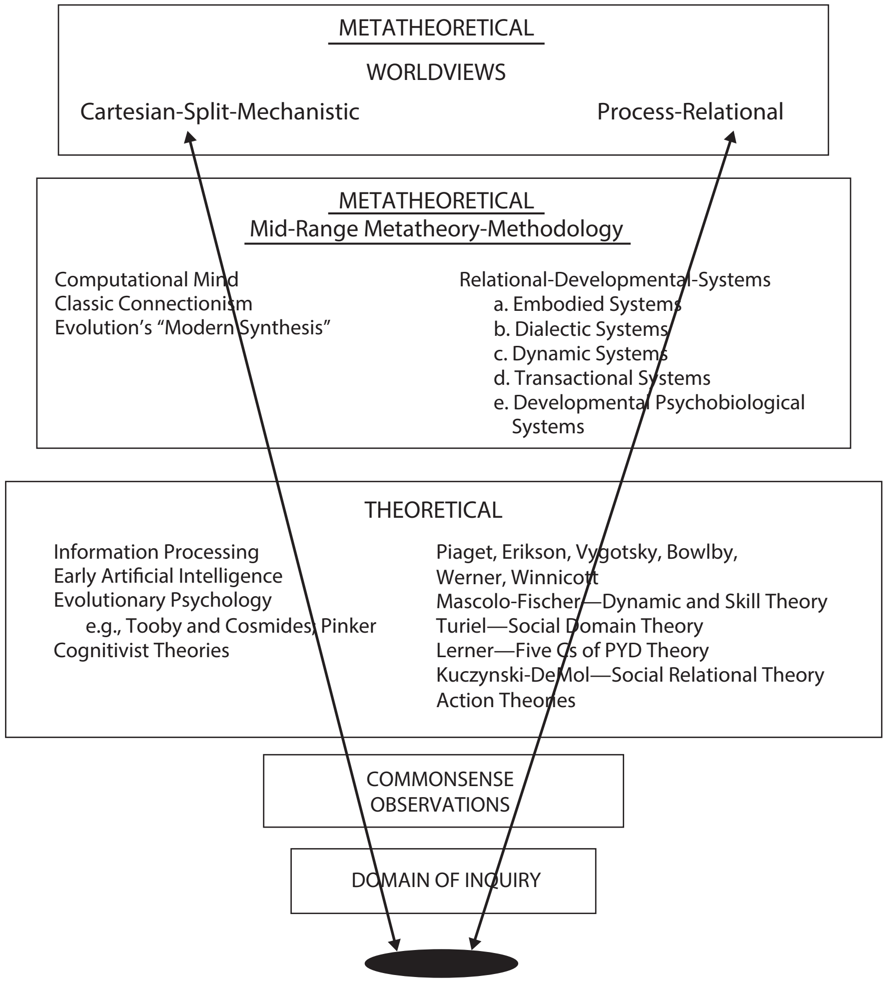

Figure 2.2 Conceptual context of the Cartesian-Split-Mechanistic and the Process-Relational paradigms.

this as the "Cartesian metaphysics, that is, the mechanistic theory of the universe—according to which the universe is a huge clockwork (and system of vortices) with push as the only cause of motion" (p. 47), and in which fundamental features of this world are split into dichotomous independent elements (Bernstein, 1983; Descartes, 1641/1996). A worldview is rarely, if ever, completely developed by any one individual, and this is true of the Cartesian-Split-Mechanistic worldview. Rene Descartes (1596–1650) is the central figure who was to have the greatest impact on the texts and subtext of this grand narrative. Descartes was preceded by Galileo Galilei (1564–1642) whose physics would first *split* the *natural world* from *mind*. Descartes himself elevated *splitting* to a first principle, established *substance* as the ultimate *foundation* of all Reality, and began the path to viewing the world in terms of the categories of the machine. The machine view was later elaborated by Newton (1643–1727) and his admirers, such as John Locke (1632–1704) and Thomas Hobbes (1588–1679), who envisioned both mind and nature in terms of an ontology of mechanically operating *atomistic materialism*.

Cartesian Substance, Splits, Foundationalism, Mechanism, Atomism, and Reductionism

The Renaissance scientific work of Galileo, more than any other person began to formally articulate ontological and epistemological *splitting* (Putnam, 1983, 1987), or a *divide and conquer* strategy (Dennett, 1991; Hundert, 1995) and *materialism*. Looking back to Democritus and anticipating John Locke, Galileo argued that matter and only matter constituted the Real and that all other perceptible qualities were only apparently real:

> The methodological precept "only the mechanical measurable properties of matter are of value in formulating scientific laws" became converted into the metaphysical statement "only the mechanical measurable properties of matter are *real*." And Galileo argued for the reality of these properties and the unreality of all others (colors, tastes, smells, etc.).... These latter properties he concluded were subjective illusions; only the former were objective, real. (Berlin, 1956, p. 47)

Thus, with Galileo, nature became split into an ontological *Real nature* identified with matter—and hence, what later became termed *materialism, naturalism*, or *physicalism*—and *apparent nature* identified with mind. Subject became split from object, with the identification of subject as the apparently real and object as the really real. There was also the anticipation of an epistemological splitting that became increasingly central in the 18th century. Galileo, while recognizing the necessity of both analysis and synthesis, argued a privileged position for analysis. By the 18th century, analysis split off from synthesis (i.e., *reductionism*; see Overton, 2002) would come to constitute the principle method for acquiring knowledge of an ontological *bedrock foundation* of *material elements* (the atoms of *atomism*) whereas synthesis became a distant second.

This analytic process, according to Galileo, is the presupposition of all exact knowledge of nature. The method of formulation of scientific concepts is both analytical and synthetic. It is only by splitting an apparently simple event into its elements and by reconstructing it from these that we can arrive at an understanding of it (Cassirer, 1951, p. 10).

Reductionism itself becomes a central feature of the Cartesian worldview. As Levins and Lewontin (1985) point out in their detailed analysis of Cartesian evolution:

> Cartesian reduction as a method has had enormous success in physics, in chemistry, and in biology ... and this has been taken to mean that the world is like the method. But this confusion of reduction as a tactic with reductionism as an ontological stance is like saying that a square wave is really the sum a large number of sine waves. In actual practice, reduction as a methodology and reductionism as a world view feed on and recreate each other. A reductionist method like the analysis of variance ... assigns weights to the "main effects" and then "first order," "second order," ... and so on—interactions as a matter of tautological bookkeeping.... Having performed this bit of number juggling, the ... scientist then reifies these numerical components as objective forces with actual physical interactions.... The scientist then sets the stage for further analyses by the same method, since, after all, it has already been shown, by the previous analysis, that the main effects exist. (p. 2)

While Galileo was a central figure in setting a framework for the ontological and epistemological presuppositions of what became the Cartesian-Split-Mechanistic worldview, it was the 17th-century philosophical work of Rene Descartes himself that firmly anchored and fleshed out most of this metatheory (Prosch, 1964). Descartes (1641/1996) began this course in his *Meditations* I and II by inventing what would become called *foundationalism*; the idea of a bedrock fixed point of certainty,

> I was convinced that I must once and for all ... build anew from the *foundation* [p. 58; emphasis added] ... Archimedes ... demanded only that one point should be fixed and immovable; in the same way I shall have the right to conceive high hopes if I am happy enough to discover one thing only which is certain and indubitable. (p. 63)

Thus, from the beginning, Descartes would split the world into *independent* parts; one constituting a fixed immovable foundational Reality, the other a derived appearance of reality. This split led Descartes to his second splitting of nature; "the assumption of bodies and minds as independent, individual substances, each existing in its own right apart from any necessary reference to each other" (Whitehead, 1925, p. 194). This is Descartes' well-known *res extensa* and *res cognitans*, an extended substance (body) and an unextended substance (mind):

> I am a thinking thing (or a substance whose whole essence or nature is to think). And ... I possess a body.... On the one side ... as I am only a thinking and unextended thing and as, on the other I possess a distinct idea of body, inasmuch as it is only an extended and unthinking thing. It is certain that this I (that is to say, my soul by which I am what I am) is entirely and absolutely distinct from my body. (Descartes, 1641/1996, Meditation Vi, p. 100)

Having created an ontological dualism by splitting nature into two distinct and independent substances Descartes—and all others who have since accepted the Cartesian categories—was faced with the problem of how to put the individual pieces back together. If there is an absolute foundational bedrock to nature and this bedrock is composed of the atoms of individual independent substances, there must be a glue that can join the pieces into the appearance of wholeness. Descartes favored the solution termed *interactionism*, a solution not unlike interactionist positions today, which split the living organism into elements such as nature-nurture, subject-object, brain-mind, body-brain, person-culture, and proposes that the whole organism is formed through the additive combination of those elements. As Descartes stated (1641/1996), the "body is by nature always divisible" (p. 105).

Substance dualism had other implications, as the philosopher Alfred North Whitehead (1925) pointed out. Descartes'

> fundamental principles are so set out as to presuppose independently existing substances with simple location in the community of temporal durations, and in the case of bodies, with simple location in the community of spatial extensions. Those principles lead straight to the theory of a materialistic, mechanistic nature, surveyed by cogitating minds. (p. 145)

And in the 18th century the British empiricist movement —as discussed later in this chapter—dismantled the cogitating mind.

The final feature of the Cartesian worldview was Descartes' use of the machine metaphor, thus ensuring the establishment of mechanistic framework (see Garber, 2002; Müller & Newman, 2008; Wright & Bechtel, 2007).

> I have described this earth and indeed the whole universe as if it were a machine: I have considered only the various shapes and movements of its parts. [Descartes, 1644, IV, Para. 188]. (quoted in Wright & Bechtel, 2007, p. 32)
>
> And as a clock is composed of wheels and counterweights . . . I consider the human body as being a sort of machine, so built and composed of bones, nerves, muscles, veins, blood, and skin. (Descartes, 1641/1996, Meditation VI, p. 104)
>
> The mechanisms familiar to Descartes (e.g., clocks . . .), typically produced their effects because of the shape, motion, and contact between their parts. So, if natural . . . [things] are mechanical they could likewise be rendered explicable by appealing to the shape and motion of their parts. (Wright & Bechtel, 2007, p. 32)

In this summary of Descartes' work we see that a nascent worldview had been established, which was fleshed out over the 18th and 19th centuries and came to dominate science, or at least the natural sciences, for three centuries. A key feature of this worldview, not yet made explicit, is its quality of "nothingbutness." Splitting yields "either/or" propositions, and the selection of one or the other of a forced choice necessarily means having nothing but this selection. Thus, knowledge arises according to the categories of materialism or idealism, subjectivism or objectivism, body (e.g., brain) or mind, and so on. Whichever category is chosen becomes the foundational Real, while the other becomes the peripheral, epiphenomenal, appearance, the *explanandum*, rather than the *explanans*. Searle (1992) captures the contemporary impact of this metatheory generally, and the impact of splitting specifically:

> Along with the Cartesian tradition we have inherited a vocabulary, and with the vocabulary a certain set of categories, within which we are historically conditioned to think about these problems. The vocabulary is not innocent, because implicit in the vocabulary are a surprising number of theoretical claims. . . . The vocabulary includes a series of apparent oppositions: "physical"; versus "mental," "body" versus "mind," "materialism" versus "mentalism," "matter" versus "spirit." Implicit in these oppositions is the thesis that the same phenomenon under the same aspects cannot literally satisfy both terms. (p. 14)

In the context of this "nothingbutness," Descartes' ontological categories can be summarized as (a) inert *substance* or matter forms an atomistic bedrock *foundation*, excluding any role for *process*; (b) inert substance does not itself change, thus, *being* or stasis (i.e., lack of change) is the natural state of things, excluding *becoming*; (c) substance is the ultimate indivisible particles or atoms, hence *atomism* (also termed *elementarism*), excluding *holism*; (d) atoms are identical, yielding a *uniform universe*, excluding a *pluralistic universe*, and excluding *necessary organization*; (e) *splitting*, both vertically (appearance-foundation) and horizontally (body-mind), excluding *relational* analysis and *multiple perspectives*; and (f) *interaction* as the additive combining of elements, excluding *coaction* of *parts and wholes*.

To flesh out the Cartesian-Split-Mechanistic worldview, the following section will briefly examine the period termed *Modernity*, and particularly the *empiricist* line of Modernity that emerged in the 18th century, an era termed the *Enlightenment*.

The Modern Period, the Enlightenment, and Rise of Radical Empiricism

Although there is some disagreement about the date, the modern period began around 1600 to 1650 (Toulmin, 1990). *Modernity* was defined both by a quest for absolute certainty of knowledge and by an effort to expand individual freedom, especially freedom of thought. Building knowledge on rational and reasoned grounds, rather than on the grounds of authority and dogma was understood as the key to each of these goals. The works of the early protagonists—Galileo, Descartes, Hobbes—have already been discussed. Building on these came the Newtonian (1643–1727) contribution (publishing *Principia* in 1687), the 18th-century *Enlightenment*, and the 19th-century *Utilitarian* movement.

Newton and the Mechanistic Split Tradition

The thought of the English Enlightenment emerged from the background of the earlier advances of the physical sciences, particularly the work of Newton. Building on Descartes' categories, Newton's major contribution was the scientific redefinition of the nature of matter in a way that conceived of all bodies as fundamentally *inactive*. Prior to Newton, scientifically, matter was understood as *inherently active*. Matter was thought of in terms of the *relation* of *being* (static, fixed) and *becoming* (active, changing). Newton, however, through his concept of *inertia*, split activity and matter and redefined matter as inactivity. For Newton,

> "Being" seemed to be simply the power, or "force," of inactivity, the passive power of remaining in motion in a straight line, unless acted upon by another force, and the passive power of remaining at rest unless and until acted upon by another force. "Being" and (active) "force" were thus separated. (Prosch, 1964, p. 52; see also, Schelling, 1803/1988, p. 154)

The redefinition of bodies as inert matter, and the assumption of the *atomicity of matter*, (i.e., following Descartes, bodies were thought of as ultimately composed of some *elementary substance that is uniform in nature*, and in combination, yields the things of the world), were basic for Newton's formulation of his laws of motion. These ideas were also ones that a later generation, working from the Cartesian categories, generalized into a metaphysics that identified the nature of the Real as fixed inert matter and *only* fixed inert matter. This view has been called the *billiard ball* notion of the universe, "the notion that basically everything . . . was made up of small, solid particles, in themselves inert, but always in motion and elasticitly rebounding from each other, . . . and operating mechanically" (Prosch, 1964, p. 66).

The impact of this extension of Descartes categories as a *billiard ball* or *clockwork* or *mechanistic* universe was, and continues to be, several-fold. First, the reduction of the subject to the object meant that the object approach was to be the only legitimate scientific approach to knowing. Given the split of subject (Spirit) from object (Matter), and given that the Real was understood to reside in the object, it was not possible to entertain the subject *point of view* as a legitimate perspective for scientific inquiry. In fact, there is no possibility of entertaining even the notion of *point of view* within this universe, because, within a mechanistic ontological-epistemological framework, there is only the truth of object, or the falsity of error.

Because fixity and uniformity constituted the Real, a second impact of the Newtonian tradition (Matson, 1964) was that change, other than random movement (a split-off notion of Aristotle's *alternation* or variational change), came necessarily to be treated as Appearance. The notion of developmental change as *transformational change* (see Ram & Grimm, Chapter 20, this *Handbook*, this volume) along with its allied concepts of *sequence, discontinuity, emergence, nonlinearity, novelty, direction*, and *irreversibility* became problems, not solutions. Similarly, the idea of *complex organization* presented a problem not a solution. These problems could not be solved until they were reduced to unchanging laws of the motion of the fixed and uniform smallest possible elements of matter, the atom (i.e., *atomism*). Whether the atoms of inquiry were the material *particles* of the early physicist, the *genes and DNA* of later day molecular biologist, the *neurons* of the neurophysiologist, the *elements of consciousness* of the early structuralist psychologists, the *responses* of the later behavioral psychologists, or the *output* of contemporary cognitive psychologists, these were the bedrock material elements that, interacting in linear combination with causal forces, generated the illusion of transformational change and complex organization. In this framework observable change was represented by the metaphor of the *Cycle of Time*, according to which seemingly transformational change is ultimately reduced to contingently determined and totally reversible movement (Coveney & Highfield, 1990; Gould, 1987; Nisbet, 1969; Overton, 1994a; Valsiner, 1994). And complex organization is treated as a *complicated* network, that can be analyzed into simple elements with sufficient reductive efforts.

The impact of the Newtonian mechanistic-split categories was not limited to ontological issues. The epistemological legacy of this tradition also reflects the assumptions of inert matter and atomism. From the Reality of the split-off object there grew the doctrine of *objectivism* or *scientific realism*, or what the American philosopher Hilary Putnam (1990) has called the *God's eye view*. According to this doctrine of objectivism there is a mind-independent fixed Real, and this Real forms the essential absolute foundation for all knowing; hence the Newtonian version of *foundationalism*. If the flux of the manifest world constituted the illusion of Appearance, then the task of knowing was the task of analysis down to the level of the Real mind-independent fixed base, and the detection of forces acting on these elements. Further, analysis and detection were to take the form of closer and closer observations until the "laws of nature would stand forth"—not as subjectively generated hypotheses, or suppositions drawn deductively from some higher-order premises ("Hypotheses non fingo," "I make no hypotheses," said Newton)—but as "observed correlations" or "empirical generalizations" *inductively* generated from these same observations (Wartofsky, 1968, pp. 183–184). Thus, the epistemological legacy of the Newtonian tradition was a nascent thoroughgoing radical empiricism and realism, driven by the primacy of an *analytic ideal* of complete *reductionism***,** and a synthetic method of a mind-independent *induction* (i.e., the form of logical reasoning that moves, via generalization and only generalization, from the particular to the universal). This view is summarized in the three steps of what came to be known as Newtonian "mechanical explanation" (Prosch, 1964, p. 77):

1. Take the subject matter (i.e., the commonsense understanding of some domain), and *reduce* it through analysis to its smallest invariant stable part, its atom (e.g., the atom of physics, the element of chemistry, the genes of biology, the neuron of neuroscience, the response of psychology).
2. Find, *through direct observation*, the forces, (i.e., *efficient or material causes*) that operate upon the atom (e.g., the stimulus, material or efficient, that determines the response in psychology).
3. *Induce* the laws (i.e., the observed regularities).

Locke, Hume, and the British Enlightenment

In an important sense, the 18th-century Enlightenment was a reaction against Descartes (Cassirer, 1951). In the context of a Process-Relational worldview (to be discussed later in this chapter), that traces back to the pre-Socratic Greeks and forward to Leibniz and Spinoza, to Hegel, James, Dewey, Whitehead, and Bergson, among others, an opposition arose to Descartes' inert substance, foundationalism, splitting, atomism, and mechanization. However, the line of thought that was to be known as the *English Enlightenment* or *British Empiricism*, accepted Cartesian inert substance, foundationalism, splitting, atomism, and mechanization. The British movement, founded on the ontological-epistemological implications of Newton's work, and advanced initially by philosophers John Locke (1632–1704), Bishop George Berkeley (1685–1753), and David Hume (1711–1776), continued to operate within the Cartesian categories (Searle, 1992), and introduced one additional category (i.e., the limitation of explanation to efficient and material causes and/or correlational *associations*). The British reaction against Descartes occurred on two fronts, (1) until the 18th century the primary method of both philosophy and science had been *deductive* in nature; the 18th century rejected this, and substituted *induction* as the primary method in virtually all disciplines of knowledge; (2) Descartes' "thinking substance" (mind) was to be suppressed.

Dualism had split the universe into two dichotomous elements, extended (body) and unextended (mind) substance, and the 18th-century empiricist reaction was to pursue the advocacy of a *monism* according to which the two would be reduced to a single Real. However, the ultimate *one* continued to be based on a dichotomous choice according to which *either* matter (materialism or idealism) must constitute the absolute bedrock foundational Real. The empiricist solution was to choose inert matter as the foundational Real. The difficulty with this solution, as the philosopher Charles Taylor (1991) pointed out, is that in the context of "either/or" a monism merely suppresses one of the terms of the split; it does not reject the split itself. Or, as neuroscientist Gerald Edelman (1992) has phrased it, "apparently monistic behaviorism is simply dualism reduced by a denial of the mind as a scientific object, and therefore left with one end hanging" (p. 11).

The British Enlightenment can best be understood as a progressive pacification and emptying of mind, until mind itself disappears as Appearance; something to be explained, not something that explains. Beginning with an active mind—a necessary feature of human agency—containing what Descartes' termed *innate ideas*, the mind would step-by-step be reduced from active to passive and then disappear completely. The primary tool designed to accomplish this task was the epistemological doctrine of *radical empiricism; the doctrine that all knowledge arises inductively from the senses (pristine observation) and only from the senses*.[3] John Locke, a great admirer of

[3]Some texts (e.g., Benjamin, 2009; Brennan, 2003; Goodwin, 2005) will define *empiricism* as acquiring knowledge through "*experience*." However, on closer reading it will be discovered that the author is referring to "direct *sensory* experience" or "sensation."

Newton's work, began this historical march by accepting the split Cartesian categories, and—following Galileo's lead—dividing nature into *primary* and *secondary* qualities. Primary qualities were features of Newtonian dead matter and constituted the Real.

Secondary qualities were features of mind and constituted Appearance. Locke's image of the mind of the child as a *tabula rasa* (Blank Slate) was part of this movement, as was his famous slogan that became the rallying cry for future generations of radical empiricists: *There is nothing in the intellect which is not first in the senses* (to which the relationally oriented Leibniz replied, *Nothing but the intellect itself*) (Brennan, 2003). If Locke's slogan was taken completely seriously then there are no active powers of mind; no active faculties of reflection, judging, willing, comparing; all this and more would be mere Appearance requiring explanation in terms of the ultimate atomistic foundation. In this program, mind would ultimately disappear as subject and reappear as object (Matson, 1964); in the 20th century even the objective mind would fade into objective behavior with the advent of behaviorism.

Locke's reductionism to a passive, empty mind was, however, incomplete. He advanced the empiricist program by eliminating Descartes' innate ideas, and by proclaiming the tabula rasa, and the *sensationist* thesis. The advance was based on a distinction between *complex ideas* (all universals, including *beauty, gratitude, man, woman*) and *simple ideas* (*sensations*). Simple ideas were to generate complex ideas via combinations and associations, and here Locke began what would become the school of psychological *associationism* (Heidbreder, 1933). However, Locke came to recognize the impossibility of generating the manifest world from the atomistic base of simple ideas and associations. As a consequence, he faltered at this point and allowed mind one central active power, that of *reflection*, which was comprised of the set of activities of judging, willing, and comparing.

Bishop George Berkeley, himself an idealist in matters of ontology, accepted the sensationistic thesis. He advanced the empiricist program a step beyond Locke by denying that reflection constituted an inherent central activity of mind, and by redefining ideas as particularistic images. If he had stopped there, mind would be some kind of simple storage space where particularistic images floated unconnected each to the other. Recognizing the problem, Berkeley gave a broader meaning to *perception*, beyond simple passive sensation. Perception was to include the *activity of representation*. However this activity was no longer a central power of mind, rather it was the activity of each particular sense organ; a particularistic and peripheralistic activity. To get from there to an idea (image) Berkeley argued that every sense impression becomes re-presented to consciousness and every re-presentation causes all other sense impressions it is *associated* with (contiguity in space and time). However, even this move failed to account for the experience of a world of universal order and organization (e.g., the experience of a uniform space). It was at this point that Berkeley stopped being an empiricist and appealed to God, and argued that the order, consistency, and stability of objects that are found in common sense reside in the perceiving mind of God and each individual mind is a particular of the mind of God.

Although Berkeley destroyed any central power of mind, it was left to David Hume to destroy the very notion of mind itself. Hume did this in a most direct fashion; he took the sensationist thesis seriously, and asked where in pure sensations do we find *mind, soul, self, personal identity,* or any such *universal concept*. His answer is that we do not find them in sensation, and because all knowledge must come through the senses, mind and all universal concepts are mere illusions.

> Thus, under Hume's criticism, the world collapsed into an aggregate of ideas, supported by no substance and connected by no necessity. The world as Hume saw it was a drift of [simple] ideas without connection, without permanence, without unity, without meaning, simply present and passing. (Heidbreder, 1933, pp. 48–49)

At the end of Hume's argument all the complex or abstract ideas that had constituted categories of knowing—*space, time, order, relations, necessity, universality*—were nothing but particular images called *ideas*, contingently gathered together according to principles of Association.

This position led to Hume's well-known skepticism about the possibility of valid (i.e., universal and necessary) knowledge. For Hume, all knowledge became contingent and particular. It was the more relationally oriented Kant who, while agreeing with Hume that neither necessity nor universality (i.e., valid knowledge) are found in sensations, argued that they are nonetheless critical components for understanding the world and, consequently must be found in another source (i.e., an active mind).

To this point the categories of the Cartesian-Split-Mechanistic metatheoretical worldview were complete and well formed. Hume represented the zenith of this category system with respect to knowledge, but Hume's skepticism about valid knowledge did not dampen the influence of splitting, foundationism, atomism, and mechanism on future generations in philosophy and the sciences. As precursors to the emergence of psychology, in the 19th century the Utilitarian philosophy of Jeremy Bentham, passed down through James and John Stuart Mill, and Alexander Baine, sought to apply the Cartesian paradigm, not to knowing, but to the explanation of actions, values, morals, and politics (Halevy, 1955). And then with the emergence of psychology, the *experimental* psychologies of Wundt and Titchener grew from this ground, followed in the 20th century by the functionalist approaches of Angell, Carr, Woodworth, and, ultimately, behaviorism and multiple forms of neobehaviorism, including learning and social learning theories of development.

As the 20th century progressed, the Cartesian tradition continued operating as a metatheory for various domains of inquiry, including developmental inquiry. In philosophy, the tradition extended its influence in the articulation of Anglo-American analytic philosophy, which took what has been called a *linguistic turn*. Analytic philosophy was, in one sense, a general reaction against the dominance of metaphysical systems or worldviews, including the worldview that describes the Cartesian tradition. In another sense, analytic philosophy simply drove the Cartesian worldview underground, where it continued to exert a strong contextual influence. As the name suggests, analytic philosophy has continued to maintain the Cartesian split categories, and, to the present day, in various surrogate forms, it pursues the analytic ideal of finding the *atoms*, or absolute bedrock foundational elements of knowing (Rorty, 1979). The British line of this approach located its foundationalism in the analysis of *ordinary language*. The American line pursued the same goal in the *neutral data language* and *observation sentences* of logical or neopositivism, elaborated in the writings of Moritz Schlick, Roudolf Carnap, Gustav Bergmann, Herbert Feigl, Carl Hempel, A. J. Ayer, and the "earlier" Ludwig Wittgenstein (of the *Tractatus Logico-Philosophicus*).

Contemporary Cartesian Middle-Range Metatheories

As mentioned earlier, nested within a worldview, are metatheories *of a middle range* (see Figure 2.1). These conceptual systems are consistent with but less general than worldviews and consistent with but broader than the concepts of specific theories, and they entail principles that are identifiably more specific to the observational domains of interest. Cartesian middle-range psychological metatheories characterize organisms as *inherently stable, fixed*, and *unchanging*. Both movement (behavior) and development are understood to be a result of extrinsic (whether internal biological or external environmental) *forces* (efficient and material causes), often termed *mechanisms*, and methodologically referred to as *antecedent* or *independent variables*. The Cartesian organism is complicated, but not complex. When the term *complex* is used within this framework it connotes "capable of being analyzed into simple elements"; that is, *complicated*. Because the organism is complicated, it is described as independent pieces. Biology is a piece, culture is a piece, cognition, motivation, and affect are pieces. Pieces combine (add together, interact) to form a whole that is no different than the sum of its pieces. There can be no novelty, as any apparent novelty must be reduced to the pieces. There can be no discontinuity to development, as this would constitute novelty. There can be no emergence in development for the same reason. The Cartesian organism is linear, both with respect to behavior and development (prenatal and postnatal); inputs are strictly proportional to outputs. Because of this linearity, the behavior and development of the organism is *deterministic* and, hence, in principle completely *predictable*. There is an initial uniformity or lack of organization with respect to psychological organization or psychological structure. In sum, the organism at whatever level chosen for investigation—from the biological to the psychological to the cultural—operates as an input-output device.

Beyond this general characterization, the following constitute some examples of Cartesian Middle-Range Metatheories.

Cartesian Inheritance

In classic genetics, the gene was introduced as an analog to the chemical element as the foundational biological element (Keller, 2010). The gene was conceptualized as the "master molecule" that "causes" the production of proteins. A linear additive, unidirectional causal path was asserted to operate from DNA to RNA to protein as defined by the *central dogma of molecular biology* (Gottlieb, 2000). With respect to population (quantitative) genetics, within this metatheory, the relation of genes to environment was conceptualized according to a completely additive (Lewontin, 1974; Overton & Reese, 1973) model, and statistical gene × environment interactions are themselves completely decomposable into strictly additive elements. As Turkheimer (2011) points out, this assumption of additivity is "the foundation of modern quantitative genetics" (p. 228). Partridge (2005, 2011), supporting Turkheimer's point, goes on to describe how advances in the Fisher–Wright ANOVA model, such as extensions to multivariate and latent variable models and multilevel models, adhere to the same additive structure as the original Fisher model.

Cartesian Evolution

Depew and Weber (1995) present an extensive and detailed analysis demonstrating that Darwin himself,

> Had a genuine, indeed a burning, desire to find a theory of organic origins that conformed as far as possible to Newtonian canons . . . Darwin tried systematically to operate within the prescribed Newtonian framework, where real forces impinge on real populations and organisms, rather than positing an internal developmental dynamic that is awakened, steered, or thwarted by external stimuli. (p. 110)

Levins and Lewontin (1985), in turn, analyze the continuity of this approach exhibited in the Cartesian nature of the 20th century understanding of evolution. The evolutionary *Modern Synthesis*, which in the 1930s and 1940s integrated Mendelian genetics with neo-Darwinian variation and natural selection, split phylogenesis and ontogenesis, and discarded the latter as irrelevant (see, e.g., Lickliter & Honeycutt, 2010, Chapter 5, this *Handbook*, this volume). Further, an internal is split-off from an external, yielding an isolated internalism of gene-centrism (i.e., gene as the sole unit of variation), and an isolated externalism of change (i.e., emphasis on natural selection as the virtually sole mechanism [cause] of change) (see, e.g., Pigliucci & Müller, 2010a). But change itself is restricted to a specific type. As Lewontin (2000) points out, "development is a *transformational* theory of change. . . . In contrast, the [Modern Systhesis] theory of organic evolution is based on a *variational* model of change" (p. 9). Evolutionary change, thus, becomes defined in terms of *variation* in gene frequencies *and only variation* in gene frequencies. Finally, the Modern Synthesis entails commitment to evolutionary *gradualism* (i.e., additive continuity) that derives from the same additive mathematical formalism that applies to inheritance. Pigliucci and Müller (2010a) refer to this formalism as the *backbone* of population genetics, and, hence, the backbone of the Modern Synthesis.

Present day evolutionary psychology is itself based on this Cartesian metatheory (see, e.g., Belsky, 2012; Belsky, Steinberg, & Draper, 1991; Draper & Harpending, 1982, 1988; Ellis, Schlomer, Tilley, & Butler, 2012; Richardson, 2007). Pinker (2011) emphasizes this Cartesian orientation in describing the "distinctive mechanistic" (p. 613) natural selection, and the assumption that:

> Human nature, in the sense of the cognitive and emotional inventory of our species, has been constant over . . . [a] ten-thousand year window . . . , and . . . all differences in behavior among societies have strictly environmental causes. That is a standard assumption in evolutionary psychology. (p. 612)

As an example of this standard assumption being put into a theoretical context, consider what evolutionary psychologists term *paternal investment theory*. A central component of this theory is the "assumption . . . that natural selection has designed boys' and girls' brains to detect and encode information about their fathers' social behavior and role in the family as the basis for calibrating sociosexual development in gender-specific ways" (Ellis et al., 2012, p. 329).

Cartesian Cognition

Cognition science and cognitive developmental psychology have frequently and explicitly acknowledged their roots in Cartesian metatheory. (e.g., Copeland & Proudfoot, 2007; Edelman, 1992; Marshall, 2009; Müller & Newman, 2008; Rowlands, 2010; Varela, Thompson, & Rosch, 1991; Wright & Bechtel, 2007). As the study of cognition emerged in the late 1950s, in a period known as the *cognitive revolution* (Bruner, 1990; Miller, 2003), its dominant form came to be termed *cognitivism*. This approach to thinking and other cognitive functions was contextualized by the metatheory of the *computational model of mind*. Not only did this metatheory strictly follow the dictates of the Cartesian worldview by splitting mind from body, it also explicitly framed itself within the worldview's basic category system, the machine.

As described by Marshall (2009),

> The ascent of cognitivism depended on making the mind more transparent by using computers to model mental processes. . . . The Cartesian foundation of this approach has inspired a rising tide of criticism over the last three decades, mainly centered around the problem that the computational mind of cognitivism lacks a brain, a body, and a culture. (p. 120)

Later, as Rowlands (2010) points out, "from the mid-1980s on, this [computer model of mind] emphasis gradually gave way to a renewed emphasis on 'hardware' in the form of connectionist or neural network approaches" (p. 2). These approaches—connectionism is also known as

"Neuron-like computing" (Copeland & Proudfoot, 2007, p. 440)—attempt a mechanical modeling of cognition that, although perhaps more neurobiologically realistic (see, however, Edelman, 1992, for a neurobiological critique), continue to adhere to Cartesian dictates, thereby leaving mental events locked in the brain, split-off from the full functioning of the body and from culture. This Cartesian position is clearly articulated by Adams and Aizawa (2010) in their argument that "There are processes that (1) are recognizably cognitive, (2) take place in the brain, (3) do not take place outside of the brain, and (4) do not cross from the brain into the external world" (p. 69). In the end, as Goode (2007) notes, "on the cognitivist view . . . the starting point is the solitary Cartesian subject detached from the world and its objects (including other people). Thus, the cognitivist has to account for the way the knower 'hooks on to' the world and to other people in it" (p. 272).

Earlier in this chapter Thomas Hobbes, a contemporary of Descartes, was mentioned as a central figure in the development of the Cartesian worldview. Hobbes' contribution was to argue that, along with the body, mind also operated as a machine. Mind and thought and other human activity were all reducible to motions of the animal organism. "Influenced by Galileo's conception of motion, Hobbes held that everything that happens is matter in motion, mental activities are motions of the nervous system arising as reactions to motions in the external world" (Watson & Evans, 1991). For Hobbes, thought or reasoning entailed motions, which he referred to as "computing" (Hobbes, 1655/1981) and, thus, he was an important precursor to the computational model of mind.

The idea discussed earlier in this chapter of the Cartesian organism being represented as an input-output device does not change in any essential way when the computational model of mind takes mind or brain to be an *informational processing system* and thinking becomes a form of *computation*. The insertion between input and output of a computing mechanism or neural network is merely an updating of Descartes cogs and wheels, yielding a more complicated relation between input and output; from a push-pull machine or a wind-up clock to the telegraph system, telephone switchboard, hydraulic pump, and the digital computer, this idea has been constant.

Following the work of the early behaviorists who insisted on a strict S-R model, the space between S and R began to fill with Cartesian mechanisms. With the learning theories of Hull (1943) and Spence (1956), as well as the social learning theories of Dollard and Miller (1950) and Sears, Maccoby, and Levin (1957), the space between input and output began to be filled with internal responses and internal stimuli that formed chains linking the external Stimulus with overt Response. The chains, thus mediated antecedent conditions and instrumental behaviors and were termed *mediating responses*. These internal mediating "events" were understood to have the same theoretical status as overt stimuli and responses. Thus, the meditational responses were subject to the same laws of composition and decomposition as their observable counterparts. And further, the internal mediators were understood to have originated from the antecedents and consequents according to traditional learning principles of *reinforcement* and *imitation*. As this meditational tradition expanded, particularly into clinical psychological cognitive and cognitive-behavioral approaches, the mediating responses came to be referred to as *symbols, representations, thoughts*, and *cognitions* (see, e.g., Foster, Kendall, & Guevremont, 1988).

With the rise of artificial intelligence and information processing the digital computer became the machine of choice. This machine receives sensations from the external world and transduces them into signals termed *information* or "messages" that the machine can operate on. The signals constitute the content of representations or symbols, while the mind is equipped with syntactic symbol structures and computational procedures that act as symbolic vehicles that carry the content (Eliasmith, 2007, p. 316). The procedures manipulate the symbols "in prescribed ways: it lists, orders, combines, compares . . . " (Bruner, 1990, p. 4). Is this still a Cartesian machine? According to Copeland and Proudfoot (2007) it is, given that

> The item's [computer] operation can be accounted for in monistic, materialist terms and in a manner analogous to that in which the operation of an artifact, such as a clockwork figure or church organ, is explained in terms of the nature and arrangement of its components. (p. 457)

Cartesian Culture

Inquiry into the field of culture and development has not been as enmeshed in the Cartesian metatheory as have the studies of inheritance, evolution, cognition, and cognitive development. Nevertheless, the tracks of Cartesian categories are found in several areas where individual and culture have been viewed, at least until recently as split-off independent entities. Mistry, Contreras, and Dutta (2012) describe this splitting with respect to work on cross-culture and child development investigations at the beginning of the present century.

> On the issue of how culture should be conceptualized, cross-cultural psychologists tended to view culture as an independent variable that influenced human behavior. Some cross-cultural psychologists suggested that culture should be operationalized as a set of conditions (Poortinga, 1992, 1997; Segall, 1984). For example, Poortinga (1997) defined the cross-cultural approach as: "there is a tendency to take cultural context, including ecological as well as sociocultural variables, as a set of antecedent conditions, while behavior phenomena, including attitudes and meanings as well as observed behaviors as outcomes or consequents (p. 350)." (p. 267)

In a similar vein, in the present volume Mistry and Dutta (Chapter 10, this *Handbook*, this volume) argue that in Bronfenbrenner's (1979; Bronfenbrenner & Morris, 2006) developmental bioecological model,

> Culture is represented as the outermost layer of context or macro-system. Although this model has conceptually focused on the interplay among the various layers of the context (i.e., psychological, biological, cultural, historical, institutional), empirically, the specific layers have been treated as split-off independent variables that influence behavior and development as efficient causes. Thus, culture is conceptualized as a feature of environmental or ecological context that exists independent of the person. (p. 370)

It is also the case that some who take a sociohistoric-cultural perspective (e.g., Cole, 1996; Rogoff, 2003; Wertsch, 1991), along with social constructivists (e.g., Gergen, 1994) who generally reject the Cartesian worldview, nevertheless at times become captured by the categories of foundationalism and splitting, This step occurs primarily through an allegiance to Marxism, which itself has promoted the broader split between ideas and matter, claiming a bedrock foundational primacy for material sociocultural objects; hence Marxism as dialectical *materialism*. Wertsch (1991) acknowledges the Marxist contribution and frames his own work within the person-sociocultural split and the foundationalism of "social forces," endorsing both a split interpretation of Vygotsky (i.e., "In pursuing a line of reasoning that reflected their concern with Marxist claims about the *primacy of social forces* Vygotsky and his colleagues . . . contended that many of the design features of mediational means *originated in social life*.") (p. 33; emphasis added), and a split interpretation of Luria.

> As stated by Luria (1981), "in order to explain the highly complex forms of human consciousness one must go beyond the human organism. One must seek the origins of conscious activity and "categorical" behavior *not in* the recesses of the human brain or in the depths of the spirit, *but in* the external conditions of life. Above all, this means that one must *seek these origins in the external processes of social life*, [emphasis added] in the social and historical forms of human existence (p. 25)." (Wertsch, 1991, p. 34)

At times the splitting of sociohistorical-cultural-developmental theorists and social constructivists becomes more subtle. For example, Cole and Wertsch (1996) begin one article by acknowledging, on the basis of several direct Piagetian quotes, that Piaget—a traditional villain of both sociohistorical-cultural-developmentalists and social constructivists—who is often inaccurately accused of privileging the person—"did not deny the co-equal role of the social world in the construction of knowledge" (p. 251). However, these authors then switch the ground of the issue from the social world specifically to culture mediation entailed by the social world and argue, both in headings (i.e., "The Primacy of Cultural Mediation," p. 251) and in text, that culture is to be the privileged split-off foundation.

> Social origins take on a special importance in Vygotsky's theories that is less symmetrical than Piaget's notion of social equilibration. . . . *For Vygotsky and cultural-historical theorists more generally, the social world does have primacy over the individual* in a very special sense. Society is the bearer of the cultural heritage. (p. 353; emphasis added)

To summarize the chapter to this point, the initial discussion argued for the centrality of a conceptual analysis, and the idea that any rich scientific research paradigm necessarily entails a conceptual framework. This framework consists of sets of nested concepts that are coherently related and range from the broadest in scope —worldviews—through more scope-limited metatheories of the middle range, and to the least general specific theories and hypotheses.

The discussion of a conceptual framework was followed by the analysis of the scientific research paradigm that held dominance in science for 300 years—the Cartesian-Split-Mechanistic worldview—along with worldview consistent metatheories of a middle range that are particularly relevant to developmental science; inheritance, evolution, cognition, culture. Criticisms of the Cartesian worldview as an adequate scientific paradigm for developmental science have come from many sources and many fields beyond those described in the present analysis. The criticisms arise from biology and neuroscience (e.g., Damasio, 1994; Edelman, 2006; Gallese & Lakoff, 2005; Gilbert & Epel, 2009; Mayr, 1982, 1988), philosophy (Bennett & Hacker, 2003; Gallagher, 2005; Taylor, 1995), anthropology (Ingold, 2000; Sheets-Johnstone, 1990), and psychology (Good, 2007; Hobson, 2002; Santostefano, 2010; Wheeler, 2005).

The reanalysis of the Cartesian paradigm represents, and its critiques constitute, one component of the thesis of this chapter. The second component of the thesis begins from the acknowledgment that, as Kuhn (1962) first suggested, regardless of the amount of counterevidence, empirical and conceptual, a scientific paradigm remains functional until another paradigm is available to take its place. Thus, the second component feature of the thesis of this chapter is that there is potential replacement paradigm available, one that (a) better accommodates the new data from several fields of developmental science; (b) overcomes the conceptual problems of the Cartesian-Split-Mechanistic metatheory and its subsumed middle-range metatheories; and (c) generates novel and empirically productive predictions for the field of developmental science. This scientific paradigm is defined by a Process-Relational worldview metatheory and Relational-Developmental-Systems (as middle-range metatheory) paradigm, which is the topic of the following sections.

THE PROCESS-RELATIONAL WORLDVIEW AND RELATIONAL-DEVELOPMENTAL-SYSTEMS AS SCIENTIFIC PARADIGM

The Process-Relational[4] worldview derives from a coherent synthesis of what Steven Pepper (1942) referred to as the world hypotheses *Organicism* and *Contextualism*. This metatheory counters the "nothingbutness" of the Cartesian paradigm with an inclusiveness attained by converting the Cartesian split dichotomies into coequal indissocible complementary processes. The metatheory also entails a rejection of Cartesian atomism and bedrock foundationism. As Alfred North Whitehead (1861–1947) said concerning his own *philosophy of organism*, or what is now termed *process philosophy*.

> There persists . . . the fixed scientific cosmology which presupposes the ultimate fact of an irreducible brute matter or material. . . . It just does what it does, following a fixed routine imposed by external relations which do not spring from the nature of its being. It is this assumption that I call "scientific materialism." Also it is an assumption which I shall challenge as being entirely unsuited to the scientific situation at which we have arrived. (Whitehead, 1925, p. 12)

In Pepper's (1942) work, the description of each of several worldviews begins from a basic or *root* metaphor and the categories of the worldview are generated upon this metaphor. In contrast to the Mechanistic worldview, which takes the machine as its root metaphor, the root metaphor of Contextualism is the "historical event" (p. 232); not the past event, but rather "the event alive in its present . . . in its actuality, . . . when it is going on *now*. . . . This event might be called an *act* so long as it is not thought of as an isolated act, but an act in and with its settings, an act in context." (p. 232)

This world is composed, not of dead Cartesian substance, but of these events or acts, which "are all intrinsically complex, composed of interconnected activities with continuously changing patterns. . . . Contextualism holds tight to the changing present event" (p. 233).

Pepper rejects *organism* as the root metaphor for the Organicism worldview because he judges it too loaded with biological connotations, and too static, and he finds *integration* only a bit better. He argues that, in fact, Contextualism's *historical event* is as good an approximation as possible (p. 280), and "the root metaphor of organicism always does appear as a *process*" (p. 281; emphasis added). In fact, because they share the same basic metaphor, Pepper points out that it is tempting "to regard these two theories as species of the same theory, one being dispersive [Contextualism] and the other integrative [Organicism]" (p. 280). But here the rub enters; Pepper argues that the opposition between the dispersive (spread out) and integrative (organized) is so basic that it leads to implications that constitute a "flat categorical contradiction and something that cannot be interpreted as a difference of emphasis" (p. 281).[5]

[4]As mentioned in footnote 1, in earlier writings (e.g., Overton, 2013a, 2013b) this worldview was termed *Relationism*. However, *Process-Relational* better captures the ontological as well as the epistemological groundings of this metatheory.

[5]Pepper makes a critical error of interpretation at this point in arguing that Organicism does not take time seriously and consequently does not include time and change in its fundamental categories. This position rests on a misinterpretation of Hegel's concept of the *Absolute*. Although the whole argument is too complex to present here, Pepper's basic mistake is to interpret Hegel's Absolute as a final *state* (p. 313), whereas a more reasonable interpretation is that the Absolute is a *horizon concept* (i.e., movement is toward an end that can never be reached) (Gadamer, 1960/1989). As Beiser (2006) points out, "No less than Kant, then, Schelling

The Relational Synthesis of Organicism and Contextualism

Let us suppose, however, that dispersion and integration are treated not as an oppositional dichotomous split, but rather, a relational two sides of the same coin, an indissociable complementarity—a relation. In fact, if dispersion and integration are considered in a relational context, then dispersion rather than being a random spread becomes the differentiation of parts or part processes. As a consequence the term *dispersion* will be dropped from this point forward and the discussion will entail on the one hand, *differentiation*, and on the other hand, *integration*.

To explore this relational approach consider the famous face-vase illusion (see Figure 2.3), and place *differentiation* on the black (faces) areas, and *integration* on the white (vase) area. Is the picture *either* faces (differentiation) *or* is it a vase (integration)? In this context that is no longer a meaningful question because there is a relation; the faces constitute and are constituted by the vase and the vase constitutes and is constituted by the faces. Remove either the white area or the black area and there are neither faces nor a vase. The famous ink sketch by M. C. Escher titled *Drawing Hands* gives an even more vivid visual illustration of this relational transformation. In this sketch a left and a right hand assume a relational posture according to which each is simultaneously drawing and being drawn by the other

Figure 2.3 The Face-Vase Illusion.

and Hegel warn against the fallacy of hypostasis, which treats the Absolute as if it were only a specific thing" (p. 5). Extending this error, Pepper also misinterprets the Absolute as excluding finitude (p. 314). In fact, Hegel rejected Schelling's Absolute, which did exclude finitude, and replaced it with an understanding that "it is necessary to conceive of the absolute as the *whole* of substance *and* its modes, as the *unity* of the infinite *and* finite" (Beiser, 2006, p. 7). *Change* is a basic category in both Organicism and Contextualism.

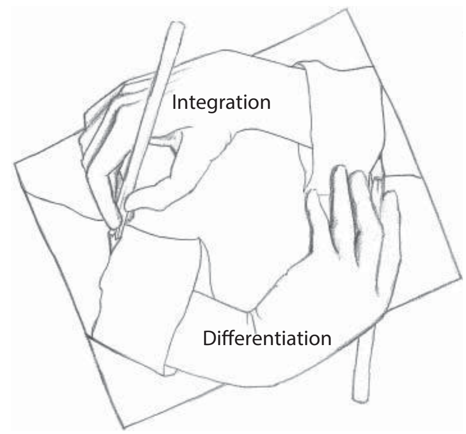

Figure 2.4 A schematic sketch of two hands drawing and being drawn by each other constituting a relational identity of opposites. With the term *integration* on one hand and *differentiation* on the other hand there results a pictorial illustration of a constitutive relation.

(a schematic outline figure rather than Escher's drawing is shown in Figure 2.4). On one hand *differentiation* is written and on the other hand *integration* is written: This figure should illustrate pictorially how these concepts can stand in a constitutive relation.

The effect of moving differentiation-integration from a Cartesian split frame to a relational frame is that Organicism and Contextualism *do* become "species of the same theory" and this is the *Process-Relational* metatheoretical worldview. Because Organicism is sometimes said to have a vertical cosmology and "contextualism is sometimes said to have a horizontal cosmology" (Pepper 1942, p. 251), the Process-Relational synthesis of the two can be represented pictorially by an intersection of a vertical and horizontal plane of a differentiated and integrated figure (see Figure 2.5). Although this is a worldview representing all of nature, we can simplify for present purposes by using the living organism as our primary model. The horizontal axis then represents the external act of the organism, and the vertical axis represents the organism performing the acting. Along with *activity* and *change* (*time-duration*), Contextualism and Organicism share *holism* and *dialectic processes* as basic categories. However, both holism and the dialectic take a different form on each plane.

Two Dimensions of Holism

First, consider *holism*, the assertion, to be repeated several times in this chapter, that the identities (meanings) of entities and events derive from the context in which they are

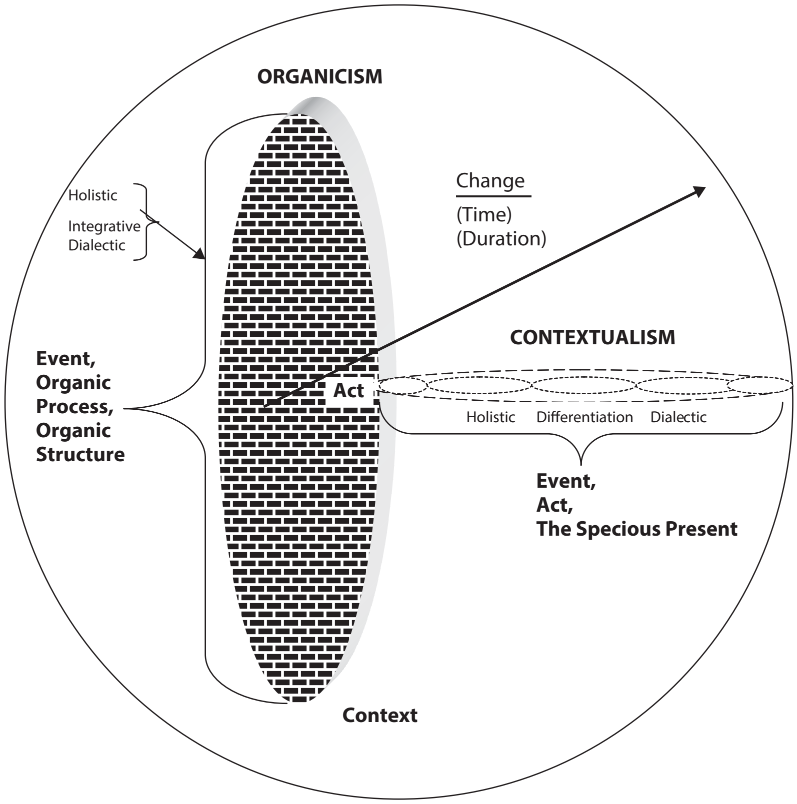

Figure 2.5 The Synthesis of Organicism (vertical plane) and Contextualism (horizontal plane) into a Process-Relational metatheoretical worldview.

embedded. The whole is not an aggregate of discrete elements, but an organization of parts, each part being defined by its relations to other parts and to the whole. The whole, in turn, through its organization has systemic features that are not features of any part. Thus, the whole is not greater than, it is *different from*, the sum of its parts.

Differentiated Holism. Along the differentiation horizontal plane of the Process-Relational metatheory shown in Figure 2.5, an *event* is an *act* composed of a series of part-acts occurring *in the here-and-now*. For example, walking to the store to buy a newspaper constitutes an event, and writing this sentence constitutes an event. The event has a beginning, middle, and end, thus a spread or a *specious present*. The holism on this plane is defined in terms of the structure of this event including its *quality* (i.e., the event's wholeness), *texture* (i.e., parts), *strands* (parts of parts) and *context*. Pepper (1942) emphasized that quality and texture are not separable, and the whole act is presumed to be different than the sum of its parts. Further, with respect to context (e.g., the physical and sociocultural environment) "the quality [wholeness] of an event is the fused quality of its strands [parts], and the qualities of the strands come partly out of its context" (p. 249). Thus, context is not causal, but constitutive, an irreducible feature or part of the event as a holistic system.

Integrative Holism. Turning to holism along the integrative vertical plane of the Process-Relational worldview (see Figure 2.5), every event in the specious present is a reflection of and reflected in an underlying (inferred) organized and organizing activity of the organism. Holism on this dimension entails the integrated quality (wholeness) of this dynamic organization. This quality is an *organic* whole in which every part "implies every other and an alteration of any . . . [part] would alter every other . . . [part] or destroy the system" (Pepper, 1942, p. 300). Two features of this dynamic organization (e.g., the organism as a dynamic system) are that (1) its relation to the horizontal plane is such that acts as external events emerge from it, and feed back to it; (2) there are *degrees* of organization, whose three main criteria are: "(1) degrees of inclusiveness, (2) degrees of determinateness, and (3) degrees of . . . [wholeness]" (Pepper, 1942, pp. 298–299). Take, as an example of both of these features the infant's act of grasping an object (actual event). Grasping emerges from a sensorimotor bodily organization and feeds back to this organization. Early grasping is global and poorly articulated; it is imprecise and limited. Its partial wholeness is indicated by the fact that, at a later time, grasping will become more finely differentiated and precise; will entail the potential of a wide variety of part-acts (e.g., one handed, two handed; with the feet); and will become a part of a broader organized system of conscious thought.

Two Dimensions of the Dialectical Process

The issue of degrees of wholeness leads to a consideration of the dialectic as it functions on each plane of the Process-Relational metatheory. Each plane affirms the centrality of the dialectical process, and each begins from the basic identification of the dialectic as a process entailing the working through of contradictions (i.e., affirmations and their negations). There are, however, as with holism two forms of dialectics, one differentiation, the other integrative.

Differentiated Dialectics. The horizontal plane (overt act, event) of the Process-Relational approach is characterized by the differentiated form of dialectics. This form has its roots in the Socratic dialogue, with "origins in living conversation in ordinary language" (Kainz, 1988, p. 31) in which contradictions appear and are resolved through dialogue. Kainz, points out that "Richard Rorty (1979) recognizing the importance of such ordinary dialectical encounter for philosophy, . . . characterizes philosophy itself as essentially 'conversations' writ large" (Kainz, 1988, p. 58). As Rorty (1979), says with respect to this differentiated form of dialectic,

> A "voice in the conversation of mankind," . . . which centers on one topic rather than another at some given time not by dialectic necessity [the integrative form of dialectic] but as a result of various things happening elsewhere in the conversation. (p. 264)

For Rorty, the differentiated form of the dialectic resulted in what has been called *edifying philosophy*, "the sort of philosophy found in the work of Kierkegaard, William James, Dewey, the later Wittgenstein, and the later Heidegger" (Kainz, 1988, p. 58), whose aim was merely to "keep the conversation going" in opposition to systematizing.

This differentiated form of dialectics operates on the horizontal plane of the Process-Relational metatheory with respect to what Pepper termed *references* and *blocking* of events. The part acts of any event along with the total event have goals (references), which have a "point of *initiation*, a transitive *direction*, and achieves an ending or *satisfaction*" (p. 252). These acts may be stopped or blocked. The goal of the event or part-event is the affirmation, while the blocking is the negation or contradiction of the act. As in the earlier given example, I may have a general goal of walking to the store to buy a newspaper. Prior to my leaving the house a downfall of rain may occur, hence "the walking to" has been blocked. Or I may walk to the store only to find they are sold out of newspapers. In this case the event itself is blocked.

The differentiated contradiction (goal and blocking of an act) leads to a form—again a differentiated form—of *novelty*, which is the resolution of the dialectic contradiction. Thus, if it is raining and I cannot walk to the store, I may decide to drive and if the store is out of newspapers I may buy a magazine. If there is a total blocking, then what Pepper refers to as *emergent novelties* may occur, as would be the case if I fell down, sprained my ankle, could not go to the store at all, and so, sat and watched TV. Novelties and emergent novelties at the level of the act taking place in the specious present are important, but they should not be confused with emergent novelties that occur on the vertical plane of the Process-Relational synthesis. The new acts of the horizontal plane generally represent *variations* of the original (e.g., news or entertainment may be achieve through both newspapers and TV) rather than the *transformations* of the vertical plane.

It might be helpful to give a developmental example here. Consider again the infant's act of grasping an object (actual event). When that event is blocked, to the extent that the infant continues, a number of variations of the form of grasping may arise, one of which attains the object. Thus, from the differentiated perspective, there are several emergent behaviors. At the same time, the blocked event feeds back to the organization of the integrative system resulting in system change, which leads to the novel actions.

Integrative Dialectics. The vertical plane of the Process-Relational approach is characterized by an integrative or *systematic* dialectics. This form has its roots in Plato's "systematic 'testing' of . . . [his] own point of view against the views of contemporaries and predecessors" (Kainz, 1988, p. 61). Aristotle's dialectic, in turn was "a continuation of the 'upward path' of the explicit dialectic in Plato, but as a systematic endeavor connotes primarily a conscientious and methodical sifting of common or influential opinions pro and con on a given controversial topic" (Kainz, 1988, p. 62). However, the most immediate precursor to the *systematic* integrative dialectics articulated by the 19th-century philosopher G. W. F. Hegel (1770–1831) is found in the works of Kant, Frichte, and Schelling (see Beiser, 2006; Schelling, 1803/1988). In Hegel's system, historical and—by extension—developmental change of the organism is a dynamic expressive/transformational process of growth, represented and defined by the dialectic.

Central to Hegel's dialectic is the idea of a *process* through which concepts or fundamental features of a dynamic system *differentiate* and move toward *integration*. Any initial concept or any basic feature of a dynamic system—called a *thesis* or an *affirmation*—contains implicit within itself an inherent *contradiction* that through action of the system in the world, becomes differentiated into a second concept or feature—the *antithesis* or *negation* of the thesis (e.g., the thesis *being* leads to its negation *nothing*). As a consequence, even in the single unity of thesis there is the implicit or potential contradictory relation of thesis/antithesis, just as in the unity of the single organic cell there is the implicit or potential differentiation into the unity of multiple cells.

The polarity of opposites that emerges from the unity of the one, as thesis leads to antithesis, does not constitute cut-off (split) contradictory categories that absolutely exclude each other. Having grown from the same soil as it were, the two, although standing in a contradictory relation of opposites also share an identity. Hegel, in fact, referred to this relation as the *identity of opposites* (Stace, 1955) and illustrated it in his famous example of the master and slave. In this example Hegel demonstrated that it is impossible to define or understand the freedom of the master (thesis) without reference to the constraints of slavery (antithesis); and consequently impossible to define the constraints of slavery without the reference to the freedom of the master. Freedom thus contains the idea of constraint as constraint contains the idea of freedom, and in this situation we see the identity of the opposites, freedom and constraint.

Through the differentiation of a polarity of opposites—a potential space between them is generated, and this space becomes the ground for the *coordination* of the two. The coordination that emerges—again through the action of the system—constitutes a novel unity or integration, called the *synthesis*. The synthesis is not some combination of thesis and antithesis, but an emergent coordinating synthesis that is itself a new system, which exhibits *novel systemic properties* while subsuming the original systems (e.g., the synthesis of *being* and *nothing* is the process *becoming*, which coordinates the two). Thus, a new dynamic matrix composed of three interconnected realms—*thesis-antithesis-synthesis*—is formed. The integration that emerges from the differentiation, like all integrations, is incomplete. The synthesis represents a new dynamic action system—a new thesis; and, thus, begins a new developmental cycle of differentiation and integration always moving toward, but never reaching the *Absolute* (the complete Whole).

Instantiations of this integrative dialectic on the vertical (organismic) plane of the Process-Relational metatheory are readily found in classic developmental theories such as those of Erikson (1968), Piaget (1970c), and Werner (1958) and in contemporary developmental theories and middle-level metatheories that view the organism as a dynamic open system operating far from equilibrium (e.g., Mascolo & Fischer, 2010, Chapter 4, this *Handbook*, this volume; Witherington, 2011, Chapter 3, this *Handbook*, this volume). Werner's *orthogenetic principle*, for example states that "development . . . proceeds from an initial state of relative globality and lack of differentiation to a state of increasing differentiation, articulation, and hierarchic integration" (1957, p. 126). Another example is found in Mascolo and Fischer (2010) description of *skill theory*: "The levels and tiers specified by skill theory reflect increasingly levels of differentiation and hierarchical integration of skill components" (p. 168). And Mascolo and Fischer (Chapter 4, this *Handbook*, this volume) elaborate by stating that "to understand psychological development, it is necessary to examine how integrative structures of thinking, feeling, needing, and acting undergo differentiation and integration as products of multiply nested coactions that operate throughout the person ←→ environment system" (p. 120).

Ontological Features of the Process-Relational Worldview (Metatheory)

With the Process-Relational worldview as a synthesis of Organicism and Contextualism it remains to detail the particular ontological and epistemological categories of this new worldview. Despite Pepper's objection that the concept *organism* can have too many biological connotations, if the reader can ignore these, *organism*, as metaphor, captures better than others the sense of this worldview. This idea is particularly true as the Process-Relational worldview aligns itself closely to Alfred North Whitehead's (1925) *philosophy of organism*.

Ontology is the domain of metaphysics concerned with question of what constitutes the *Real* (Putnam, 1987). Operating within the framework of a thorough going *holism,* it is *activity, process, change,* and *necessary organization* that constitute the Process-Relational ontological categories. As these concepts are intricately interwoven among themselves and with epistemological concepts, overlaps in their description are unavoidable.

Activity

The idea of inherent activity as a basic ontological category goes back to the pre-Socratic Greek period when Anaximander rejected Thales's assertion that a fixed substance was the basis of all things, and instead proposed that Reality was to be found in an *indeterminate stuff* that was *self-activity*. For Anaximander, any fixed elements or fixed substance grew out of this activity (Wartofsky, 1968). Heraclitus further continued this position by arguing that ceaseless flux or change constituted the ontological Real.

The ontological Reality of activity later became prominent in the German Enlightenment beginning with the work of Gottfried Wilhelm Leibniz (1646–1716). Activity and ceaseless change were fundamental to the nature of the Real. Leibniz, a contemporary of Locke, maintained against Descartes' extended substance and Newton's atom, that the fundamental unit of the Real is the *monad*. As Leibniz said, "The nature of the monad consists in being fruitful and in giving birth to ever new variety" (quoted in Toulmin & Goodfield, 1965, p. 267). The monad:

> "Is" only in so far as it is *active*, and its activity consists in a continuous transition from one new state to another as it produces these states out of itself in unceasing succession. . . . Never is one of these elements just like another; never can it be resolved into the same sum of purely static qualities. (Cassirer, 1951, p. 29)

> In Leibniz's philosophy an inalienable prerogative is first gained for the individual entity. The individual no longer functions as a special case, as an example; it now expresses something essential in itself. . . . Every individual substance [monad] is not only a fragment of the universe, it is the universe itself *seen from a particular viewpoint*. (pp. 32–33; emphasis added)

The Leibnizian tradition is relational, and it emerged, as Cassirer (1951) suggests, from an organic understanding of the nature of events. Thus, it was within an emerging organic frame that specific ontological features of the Process-Relational worldview came to be articulated.

Although it was much later, with the discovery of subatomic particles and the formulation quantum mechanics, that a notion of such fundamental activity could be taken seriously in physics, this idea continued to form the basis for the German Enlightenment's theories of mind and nature. Immanual Kant's (1724–1804) faculties of mind were the active powers that stood between the sensory aspect of experience and categories of understanding: (a) *intuition*, the faculty of receiving and organizing impressions; (b) *imagination*, the faculty of organizing (i.e., the power of analysis and synthesis) perceptions (Intuitions); (c) *understanding*, the faculty of producing rules or concepts; (d) *judgment*: faculty of determining whether a rule or concept is subsumed under other rules or concepts; and (e) *reason*, the highest faculty, which produces principles.

F. W. J. Schelling (1775–1854), a onetime philosophical ally of Hegel, presented an organic rather than a mechanical view of nature, and believed it necessary that "rather than regarding matter as static, so that it acts only upon external impulse, . . . to see it as active, as generating and organizing itself" (Beiser, 2006, p. 6; see also Schelling, 1803/1988, pp. 137–138). Hegel, in turn, inherited Schelling's organic conception with its inherent activity, including that found within the tensions of the dialectic itself. As Hegel (1830/1975) comments on the circle of the dialectical thesis-antithesis, "If we look at the distinction between the two characteristics in this unity, it realizes the concrete totality of the form, the immediate self-translation of inner into outer, and of outer into inner. This self-movement of the form is **Activity**" (p. 208; bold in original).

When early psychologists and philosophers of psychology are included along with philosophers of nature and the mind, one of the early commitments to the basic category of inherent activity is found in Franz Brentano's (1838–1917) *act psychology* in which he called for a focus on mental activity and defined psychology in terms of the study of psychic phenomena expressed as acts and process (Brentano, 1874/1995). Less commonly recognized, because of the historical impact of Titchener's (1908) later mechanistic interpretation, Wundt was an advocate of the fundamental centrality of activity; "volitional activities are the type in terms of which all other psychological phenomena are to be construed (Wundt, 1908, Vol. 3, p. 152)" (quoted in Blumenthal, 1975, p. 1083).

William James (1890/1950) argued both against the elementaristic view of mind and for the centrality of intentional acts or *functions*. James' *functionalism* was largely guided by the principle that "*The pursuance of future ends and the choice of means for their attainment are . . . the mark and criterion of the presence of mentality* in a phenomenon" (James,1890/1950, p. 8; italics in original) and stated slightly differently "*no actions but such as are done for an end, and show a choice of means can be called indubitable expressions of Mind* (p. 11). John Dewey's (1916/1966) *transactional* approach followed on from James and focused on an understanding of experience as a relational acting upon and being acted upon. "When we experience something we act upon it, we do something with it, then we suffer or undergo the consequences" (Dewey, 1916/1966 p, 139). As Alexander (1987) points out, "activity, for Dewey, is in the world before it is either subjective or objective" (p. 9). Or as Dewey (1925/1958) said himself, "Life denotes a function, a comprehensive activity, in which organism and environment are included. Only upon reflective analysis does it break up into external conditions . . . and internal structures" (p. 9).

Process

Activity, action, acts, become *process* when holistically located in a temporal order of duration. The works of Heraclitus, Leibniz, Kant, Frichte, Schelling, Hegel, James, George Herbert Mead, C. S. Pierce, Dewey, and Henri Bergson, among others, can all be counted as making significant contributions to understanding the nature and role of process. It is, however, in the writings of Alfred North Whitehead (1861–1947) (Whitehead, 1920/2004, 1925, 1929/1978, 1938/1966) and Charles Hartshorne (1897–2000) (Hartshorne, 1972, 1979, 1984) that there emerges a fully systematic *philosophy of process*—which, as mentioned earlier, Whitehead termed a *philosophy of organism*—(see also Bickhard, 2008; Rescher, 1996, 2000; Seibt, 2013).

Because of Whitehead's central contributions to a Process-Relational worldview, and because he is likely less familiar to developmental scientists than other central contributors, a brief biography is in order. Whitehead was a British mathematician, logician, and philosopher. He is well known for his work in mathematical logic as the coauthor with Bertrand Russell of the groundbreaking three-volume *Principia Mathematica* (Whitehead & Russell, 1910, 1912, 1913/1927). He was also intimately familiar with the physics of his day, including Einstein's relativity, as well as early quantum theory. In this context, he produced his own theory of relativity (Whitehead, 1922, 1929/1978; see also Desmet, 2009; Seaman, 1955). As a philosopher, he focused on the philosophy of science (Whitehead, 1925), but his central contribution was, as stated earlier, as the original pioneer of what today is known as the *process philosophy*.

Whitehead's (1925) discussion of process begins with the challenge, quoted earlier, to the idea of an ontology of fixed substance; an idea that had been foundational in philosophical and scientific thought from Aristotle to Descartes through the history of the doctrine of *materialism*:

> There persists . . . the fixed scientific cosmology which presupposes the ultimate fact of an irreducible brute matter, or material, spread throughout space in a flux of configurations. In itself such a material is senseless, valueless, purposeless. It just does what it does do, following a fixed routine imposed by external relations, which do not spring from the nature of its being. It is this assumption that I call "scientific materialism." Also it is an assumption which I shall challenge as being entirely unsuitable to the scientific situation. (p. 18)

Whitehead (1938/1966) extends this challenge to the epistemology associated with materialism in stating that, "my quarrel with modern epistemology concerns its exclusive stress upon sense perception for the provision of data respecting nature. Sense perception does not provide the data in terms of which we interpret it" (p. 133).

As illustrated in the title of his philosophical system, Whitehead argues that the world is organic rather than materialistic. Activity, process, and change "are the matter of fact" (p. 146). And as a broad overview of his position he states,

> At an instant there is nothing. Each instant is only a way of grouping matters of fact. Thus since there are no instants, conceived as simple primary entities, there is no nature at an instant. Thus all the interrelations of matters of fact must involve transition in their essence. All realizations [*actual entities*, see below] involves implication in the creative advance. (p. 146)

A key concept in Whitehead's philosophy is the *actual entity* or *actual occasion*. These "are the final real things of which the world is made" (Whitehead, 1929/1978, p. 18). They may be subatomic particles or electrons, and they may also be a tree, house, the person or the act of the person. "There is no going behind actual entities to anything more real" (p. 18). "Each actual entity is conceived as an *act* of experience" (p. 40; emphasis added). Also, while actual entities may differ from each other, their commonality is that they are all "drops of experience, complex and interdependent" (p. 18).

An actual entity, as well as all of nature, is considered a process and consequently, "is not describable in terms of the morphology of a 'stuff'" (p. 41). The actual world, composed of actual entities,

> Is a *process* and that *process* is the *becoming of* actual entities. . . . In the becoming of an actual entity, the potential unity of many entities . . . —actual and non-actual—acquires the real unity of the one actual entity; so that the actual entity is the real . . . [process of unifying] of many potentials. (p. 22; emphasis added)

As a consequence, the

> "Substance-quality" concept is avoided, and that morphological description is replaced by description of *dynamic process* [a growing together, becoming] . . . The process . . . of any one actual entity involves the other actual entities among its components. In this way the obvious solidarity of the world receives its explanation. (p. 7; emphasis added)

Whitehead introduces the term *event* in a fashion consistent with Pepper's (1942) Contextualist *event* (i.e., "an *act* . . . But . . . not an act conceived as alone or cut off; it is an act in and with its setting, an act in its context" (p. 232) and Dewey's (1925/1958) *event* (i.e., "nature is viewed as consisting of events rather than substances, it is characterized by *histories*, that is, by continuity of change proceeding from beginnings to endings" [p. xii]). For Whitehead, the process of becoming (*realization*) an actual entity is an event. "Nature is a structure of evolving processes. The reality is the process. The realities of nature are . . . the events in nature" (1925, p. 74). And further, activity is central as each "event is an individual matter of fact issuing from an individualization of the substrate activity" (1925, p. 71). There is an essential unity to an event, a pattern; it is not the mere assembly of ingredients. "Space-time is nothing else than a system of pulling together of assemblеages into unities. But the word *event* just means one of these spatio-temporal unities" (1925, p. 74).

An event (process of becoming), whether we are addressing the horizontal dimension of an external act, or the vertical dimension of person, has a past, present, and future. The past entails the necessary (not sufficient) conditions of the present, and the present entails anticipations of the future. A *moment* in the event is an actual occasion in the "life-histories of enduring non-living objects, enduring living objects, and enduring objects with conscious knowledge" (Whitehead, 1929/1978, p. 177). A *duration* is "a complete locus of actual occasions in 'unison of becoming.' It is the old fashioned 'present state of the world'" (Whitehead, 1929/1978, p. 320). Both Henri Bergson (1911) and William James (1890/1950) employ highly similar concepts of *duration*. The durational present James terms—like Pepper (1942)—the *specious present* and describes this situation as "no knife-edge [Newton's instant], but a saddle-back, with a certain breadth of its own . . . with a bow and a stern, as it were—a rearward- and a forward-looking end" (James 1890/1950, p. 613).

As a broad summary of his position, Whitehead argues that, "nature is a process. . . . It is an exhibition of the process of nature that each duration happens and passes. The process of nature can also be termed the passage of nature" (1920/2004, p. 29). Whitehead's philosophical system is obviously complex, and it is also counterintuitive for those raised on a diet of mechanistic materialism. These few paragraphs can do little more than hint at the breadth and complexity of the complete system, and of the implications for developmental science of taking process seriously. Three of these implications, however, require at least brief mention.

First, because actual entities constitute the Real, and they are in process of becoming and passing away, as both Leibniz and Whitehead argue, the universe is not monistic, nor dualistic, but *pluralistic* (see also Smolin, 1997). Or as Hartshorne (1979) expresses it, "It is not one entity different at different times, but different entities or single events, one after another" (p. 254). With respect to methodology, in the Cartesian universe, understanding is achieved by reducing the many appearances to the one Real. In the Process-Relational universe reductionism becomes meaningless, and understanding is achieved through the rational discovery (i.e., abductive inference; Overton, 2014) of patterns of activity and transitions among patterns. The focus of understanding is, therefore, not on things but on the *relation*s among things. Thus, unity is found in multiplicity and not by reducing the many to the one.

A second implication of taking process seriously is also methodological. This is the need to ensure that process is the center of attention, and part and parcel of the methodology of developmental science. The work of two contemporary developmental methodologists, Nesselroade and Molenaar (Molenaar & Nesselorade, Chapter 17, this *Handbook*, this volume; Nesselroade & Molenaar, 2010), is illustrative of this implication of taking process seriously. In fact the Nesselroade and Molenaar

(2010) methodological understanding of the nature of development and process, is a precise reflection of the Process-Relational metatheoretical concepts:

> Development includes many processes occurring simultaneously. . . . We subscribe enthusiastically to the value of going beyond basic notions of change to focus on more highly structured temporal organizations, which is what we believe researchers are trying to convey with the use of the term *process* and the application of a variety of approaches, including "person-centered" ones and various systems theoretic ideas. (p. 32)

A third implication of taking process seriously follows from the fact that the pluralistic universe is also a holistic universe. Because, as every monad in Leibniz's system, and actual entity in Whitehead's, is related to every other one, no single entity is merely a "fragment of the universe, it is the universe itself seen from a particular viewpoint and only the totality of these unique points of view gives us the truth of Reality" (Cassirer, 1951, pp. 32–33). This unity of the whole yields a *perspectivist* position, which is not relativistic, but entails a coherence theory of truth and within the scientific arena encourages interdisciplinary approaches to research.

Change

Just as activity blends into process so also does process blend into a third ontological category of the Process-Relational worldview, *change*. If "the process of nature . . . [is] the passage of nature" (Whitehead,1920/2004, p. 29), then change is categorical, or, as Whitehead says, "for the modern view process, activity, and change are the matter of fact" (1938/1966, p. 146). Considerations of change necessarily involve a discussion of the concept of time. In a book titled *Time Reborn* (2013), Smolin—the theoretical physicist mentioned earlier—has developed the argument that philosophers and physicists alike—from Plato to Newton to Einstein—have held fast to the claim that time is ultimately an illusion; replaceable by immutable, absolute, timeless laws. Smolin's thesis is that solutions to the current conundrums in theoretical physics and cosmology can only be found by taking time seriously, by thinking in time, which he terms "a form of relationism" (p. xvi). He further argues that the physics of the 20th century represented a "partial triumph of the relational view over the older Newtonian conception nature" (Smolin, 1997, p. 19), but even today this triumph is only partial.

In Newton's system, space and time are taken as absolutes. Matter is conceived of as inert bodies occupying a spatial location at a particular instant. Time is conceived of as simply a series of instances. Bergson (1960), James (1890/1950), Smolin (1997, 2013) and Whitehead (1938/1966) have all objected to this conception, particularly as it spacializes time, reducing it to a simple juxtaposition of instances. And, as stated earlier, "at an instance there is nothing . . . there is no nature at an instant" (Whitehead, 1938/1966, p. 146). Time, to the contrary, has moments, durations, events, transitions. Time is filled with nature, as activity, process, and change.

Change as the active process of becoming, moving from phase to phase, from potential to actuality, rather than split-off static being moved about by external forces, is the central theme that pervades the works of the advocates of a Process-Relational worldview. "All things change, the activities and their interrelations" (Whitehead, 1938/1966, p. 146). Yet, concurrently there is no denying of a relational *being*. This perspective is captured in the opening pages of Whitehead's *Process and Reality* (1929/1978) in his assertion that the lectures the text is based on are "concerned with the becoming, the being, and the relatedness of 'actual entities'" (p. xiii). And this theme is repeated throughout Whitehead's writings: "Every scheme for the analysis of nature has to face these two facts, *change and endurance*" (1938/1966, p. 88; emphasis added). "There are two principles inherent in the very nature of things, recurring in . . . whatever field—the spirit of change, and the spirit of conservation. There can be nothing real without both. Mere change without conservation is a passage from nothing to nothing. . . . Mere conservation without change cannot conserve" (1938/1966, p. 201). In the Process-Relational worldview, relational Being is found in Becoming and this attitude has come to be termed the *Becoming* tradition to distinguish it from the split off Cartesian-Newtonian-Mechanistic "nothingbutness" *Being* tradition.

Becoming. Heraclites is credited with the initiating the Becoming tradition in his claim that not fixed substance, but change was the fundamental underlying Real. As he wrote: "Everything flows and nothing abides; everything gives way and nothing stays fixed. You cannot step twice into the same river, for other waters and yet others, go flowing on" (quoted in Savitt, 2013). If this is so, then the stable objects we experience are phases in the process of change. With change or becoming as fundamental *being or endurance* is somewhat akin to a photographic snapshot that captures a moving object in a single stopped frame. From the becoming perspective there are no causal forces that lead to the composition of a "new" object. Change is imminent and necessary. A new seemingly stable object is a moment—that has endurance, duration—in the coming into being and passing away of process. Hence, *Being* is found in *Becoming*, *Constancy* is found in *Change*.

Before proceeding, it may be helpful to clarify what exactly is meant by the Process-Relational assertion that change is *necessary*. The distinction between the *necessary* and *accidental* was first articulated by Aristotle in his *Physics* (Book II, Chapter 9). Change that is accidental is change that arises in association with fortuitous or contingent events. Necessary change qua change is free from external causal forces and is natural to the entity being considered. For example, a plant goes through a sequence of changes that are as necessary to the essence of the plant as are any other intrinsic features. That is, the changes must occur or the plant would be something other than itself. On the other hand, the plant has a history during which accidental conditions such as favorable or unfavorable nutrients or good or bad weather may occur. These accidental conditions are not features of the plant qua plant, but they may be conditions closely associated with changes in the rate or ultimate level of the plant's growth. From this example it should be clear that the Cartesian-Newtonian-Mechanistic position's acceptance of a "nothingbut" Being assumption entails the proposition that there are no necessary changes. Indeed, as mentioned earlier, it was Newton who first split-off Being from Becoming. From the Process-Relational perspective change is necessary, hence categorical.

The traditions of Becoming were further elaborated across the centuries (see Allport, 1955; Nisbet, 1969). Plato's and Aristotle's positions are ambiguous, but important. Plato as the father of the search for *essences* of nature and, thus, what has been called *essentialism* (see Mayr, 1982; Overton, 2006) was taking an ultimate position of natural fixity. However, Plato himself also specifically stated that "*only* the divine is changeless; that the world of man and society is an incessant process of becoming" (Nisbet, 1969, p. 308). Aristotle has been criticized for his advocacy of primary substances as the fundamental entities in his ontology (Whitehead, 1929/1978, p. xiii) and for his static classificatory system of logic (Whitehead, 1920/2004, p. 10). On the other hand, a Becoming orientation is expressed in his relational concepts of the *potentiality* and *actuality* of individual entities (*Physics*, Book III). The actuality of an object of inquiry (i.e., what the object is at a given moment) points to its being. The passage from potentiality to actuality points to the becoming of the object (Ross, 1959, p. 176). Coming into being (i.e., becoming) constituted Aristotle's conceptualization of developmental change and—as in a definition of development to be elaborated later in this chapter—he emphasized both the transformational and variational nature of change as critical relational features of becoming. Aristotle referred to *transformational change* as *generation and destruction*, and he termed *variational change alteration* (Ross, 1959, pp. 101–102).

In the 17th century Leibniz further expanded the Becoming position through his, earlier discussed, concept of the *monad*. The monad was considered to be the basic irreducible feature of all substance. It differed from the atom, however, in that it was thought of as inherently active and continuously changing. Because of the existence of constant change, knowledge of the world could not be obtained by attempting to reduce the events of experience down to some stable and fixed feature. The approach to be taken was to discover, by a rational, logical method, according to his *principle of sufficient reason*, the rules according to which the change operated. The concept of the monad served to establish the basic idea and set the stage for the 18th-century expansion of the idea to an understanding of man, society, and nature.

In 1725 Giambattista Vico attacked the static view of human nature and proposed the changes of society to be the reflection of the imminent and necessary development of the human mind. In his *General History of Nature and Theory of the Heavens*, Immanuel Kant (1755) (cited in Toulmin & Goodfield, 1965, p. 130) applied this idea to the material world and maintained that the world was continuously evolving in a systematic and ordered fashion. And from 1784 on, in a series of four volumes, Johann Gottfried Herder (1744–1803) extended the idea of *Becoming* to include all nature, animal species and human society alike (Toulmin & Goodfield, 1965).

In the late 18th and early 19th centuries Hegel was the most influential figure to advance the Becoming tradition. For Hegel, history was a necessary, dynamic process of change. The nature of this change was defined by the integrative dialectic, which, as discussed earlier, is the process through which concepts or fundamental features of a system *differentiate* and move toward *integration*. This process, in fact, suggests a grounding for understanding developmental change as directional. Within the dialectical process, the dichotomy of thesis and antithesis (i.e., a differentiation) is resolved through the emergent synthesis (integration), which itself then becomes the new thesis and the process continues and thus represents a cycle. However, the cycle is never closed, as they would be in a circle. When a circle is opened a bit, it does not return precisely to its starting point. As a consequence, with the continuation of activity, the open cycle forms a spiral (the synthesis or integration). With the repetition of spirals, a direction is formed (see Overton 1994a, 1994b) and cycles of time (durations) become the Arrow of Time (see Figure 2.6) (Coveney & Highfield, 1990; Gould, 1987; Nisbet, 1969; Overton, 1994a). The integrative dialectic also provides the ontological background for the relational continuity-discontinuity and emergence within the developmental processes. Hegel expresses this most clearly in his introduction to the *Phenomenology of Spirit*:

> The bud disappears in the bursting-forth of the blossom, and one might say that the former is refuted by the latter; similarly, when the fruit appears, the blossom is shown up in its turn as a false manifestation of the plant, and the fruit now emerges as the truth instead. These forms are not just distinguished from one another, they also supplant one another as mutually incompatible. Yet at the same time their fluid nature makes them moments of an organic unity in which they not only do not conflict, but in which each is as necessary as the other; and this mutual necessity alone constitutes the life of the whole. (Hegel, 1807, p. 2)

In the 19th century the Becoming tradition flourished in the works of social theorists such as Comte, Marx, and Spencer and in the writings of biologists such as Wolff, Goethe, and von Baer. And later into the 20th century, figures who contributed to the ontology of becoming included, along with Nietzsche and Heidegger, the various process philosophers mentioned earlier, especially Whitehead. It should be noted, however, that, in general, the process philosophers tended to focus their attention on the differentiation dialectic.

In the late 19th century and into the 20th and 21st centuries, the Becoming tradition, along with the other ontological features of the Process-Relational worldview, became background assumptions of the grand developmental theories of James Mark Baldwin (1895, 1897/1973, 1902/1976), Jean Piaget (1967, 1970), Heinz Werner (1957, 1958), and Lev Vygotsky (1978). Baldwin was the first to formulate a developmental psychology specifically in terms of integrative dialectical categories. As Broughton (1981) points out, "his [Baldwin's] . . . orientation came to be tempered with a Hegelian view of dialectical progress through qualitatively distinct levels of consciousness" (p. 399) (see also Freeman-Moir, 1982).

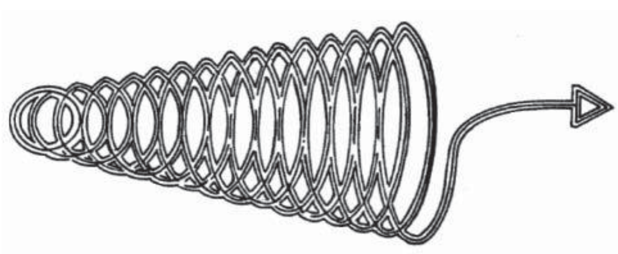

Figure 2.6 Spirals of time transform into an arrow of time.

Werner (1957, 1958) drew his own theoretical approach from the systematic dialectical feature of Becoming. In this context, he proposed the orthogenetic (normal development) principle as a universal explanatory principle, or law, of transformational change. As mentioned earlier in this chapter, the *orthogenetic principle* asserts that development proceeds from an initial relative globality and lack of differentiation to increasing differentiation, articulation, and hierarchic integration. Piaget draws from the same Becoming tradition in laying out the metatheoretical grounding for his *equilibration* explanation of human transformational change: "These global transformations . . . gradually denote a sort of law of evolution which can be phrased as follows: assimilation and accommodation proceed from a state of chaotic undifferentiation to a state of differentiation with correlative coordination" (Piaget, 1954, p. 352). Similarly, Vygotsky (1978) maintains that development is best characterized as "a complex dialectical process characterized by periodicity, unevenness in the development of different functions, metamorphosis or qualitative transformation of one form into another" (p. 73).

It is significant also that the three major developmentalists of the last half of the 20th century—Piaget (Piaget & Garcia, 1991), Werner (Werner & Kaplan, 1963) and Vygotsky (1978)—all considered development to be change entailing a spirality that emerges from cycles and yields direction (see Figure 2.6). As Vygotsky noted specifically with respect to higher psychological functions, "Development, as often happens, proceeds here not in a circle but in a spiral, passing through the same point at each new revolution while advancing to a higher level" (p. 56).

Along with the classical developmental theorists Werner, Piaget, and Vygotsky, dynamic theorists, both from the British object-relations school (e.g., Fairbairn 1952; Winnicott, 1965) and the ego psychology school (e.g., Erikson, 1968) found the core systematic dialectical Becoming, along with concepts of *process*, *differentiation*, and *integration* central to an understanding both normal and pathological human ontogenesis (Overton & Horowitz, 1991).

Necessary Organization

Organization enters the blend of the Process-Relational ideas of activity, process, and change as a final ontological category. *Organization*, and its synonyms *pattern, structure,* and *system*, is about the form or pattern of an actual entity—both the horizontal dimension of the overt act and the vertical dimension of the individual organism. The categorical nature of this concept in a Process-Relational worldview is acknowledged by Whitehead in his statement, "Pattern involves the concept of different modes of togetherness. This is obviously a fundamental concept which we ought to have thought of as soon as we started with the notion of various types of fundamental things" (1938/1966, p. 143). And as to its blending with other categories Whitehead says further,

> In the place of the Aristotelian notion of the procession of forms ... [there is] substituted the notion of the *forms of process* .... The study of the *internal relations within a complex state of activity*. This complex state is in one sense a unity. There is the whole universe of physical action extending to the remotest star cluster. In another sense it is divisible into parts. We can trace interrelations within a selected group of activities and ignore all other activities. (1938/1966, p. 140)

Organization or form as an ontological category was first proposed in the pre-Socratic Greek period by Anaxagoras, who rejected the reductionism of the many manifest qualities to the one Real (i.e., termed the problem of the *one and the many*) (Wartofsky, 1968). Anaxagoras postulated an indefinite number of real qualities and argued that their essence was in their form. Plato later argued that forms (also termed *ideas*), nonmaterial entities that do not exist in the world of sense perception, but underlie it (Wartofsky, 1968, p. 86), constituted the ultimate Reality. Although Aristotle argued that Plato's ideal forms do not exist apart from things themselves, his major contribution is found in his relational dialectic understanding that things are composed of matter and form and "form is not separable from the thing itself" (*Physics*, Book II, Chapter 1). Aristotle further argued that the form is what is unique to the entity in question; what makes it what it is and makes it distinctive from other entities. For example, if we did not understand the form of a statue then it would have no meaning as a statue, but would be merely a piece of marble. Further, if we did not understand the form of marble it would have no meaning as marble but would be merely stone and if we did not understand the form of stone, and so on. Finally, for Aristotle, form ("the form or pattern") was one of the four (efficient, material, formal, final) types of explanation (*Physics*, Book II, 3) that were required for a complete explanation of any phenomenon.

In the early 17th century, Schelling (1803/1988) elaborated on the centrality of necessary organization of the organic world, arguing that the organism

> Organizes itself.... It could not organize itself without already being organized. The plant nourishes itself and subsists through assimilation of external matter, but it can assimilate nothing to itself unless it is already organized.... Thus organization constructs itself out of organization. (p. 31)

The concept of necessary *organization*, (*pattern*, *structure*, *system*) within the modern Process-Relational worldview is the ontological face of the principle of *holism*. A whole, unity, or system is a relational set of processes, such that the whole determines the nature of the part processes and the part processes determine the nature of the unity. The unity exhibits systemic qualities that are different than any single part process or the sum of the part processes. Thus, these systemic qualities are *emergent novelties*. Consider the simple example of vision and the visual system: cornea, pupil, iris, lens, retina, optic nerve, lateral geniculate nucleus, optic radiation, primary visual cortex, and associative visual cortex: Where is vision? Vision does not reside in any of the part processes, nor is vision found in the aggregate sum of the parts. Vision is an emergent function of the whole organization; the pattern of coacting part processes.

Structure-Function Relations. Within the Process-Relational worldview, structure (organization, pattern; Aristotle's "formal" explanation) and process constitute a necessary indissociable relation; there can be no process without structure and no structure without process. This relation is generally referred to as a *structure-function* relation. Within the Cartesian worldview, this relation is one that is split off with organization being treated as trivial, epiphenomenal, or the outcome of causal forces. An early example of the splitting of structure-function in the field of psychology occurred when Titchener (1898) first coined the term "functional psychology" (p. 451) to describe the theoretical approach of James, and Dewey, and to contrast it to his and Wundt's "structural psychology" (p. 449). The split and contrast was explicit in his reference to the Wundt/Titchener paradigm as "experimental" and functional psychology as "descriptive" (p. 452). In fact, the Wundt/Titchener approach was irrelevant to the current use of the term structure, as it was a reductionistic approach to bedrock "elements of mind, their number and nature" (p. 455). The important point here, however, is the splitting of structure and function. A related point is that, whereas Titchener was exhibiting this "nothingbutness" of the Cartesian worldview, the holism of structure-function (organization-process) was, in fact, a primary characteristic of James's philosophy (Putnam, 1995). Ironically, in the hands of the later American functionalists James Rowland Angell, Harvey A. Carr, and Robert S. Woodworth, function became increasingly detached from structure to the point that the categorical nature of organization was lost and the appearance of organization was reduced to a Reality of stimuli, responses, and drives (i.e., motivational forces). And contemporary "functionalists" maintain this Cartesian split (for examples, see Overton & Horowitz, 1991).

A contemporary developmental example of the splitting of structure-function is found in a variant of *dynamic systems* developed by Thelen and Smith (1998, 2006) and, Spencer (Spencer, Perone, & Buss, 2011; Spencer, Perone, & Johnson, 2009). As Witherington (2011; Chapter 3, this *Handbook*, this volume) demonstrates in detail, these authors deny the ontological status of structure and argue that structure is itself generated solely by the activity entailed in the process of self-organization. As Witherington (2014; Chapter 3, this *Handbook*, this volume) further demonstrates, arguing that sensorimotor activity (function) in and of itself generates mental structures opens this variant of dynamic systems to a new type of reductionism. Other dynamic system models such as those of Lewis (1997, 2011), van der Maas (1995; van der Maas & Raijmakers, 2009), van Geert (2003; van Geert & Steenbeek, 2005) and Witherington (2011, 2014; Chapter 3, this *Handbook*, this volume) recognize the unity of structure and function and, hence, recognize the fact that regardless of level of analysis some organization is never lacking.

Although present in the developmental theories of Baldwin, Stern (1938), Vygotsky, and Werner, the most clearly defined systematic articulation of the necessary joining of structure-function is found in Piaget's developmental theory. In fact, Piaget's theory is a paradigmatic example of a Process-Relationally derived developmental theory. However, in the vast majority of Piaget's writings the Process-Relational details are embedded in his empirical, methodological, and theoretical concerns about the specific nature of knowing and development. Given this fact, Piaget is often read in a Cartesian framework and this reading, in turn, has generated serious misunderstandings (see Lourenço & Machado, 1996, for examples) about Piaget's theory itself and empirical findings concerning the nature and development of mind, and human functioning generally.

With respect specifically to structure-function, Piaget explicitly asserts, "structures are inseparable from performance, from functions" (Piaget, 1970a, p. 69). The simple fact of the matter is that structures function and functions have structure. Within Piaget's theory, structure-function is frequently translated into the concepts *organization* and *adaptation*, and again at this level, Piaget is insistent that that there can be no Cartesian split between them.

> Organization is inseparable from adaptation: . . . The first being the internal aspect of the cycle of which adaptation constitutes the external aspect. (Piaget, 1952, p. 7)
>
> The "accord of thought with things" and the "accord of thought with itself" expresses this dual functional invariant of adaptation and organization. These two aspects of thought are indissociable: It is by adapting to things that thought organizes itself and it is by organizing itself that it structures things. (p. 8)
>
> The organism and the environment form an indissoluble entity, . . . there are adaptional variations simultaneously involving a structuring of the organism and an action of the environment, the two being inseparable from each other. (p. 16)

Further Piaget offers numerous testimonials to the theory's commitment to necessary organization or ontological holism:

> Wholes do not result from putting together a bunch of parts; parts result from differentiation of the whole. This means that autoconservative properties of the whole provide a cohesive force that distinguishes the whole from inorganic psychochemical totalities. (Piaget, 1985, p. 20)
>
> Wholeness is a defining mark of structures . . . all structuralists . . . are at one in recognizing as fundamental the contrast between *structures* and *aggregates*, the former being wholes, the latter composites formed of elements that are independent of the complexes into which they enter. To insist on this distinction is not to deny that structures have . . . [parts], but the [parts] of a structure are subordinated to laws, and it is in terms of their laws that the structure *qua* whole or system is defined. Moreover, the laws governing a structure's composition are not reducible to cumulative one-by-one associations of its elements: they confer on the whole, as such, over-all

> properties distinct from the properties of its [parts]. (Piaget, 1970a, pp. 6–7)

Structure is a totality; that is, it is a system governed by laws that apply to the system as such, and not only to one or another element in the system (Piaget, 1970b, p. 22).

> The concept of totality expresses the interdependence inherent in every organization. . . . The correlative of the idea of totality is . . . the idea of *relationship*. Every totality is a system of relationships just as every relationship is a segment of totality. (Piaget, 1952, p. 10)

In the living organism, the reflexes form organized totalities and not juxtaposed mechanisms (Piaget, 1952).

Summary

To this point, the ontology of Process-Relational metatheory has been described both in terms of its synthesis of Organicism and Contextualism, and in terms of its essential ontological commitments of this synthesis to the necessary inherent activity of nature, the necessary inherent nature of change and becoming, of process, and of organization. As a consequence of this presentation most of the promises shown in bullet points early in the chapter have been fulfilled: *Holism* has replaced Cartesian *Atomism,* the *Activity* of nature has replaced Cartesian *Fixity*, *Change* and *Becoming* have replaced Cartesian *Stasis and Being*, Nature as *Process* has replaced Cartesian *Substance*, the *Necessary Organization* of nature has replaced Cartesian *Uniformity*, and a *Pluralistic Universe* has replaced the Cartesian *Dualistic* or *Monistic Universe*. What remains to be discussed are the epistemological commitments of the Process-Relational paradigm including Relational Understanding, and the multiple perspectives and multiple forms of explanation it entails.

Epistemological Features of the Process-Relational Worldview (Metatheory)

As ontology is the domain of metaphysics concerned with the question of what constitutes the "Real" (Putnam, 1987), epistemology is about knowing, and its primary question concerns the validity of what and how we know. Understood relationally, epistemology is a narrative about *how* we know what is Real, and ontology is a narrative about the *Real* as we know it. Classically, the fundamental questions of epistemology have concerned the relation of the knower to the known, or the question of the source of knowledge. And once the Cartesian paradigm had split the world, the question became do we know the world through *pristine* observation *or* reason? The relational answer to this question is *both*.

The epistemology of the Process-Relational paradigm is, first and foremost, a *relatively inclusive* epistemology, involving both knowing and known as equal and indissociable complementary processes in the construction, acquisition, and growth of knowledge. It is *relatively* inclusive, because *inclusion* itself—much like Hegel's master-slave dialectic—can be grasped only in relation to its complement *exclusion*. Thus, just as *freedom* must be identified in the context of *constraint*, *inclusion* must be identified in the context of *exclusion*. Relational epistemology specifically excludes Cartesian dualistic ways of knowing because Cartesian epistemology trades on exclusivity; it constitutes an epistemology of "nothingbutness." For the same reason, the Relational-Process paradigm rejects both the Mechanistic worldview and a strict contextualist interpretation of the Contextualist worldview (Overton, 2007; Witherington, 2007, 2011, 2014).

Epistemologically, the Process-Relational position begins by clearing the "nothingbutness" of splitting from the field of play. Splitting was described earlier. It originates from the original Cartesian splits of mind and body, subject and object, appearance and foundation, and it consists of the formation of a *conceptual dichotomy*, a separation of components of a whole into *mutually exclusive* pure forms or elements. In splitting, these ostensibly pure forms are cast into an exclusive *either/or* logical framework that forces them to be understood as contradictions in the sense that one category *absolutely* excludes the other (i.e., following an Aristotelian classificatory logic as the *law of contradiction* according to which it is never the case that A = Not A). When splitting is combined with the idea of there being an absolute bedrock foundation, a one certain Real, then one of the alternatives becomes privileged over the other and this idea leads to theoretical and methodological wars over which alternative constitutes the "legitimate" or "significant" or "meaningful" approach to inquiry. Nature and Nurture, Idealism and Materialism, Reason and Observation, Subject and Object, Constancy and Change, Biology and Culture, among others (see Table 2.1 for a list of common antinomies that can be converted into relational complementarities) and under the influence of Cartesian epistemology are presented as split-off competing alternatives. Choose one concept as the foundational "Real" and

TABLE 2.1 Fundamental categories: Interpreted in the Cartesian-Split-Mechanistic paradigm as dichotomous antinomies. Interpreted in the Process-Relational and Relational-Developmental-Systems paradigm as coequal indissociable complementarities.

Fundamental Categories	
Subject	**Object**
Mind	Body
Form	Matter
Differentiation	Integration
Stability	Change
Universal	Particular
Transcendent	Immanent
Analysis	Synthesis
Unity	Diversity
Certainty	Doubt
Absolute	Relative
Expressive	Instrumental
Variation	Transformation
Intrapsychic	Interpersonal
Reason	Emotion
Biology	Culture
Person	Biology
Culture	Person
Nature	Nurture
Interpretation	Observation

it follows, under a split epistemology, that the other is mere Appearance or epiphenomenal.

In place of the rejected splitting and foundationalism, the Process-Relational metatheory installs *holism* as the over-arching epistemological first principle. Building from the base of holism, Process-Relationism moves to specific principles that define the relations among parts and the relations of parts to wholes. In other words, relational metatheory articulates principles of analysis and synthesis necessary for any scientific inquiry. These principles are (a) *The Identity of Opposites*, (b) *The Opposites of Identity*, and (c) *The Synthesis of Wholes*.

Holism

Holism has already been discussed with respect to the Process-Relational synthesis of Organicism and Contextualism and, more specifically with respect to ontological face of holism. Now holism is presented, as mentioned above, as the epistemological first principle. To repeat, holism is the principle that the identities of objects and events derive from the relational context in which they are embedded. Wholes define parts and parts define wholes. The classic example is the relation of components of a sentence. Patterns of letters form words and particular organizations of words form sentences. Clearly, the meaning of the sentence depends on its individual words (parts define whole). At the same time, the meaning of words is often defined by the meaning of the sentence (wholes define parts). Consider the word meanings in the following sentences: (a) The *party leaders* were *split* on the *platform*; (b) The *disc jockey* discovered a *black rock star*; and (c) The *pitcher* was *driven home* on a *sacrifice fly*. The meaning of the sentence is obviously determined by the meaning of the words, but the meaning of each *italicized* word is determined by context of the sentence it is in. Parts determine wholes, and wholes determine their parts (Gilbert & Sarkar, 2000).

Holistically, the whole is not an aggregate of discrete elements subject to a reduction to an ultimate foundation, but an organized system of parts, each part being defined by its relations to other parts and to the whole. Complexity in this context is *organized complexity* (Luhmann, 1995; Nicolis & Prigogine, 1989; von Bertalanffy, 1968a, 1968b), in that the whole is not decomposable into elements arranged in additive sequences of mechanistic cause–effect relations (Overton & Reese, 1973). In the context of holism, principles of splitting, foundationalism, and atomism are, by definition, rejected as meaningless approaches to analysis, and fundamental antimonies are similarly rejected as false dichotomies (see Table 2.1). In an effort to avoid *standard* (i.e., neopositivistic and conventionalist) misunderstandings here, it must be strongly emphasized that *nondecomposability does not mean that analysis itself is rejected*. It means that *analysis of parts must occur in the context of the parts' functioning in the whole*. It is difficult to overemphasize this point, as the most shopworn and illegitimate criticism of holism, repeated again and again, is the notion that if one accepts holism then one is committed to examine everything simultaneously. This assumption is simply false and it has always been false.

What is true is that the *context-free specifications* of any object, event, or process—whether it be a DNA, molecule, cell, neuron, evolution, the architecture of mind, or culture—is illegitimate within a holistic system (see, e.g., Ingold, 2000, 2004). Bunge (2003) nicely captures both the problem of reductionism and the issue of holism in the following:

> At first sight, the discovery that genetic material is composed of DNA molecules proves that genetics has been reduced to chemistry.... However, chemistry only accounts for DNA chemistry: it tells us nothing about the biological functions of DNA—for instance that it controls morphogenesis and protein synthesis. In other words, DNA does not perform

> any such functions when outside a cell, anymore than a stray screw holds anything together. Besides, DNA does nothing by itself: it is at the mercy of the enzymes and RNAs that determine which genes are to be expressed or silenced. In other words, the genetic code is not the prime motor it was once believed to be. This is what epigenesis is all about. (p. 138)

Although holism is central to the Process-Relational paradigm, holism does not, in itself, offer a detailed program for resolving the many dualisms that have framed scientific knowing and knowledge. A complete relational epistemological program requires principles according to which the individual identity of each concept of a formerly dichotomous pair is maintained, while simultaneously it is affirmed that each concept constitutes, and is constituted by, the other. This understanding is accomplished by considering identity and differences as two *moments of analysis*. The first moment is based on the principle of the *identity* of opposites; the second moment is based on the principle of the *opposites* of identity.

Identity of Opposites

The principle of the identity of opposites establishes the *identity among parts* of a whole by casting them not as exclusive contradictions as in the split epistemology but as differentiated polarities (i.e., coequals) of a unified (i.e., indissociable) inclusive matrix—as a *relation*. As differentiations, each pole is defined recursively; each pole defines and is defined by its opposite. In this identity moment of analysis, the law of contradiction is suspended and each category contains and, in fact, *is* its opposite. Further—and centrally—as a differentiation, this moment pertains to character, origin, and outcomes. The character of any contemporary behavior, for example, is 100% nature because it is 100% nurture; 100% biology because it is 100% culture. There is no origin to this behavior that was some other percentage—regardless of whether we climb back into the womb, back into the cell, or back into the DNA—nor can there be a later behavior that will be a different percentage.

There are a number of ways to illustrate this principle; as discussed earlier in this chapter, a particularly clear illustration is shown in the schematic sketch of hands drawing hands (see Figure 2.4). As a reminder, this sketch shows a left and a right hand assuming a relational posture according to which each is simultaneously drawing and being drawn by the other. In this matrix, there is a sense in which each hand is different (opposite left and right hand) and a sense in which the hands are identical (each is drawing and being drawn). It is in the latter analytic *Identity of Opposites* moment, that the hands are identical (i.e., A = Not A), and thus they are coequal and indissociable. This moment of analysis is one in which the law of contradiction (i.e., not the case that A = Not A) is relaxed and identity (i.e., A = Not A) reigns. In this identity moment of analysis, pure forms or the notion of *natural kinds* collapse and categories flow into each other. Here, each category contains, and is, its opposite. As a consequence, there is a broad inclusivity established among categories.

The justification for the claim that a law of logic—for example, the law of contradiction—can reasonably both be applied and relaxed depending on the context of inquiry requires a recognition that the laws of logic themselves are not immutable and not immune to background ideas. In some metatheoretical background traditions (i.e., epistemological Realism), the laws of logic are understood as immutable realities given either by a world cut off from the human mind or by a prewired mind cut off from the world. However, in the background tradition currently under discussion (i.e., epistemological Constructivism) the traditional laws of logic are themselves ideas that have been constructed through the reciprocal action of human minds and world. The "laws of logic" are simply pictures that have been drawn or stories that have been told. They may be good pictures or good stories in the sense of bringing a certain quality of order into our lives, but, nevertheless, they are still pictures or stories, and it is possible that other pictures will serve us even better. Whitehead (e.g., 1922/1978) often complained that we have become prisoners of Aristotelian classificatory logic. Wittgenstein, whose later works focused on the importance of background or what we are calling *metatheoretical ideas*, made this point quite clearly when he discussed another law of logic—the law of the excluded middle—as being one possible *picture* of the world among many possible pictures.

> The law of the excluded middle says here: It must either look like this, or like that. So it really . . . says nothing at all, but gives us a picture. . . . And this picture *seems* to determine what we have to do and how—but it does not do so. . . . Here saying "There is no third possibility" . . . expresses our inability to turn our eyes away from this picture: a picture which looks as if it must already contain both the problem and its solution, while all the time we *feel* that it is not so. (1953, para. 352)

Within the identity moment of analysis, it is often a useful exercise to write on each hand one of the bipolar terms of

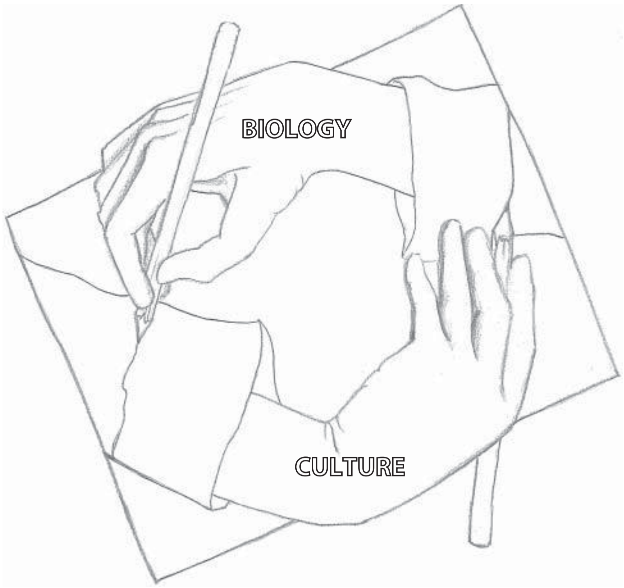

Figure 2.7 A schematic sketch of hands drawing hands demonstrating the indissociable relation between biology and culture. An *Identity of Opposites*.

the Cartesian split dualisms (mentioned earlier were *differentiation* and *integration;* others include, e.g., *genotype* and *phenotype*; *development* and *evolution*; *subject* and *object*; *biology* and *culture*) and to explore the resulting effect (see, for example, Figure 2.7). This exercise is quite different than an illustration of a familiar bidirectionality of mechanical cause and effects. This exercise makes tangible a central tenet of the relational metatheory; seemingly dichotomous ideas often thought of as competing alternatives (see Table 2.1) can, in fact, enter into inquiry as coequal and indissociable. This exercise also concretizes the meaning of *causality* as used within the Process-Relational framework. In this framework, the concepts of *reciprocal determination* (Overton & Reese, 1973), *coaction* (Gottlieb et al., 2006), *fusion* (Greenberg, 2011; Partridge, 2011), as well as *relational bidirectional* (←→) *causality* (Lerner, 2006), *relational causality* (Gottlieb, 2003), and *circular and downward causality* (Witherington, 2011), are relatively similar terms used to differentiate the positive and negative feedback loops of the Process-Relational worldview from additive (even bidirectionally additive) efficient causality of the Cartesian-Split-Mechanistic worldview.

The principle of the Identity of Opposites imposes theoretical and methodological constraints on any field of inquiry—biological, evolutionary, individual, and cultural—just as other metatheories impose constraints on any field of inquiry. The primary constraints within the Process-Relational metatheory are that (a) splits are not permitted (e.g., the split of genotype and phenotype in genetics, the split of internalism and externalism in the Modern Synthesis, the split of brain, body, and culture in cognitivism, and the cultural split of individual and culture) and (b) phenomena cannot be thought of as being decomposable into independent and additive pure forms (e.g., the Fisher–Wright AVOVA model in genetics and in the Modern Synthesis).[6]

If the principle of the Identity of Opposites introduces constraints, it also opens possibilities. One of these is the recognition that—to paraphrase Searle (1992)—the fact that a behavior implicates activity of the biological system does not imply that it does not implicate activity of the cultural system, and the fact that the behavior implicates activity of the cultural system does not imply that it does not implicate activity of the biological system. In other words, the Identity of Opposites establishes the metatheoretical rationale for the theoretical position that biology, person, and culture operate in a truly *interpenetrating relational* manner.

Opposites of Identity

Although the Identity of Opposites sets constraints and opens possibilities, it does not in itself set a positive agenda for empirical scientific inquiry. The limitation of the identity moment of analysis is that, in establishing a flow of categories of one into the other, a stable base for inquiry that was provided by bedrock material *atoms* of the Cartesian-Split-Mechanistic metatheory is eliminated. In the split approach, no relativity entered the picture; all was absolute. Reestablishing a *stable base*—not an absolute fixity, nor an absolute relativity, but a *relative relativity* (Latour, 1993)—within Process Relational metatheory requires moving to a second moment of analysis. This is the *oppositional moment where the figure of identity and the ground of opposites reverses, and opposites become figure*. This moment—the Opposites of Identity—becomes dominated by a *relational exclusivity*.

[6]West-Eberhard's (2003) evolutionary work provides a biological example of the identity of opposites in her resolution of the conflict between the quantitative genetics of continuous variation and the developmental biology of discrete traits. This resolution is "a theory of the phenotype based on the *complementarity* of continuous and discrete variation" (p. 13; emphasis added). All antimonies are best viewed as complementaries. The Process-Relational metatheory articulates the meaning of *complementarity*.

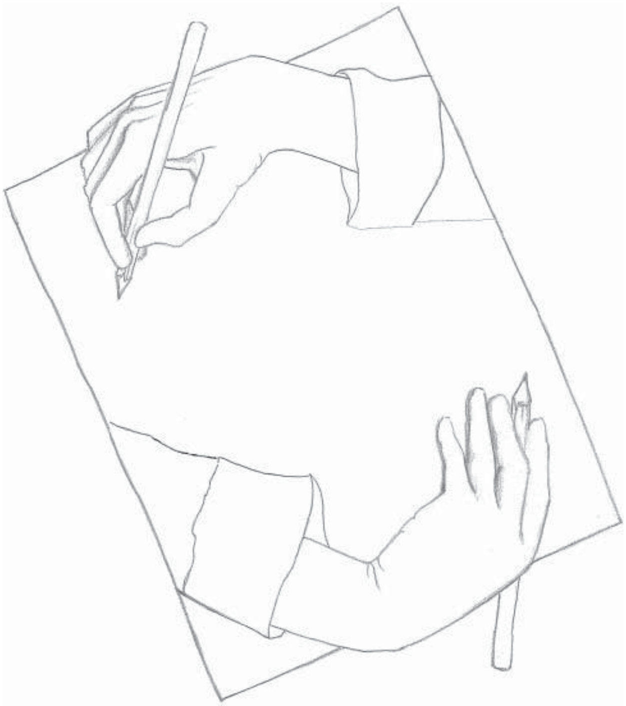

Figure 2.8 A schematic sketch drawing hands separated. *Opposites of Identity*—constituting standpoints, points-of-view, lines-of-sight.

Thus, in this oppositional moment of analysis, it becomes clear that despite the earlier identity, the hand sketch does illustrate both a *right* hand and a *left* hand (see Figure 2.8). In this moment of opposition, the law of contradiction is reasserted and categories again exclude each other. As a consequence of this exclusion, parts exhibit *unique* identities that differentiate each from the other. These unique differential qualities are stable within any holistic system and, thus, may form relatively stable platforms for empirical inquiry. The platforms created according to the principle of the Opposites of Identity become *standpoints, points-of-view,* or *lines-of-sight,* in recognition that they do not reflect absolute foundations (Latour, 1993, 2004) but perspectives in a *multiperspective world*. See Figure 2.8.

Again, looking back to the hand sketch designating the relational Biology-Culture (see Figure 2.7), when left hand as left hand and right as right are in relation but separately the focus of attention, it then becomes quite clear that, were they large enough, one could stand at either hand and examine the structures and functions of that location, as well as its relation to the other location (i.e., the *coactions* of parts). Thus, to return to the example of nature–nurture, although explicitly recognizing that any behavior is both 100% biology and 100% culture, alternative points of view permit the scientist to analyze the acts of the person from a *biological* or from a *cultural standpoint*. Biology and culture no longer constitute competing alternative explanations; rather, they are two points of view on an object of inquiry that has been created by, and will be fully understood only through, multiple viewpoints. More generally, *the unity that constitutes nature, the organism, and development becomes discovered only in the diversity of multiple interrelated lines of sight*.

Synthesis of Wholes

Engaging fundamental bipolar concepts as relatively stable standpoints opens the way, and takes an important first step toward establishing a broad stable base for empirical inquiry within Process-Relational Metatheory. However, this solution is incomplete as it omits a key relational component, the relation of parts to the whole. The oppositional quality of the bipolar pairs reminds us that their contradictory nature still remains, and still requires a resolution. Further, as discussed, the resolution of this tension cannot be found in the Cartesian-Split-Mechanistic approach of reduction to a bedrock absolute Real. Rather, the Process-Relational approach to a resolution is to move away from the extremes to the center and above the conflict, and there discover a novel system that will *coordinate* the two conflicting systems. This principle is the *Synthesis of Wholes*, and the synthesis that emerges itself becomes yet another standpoint in this multiperspective mode of understanding.

The synthesis of interest for the general metatheory would begin from a system of opposites that would constitute the most universal bipolarity that can be imagined. Arguably, there are several candidates for this level of generality, but the polarity between the *physical*, on the one hand, and *society*, on the other, is sufficient for present purposes (Latour, 1993). The physical and society represent systems that stand in an Identity of Opposites. To say that an object is a social or cultural object in no way denies that it is physical; to say that an object is physical in no way denies that it is social or cultural. And further, the object can be analyzed from either a social-cultural or a physical standpoint. The question for synthesis becomes the question of *what new system will coordinate these two systems*. Arguably, the answer is that it is *life* or living systems that represent the coordination of the physical and sociocultural. Because our specific focus

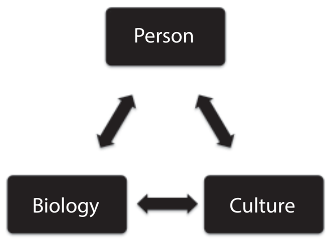

Figure 2.9 *Synthesis of Wholes*. Three of multiple possible standpoints.

of inquiry is the psychological subject, we can reframe this physical-societal polarity back into a nature–nurture polarity of *biology* (physical) and *culture*. If we again write *biology* on one, and *culture* on the other drawing hands schematic (see Figure 2.7), and question what system represents the coordination of these systems, it is life, the living organism, the *person* (see Figure 2.9). That is, within a psychological perspective, the person is the relational synthesis of biological and sociocultural processes.

At the synthesis, then, a standpoint coordinates and resolves the tension between the other two components of the relation. This particular synthesis provides a broad and stable base for launching empirical inquiry. A *person standpoint* opens the way for the empirical investigation of universal dimensions of psychological structure–function relations (e.g., processes of perception, thought, emotions, values), the particular variations associated with these wholes, their individual differences, and their development across the life span. Because universal and particular are themselves relational concepts, no question can arise here about whether the focus on universal processes excludes the particular; it clearly does not as we already know from the earlier discussion of relations. The fact that a process is viewed from a universal standpoint in no way suggests that it is not situated and contextualized; the fact that it is viewed from an individual standpoint in no way denies its universality.

It is extremely important to recognize that one standpoint of synthesis is relative to other synthesis standpoints. *Life and Society* are coordinated by the *Physical*. As a consequence, if we are broadly considering the scientific field of psychology, *biology* represents a standpoint as the synthesis of person and culture (see Figure 2.9). The implication of this idea is that a relational biological approach to psychological processes investigates the biological conditions and settings of psychological structure–function relations and the actions they express. This exploration is quite different from split foundationalist Cartesian-Split-Mechanistic approaches to biological inquiry that assume an atomistic and reductionistic stance toward the object of study. Neurobiologist Antonio Damasio's (1994, 1999) work on the brain–body basis of a psychological self and emotions presents an excellent illustration of this biological relational standpoint. In the context of this standpoint, Damasio (1994) is emphatic that:

> A task that faces neuroscientists today is to consider the neurobiology supporting adaptive supraregulations [e.g., the psychological subjective experience of self] . . . I am not attempting to reduce social phenomena to biological phenomena, but rather to discuss the powerful connection between them. . . . Realizing that there are biological mechanisms [sic] behind the most sublime human behavior *does not imply a simplistic reduction* to the nuts and bolts of neurobiology. (pp. 124–125; emphasis added)

A similar biological example comes from the Nobel laureate neurobiologist Gerald Edelman's (1992, 2006) work on the brain–body base of consciousness:

> I hope to show that the kind of reductionism that doomed the thinkers of the Enlightenment is confuted by evidence that has emerged both from modern neuroscience and from modern physics. . . . To reduce a theory of an individual's behavior to a theory of molecular interactions is simply silly, a point made clear when one considers how many different levels of physical, biological, and social interactions must be put into place before higher order consciousness emerges. (Edelman, 1992, p. 166)

And finally, to return in the present context to a point made earlier, Gilbert and Epel (2009), in presenting ecological developmental biology (eco-devo), describe several "revolutions" occurring in biology, including a new relational orientation: "Rather than analyzing independent 'things' a new focus of developmental biology concerns '*relationships*.' Nothing, it seems, exists except as part of a network of interactions" (p. xiii; emphasis added).

A third synthesis standpoint recognizes that *Person and Physical* are coordinated by *Society*, and again granting that our domain of scientific interest is psychological (i.e., inquiry about psychological processes), then *culture* or *sociocultural* represents a standpoint as the synthesis of *person* and *biology* (see Figure 2.9). Thus, a relational cultural approach to psychological processes explores the cultural conditions and settings of psychological structure–function relations. From this *cultural standpoint*, the focus is on cultural differences in the context of psychological functions as complementary to the person standpoint's focus on psychological functions in the context of cultural differences.

Valsiner (1998) gives one illustration of a relational, developmentally oriented *cultural standpoint* in his examination of the "social nature of human psychology." Focusing on the "social nature" of the person, Valsiner stresses the importance of avoiding the temptation of trying to reduce person processes to social processes. To this end, he explicitly distinguishes between the *dualisms* of split foundationalist metatheory and *dualities* of the relational stance he advocates.

When the three points of synthesis—biology, person, and socioculture—are cast as a unity of interpenetrating coacting processes, there emerges what Greenberg and Partridge (2010) describe as a *biopsychosocial* model of the organism. But it is important to note that synthesis of wholes is not limited to only three. For example, *discourse or semiotics* may be taken as a synthesis of *person* and *culture* (Latour, 1993). In this case biology and person are conflated and the biological/person and culture represents the opposites of identity that are coordinated by discourse. The point of greatest significance is that it is in the synthesis of wholes, of however many can be generated, that we find the justification for *Multiple perspectives* or *standpoints* as a replacement for the *Cartesian*-Split perspectives of *Objectivism vs. Subjectivism.*

Explanation and Understanding

Explanation and understanding are properly epistemological topics. It would take, and has taken, volumes (e.g., see, Bunge, 1979; von Wright, 1971) to come close to adequately discussing this central yet unresolved feature of knowing generally, and scientific knowing specifically. Here only a hint of an outline can be presented (see Overton, 2006, 2014, for more extended discussions).

In the Cartesian-Newtonian materialist approach, explanation, as discussed earlier, is *mechanical explanation*, which proceeds according to the rules of (a) reduction, (b) finding the "forces," and (c) inductively generalizing the law. In finding the forces, Newton limited explanation to ontological *efficient* cause. The meaning of this cause comes from Aristotle as "the original source of change or rest. For example, . . . a producer causes a product and a changer causes a change" (*Physics*, Book II, 3). As Bunge (1979) points out,

> What must now be stated is the peculiarity of mechanics and mechanistic philosophy with regard to the causal problem, namely, the reduction of *cause to force* . . . . It was Newton who enlarged the notion of force, the mechanical representative of cause. . . . In short what was peculiar to both mechanics and mechanistic philosophy, from Galileo to the Newtonians, was not causality but . . . *mechanical causality* as contrasted to the richer but chimerical forms of causation imagined by Aristotle. (p. 108)

At this point, in embracing a Process-Relational worldview we have moved from a mechanical to an organic understanding of nature, and there is no room for mechanical causality in this understanding. As Schelling (1803/1988) pointed out,

> As soon as we enter the realm of the *organic nature* all mechanical linkage of cause and effect ceases for us. Every organic product exists *for itself*. . . . The organic . . . produces *itself*, arises *out of itself* . . . . Every organic product carries the reason of its existence in itself, for it is cause and effect of itself. No single part could arise except in this whole, and this whole itself consists only in the *interaction* of the parts. . . . It *organizes itself* . . . . Not only its form but its *existence* is purposive. It could not organize itself without already being organized. The plant nourishes itself and subsists through assimilation of external matter, but it can assimilate nothing to itself unless it is already organized. (pp. 30 –31)

Keeping in mind that actual entities like food, water, parents, siblings, and communities constitute the process-relational context or greater whole, within which the individual organism develops, these actual entities come to constitute *resources, assests,* or *affordances* (Good, 2007) for the further becoming of organization. They are not, however, efficient causes.

Structure-Function Explanation. With the elimination of mechanical efficient cause, and its close relative, material cause ("that from which a thing is made"), any causal understanding of process is limited to Aristotle's formal ("the form or pattern") and final ("what the happening is for") (*Physics*, Book II, 3) explanatory forms.

Formal explanation has already been mentioned in connection with necessary organization and structure-function relations. Taking the psychological person as an example, this organized actual entity (structure of processes) (our vertical dimension of Process-Relational) acts in the world (function of structure) (our horizontal dimension). The act itself is successful or unsuccessful in achieving a goal (reaches a *satisfaction*, for both Pepper and Whitehead). If unsuccessful, then variations arise and, perhaps, there is an emergent novel act (take the car rather than walk to the store). The degrees of success/nonsuccess feeds back to the person and to some degree the structure changes to accommodate this feedback (e.g., see Schneirla's, 1957, concept of *circular functions and self-stimulation in ontogeny*). As this process repeats and repeats, the structure of the person changes to the point that a novel integration emerges and the actions operate within the novel structural pattern. A concrete example is that of the infant with a sensorimotor structure of action searching for and attaining a hidden object. Novel actions emerge such a removing a cover to attain the object. Based on the repetition of many varied sensorimotor actions in many different problem contexts a novel vertical structural integration emerges, which may be described as thinking.

Aristotle's *final explanation* enters in two ways. Following Brentano, James, Dewey, and Whitehead, all acts, even those at the most basic sensorimotor level have an intention, aim, direction, goal, satisfaction. Thus, all of nature is the passage of nature directed toward an end. This view is final explanation with respect to the horizontal dimensions of external acts. Along with this becoming there is also a necessary becoming from potential to actual along the vertical or person dimension. Whether from fetus to late adulthood, or from global and lack of differentiation to differentiation and hierarchical integration, again, all of nature is the passage of nature directed toward an end.

The Process-Relational approach, thus, introduces *multiple explanatory types* substituting for the single Newtonian efficient cause. There is, in fact, a reasonable argument that the term causality be dropped from the vocabulary of science. Thus, Miller (2010) suggests that in place of *causality* we use "perhaps with less baggage, *explanation*, or even just discoveries of regularities in nature" (p. 725), while Redhead (1990) goes further and argues against the need for the concept of causality at all in science. *Causality* is confusing and arguments for its elimination have merit. Even those causal concepts associated with the Process-Relational approach—*relational bidirectional causality*, *relational causality*, *circular* and *downward causality*—could readily be eliminated in favor of structure-function analyses where these ideas divide into systems investigations (formal explanation) and becoming or becoming investigations that examine transitions from one form to the next.

Resources and Conditions. There are two further features of explanation within a Process-Relational approach that requires mention. The first is simply to point out that the notions of resources, assets, and affordances do not constitute sufficient conditions for the process of becoming. Resources, assets, and affordances may be conditions that facilitate the optimization or the retardation of the becoming process, but as will be described next, they are not sufficient conditions of the process.

For the second point, it will be recalled that Whitehead (1929/1978), in discussing an event as a process of becoming, described the event as having a past, present, and future. The present entails anticipation of the future (formal and final explanation), whereas the past entails the necessary conditions of the present. This idea means that once we grant with Schelling (1803/1988) that, "the organic . . . produces *itself*, arises *out of itself*" (p. 30), we have found the sufficient reason for becoming (i.e., the action of the process itself). As a consequence logically the search for sufficient conditions (or causes) must cease. One of the most eminent methodological developmental scientists of the 20th century, Joachim Wohlwill (1973), expressed this fact as follows:

> Once we grant the existence of "normal developmental processes," that is, acting independently of *particular* specifiable external agents or conditions, there follows a much more far-reaching consequence. That is that we can only hope to isolate necessary, rather than sufficient . . . [conditions] i.e., those without which we can assert development does not take place, rather than those thanks to which it does take place. (p. 319)

The final conclusion to be drawn is that with respect to explanation and understanding there are three primary tasks to be undertaken. First there are the structure-function analyses, which will entail system modeling; second there is the enquiry into the necessary conditions associated with the process of becoming; and third there is the enquiry into resources, assets, and affordances that facilitate the optimization or the retardation of the normal process of becoming.

To this point the ontological and epistemological categories of the Cartesian-Split-Mechanistic and the Process-Relation worldviews or metatheories have been compared and contrasted (see Table 2.2 for a summary) and several Cartesian metatheories of the middle range have been described. The chapter now turns to a presentation and discussion of a broad middle-range metatheory constructed within the conceptual frame of the Process-Relational metatheory: Relational-Developmental-Systems.

TABLE 2.2 A comparison of the ontological and epistemological categories of the Process-Relational and Cartesian-Split-Mechanistic metatheories.

Worldviews	
Process-Relational	**Cartesian-Split-Mechanistic**
Ontological Categories	
Holism	Atomism
Activity	Fixity
Nature as Process	Nature as Substance (Matter)
Change—Becoming	Stasis—Being
Dialectic	
Necessary Organization	Uniformity
Structure-Function Relations	
Pluralistic Universe	Dualistic/Monistic Universe
Epistemological Categories	
Holism	Reductionism
Constructivism	Realism
Relational Understanding	Split Understanding
Identity of Opposites	
Opposites of Identity	
Synthesis of Wholes	
Multiple Standpoints of Analysis	Objectivism vs. Subjectivism
Multiple Forms of Explanation	Efficient/Material Causal Explanation
Formal Explanation	
Structure-Function	
Final Explanation	
Necessary Conditions	

RELATIONAL-DEVELOPMENTAL-SYSTEMS

Taken as a whole—including both ontological and epistemological assumptions—Process-Relational metatheory operates as the contextual frame for the construction of middle-range metatheories. As discussed earlier, middle-range metatheories are less broad in scope, more specific to particular domains of inquiry, and together with a worldview metatheory, constitute a *conceptual framework* for a scientific paradigm. Relational-Developmental-Systems is the most inclusive of several middle-range metatheories that are contextualized by the Process-Relational metatheory, and all of these middle-range metatheories incorporate systems concepts—including developmental, dynamic (Witherington, Chapter 3, this *Handbook*, this volume), psychobiological (Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume), dialectical, and transactional (Kuczynski & De Mol, Chapter 9, this *Handbook*, this volume), systems, as well as a model termed *enaction* (Stewart et al., 2010).

It is important to note that there is *no* Relational-Developmental-Systems *theory*; Relational-Developmental-Systems is a metatheory (see Figure 2.2). There are, however, theories that are informed by Relational-Developmental-Systems and, hence, one might say that there are *relational developmental systems theories*. Also, it is the case that the actual entity that develops is the *relational developmental system*. Relational-Developmental-Systems represents an extension (Lerner, 2006, 2012a; Lerner & Benson, 2013; Lerner & Overton 2008, 2014; Overton, 2006, 2010, 2013a, 2013b; Overton & Lerner, 2012, 2014) of the original developmental systems "theory" described by Ford and Lerner (1992) and Gottlieb (1996) (see also, Lerner, 2002). This extension was motivated by an increasing recognition of the Process-Relational worldview as a central component of the conceptual framework of this alternative scientific paradigm to that formulated within the Cartesian-Split-Mechanistic worldview.

The broad aims of Relational-Developmental-Systems coincide with the aims of contemporary Developmental Science, which are "to describe, explain, and optimize intrandividual changes in adaptive developmental regulations as well as interindividual differences in such relations across life" (Lerner, 2012a, p. 29). As noted early in this chapter, deriving from the ontological and epistemological Process-Relational categories, Relational-Developmental-Systems as metatheory characterizes the living organism as an *inherently active, self-creating (autopoetic, enactive), self-organizing, and self-regulating, relatively plastic, nonlinear complex adaptive system*. The system's development occurs through its own *embodied activities and actions* operating *coactively* in a lived world of physical and sociocultural objects, according to the principle of *probabilistic epigenesis*. This development leads, through positive and negative feedback loops created by the system's organized embodied action, to increasing system differentiation, integration, and complexity, directed toward adaptive ends.

The Process-Relational-System and Developmental Process

Relational-Developmental-Systems takes a life-span approach to the scientific study of *systematic intraindividual changes*—from conception to the end of life—of an organism's behavior, and of the systems and processes involved in those changes and that behavior. This approach encompasses the study of several categories of change such as ontogenesis (development of the individual across the life span), embryogenesis (development of the embryo), orthogenesis (normal development), pathogenesis (development of psychopathology), and microgenesis (development on a very small time scale such as development of a single precept). But the approach is also comparative and, thus, includes the study of phylogenesis and evolution (development of the species), as well as historical and cultural development.

Intraindividual change processes constitutes the fundamental defining feature of development, but it is important to immediately emphasize that not all change is necessarily developmental change. Developmental change processes and the relational developmental system itself entails six necessary defining features: (1) *organization of processes* (also termed *structure* and *system*); (2) *embodiment;* (3) *order* and *sequence*; (4) *direction*; (5) *epigenesis* and *emergence*; and (6) *relative permanence* and *irreversibility*. These features frame two broad forms of change that traditionally have been considered developmental, but have also at times been considered competing alternative definitions of developmental change—transformational change (i.e., morphological change or change of form) and variational (the degree or extent that a change varies from a standard, norm, or average) (see Ram & Grimm, Chapter 20, this *Handbook*, this volume, for an extended methodological discussion of transformational and variational change).

Transformational and Variational Change

Understanding the place of transformational and variational change in development requires a type-token distinction, which is also a distinction between structure and content. Perception, thinking, memory, language, affect, motivation, and consciousness are *universal* psychological processes (*types*), characteristic of the human species as a whole. Any given percept, concept, thought, word, memory, emotion, or motive represents a *particular expression* of a universal process (*tokens*). Although each form of change is entailed by any behavioral act, transformational change primarily concerns the acquisition, maintenance, and retention, of *universal* processes (types), whereas variational change primarily concerns the acquisition, maintenance, retention, or decline of *particular* expressions (tokens) and individual differences in expressions.

Historically, within the Cartesian-Split-Mechanistic paradigm transformational and variational change were considered competing alternative for the term *development*. From a Process-Relational perspective this competition is unnecessary and unwise. The two types of change constitute a whole reflecting two coequal and indissociable complementary processes. This solution claims a reality in which the processes assume differentiated functional roles, but each process in itself explains and is explained by the other. Put simply, the relational developmental system acts, acts show variation, and variations feedback to the system, which leads to transformation of the system (see Figure 2.10 and refer back to Figure 2.5) (Overton & Ennis, 2006). Any relational developmental system by its nature produces acts consistent with the structure of the system (flies produce fly acts; pigeons, pigeon acts; and humans, human acts). *Acts are embodied actions in the world, and they succeed or fail to various degrees in attaining their intended goals*. Partial success feeds back to the system, which uses the feedback as a resource in changing (transforming) the system. The transformed system, in turn, produces further variants of the act. Thus, all development entails cyclical movements between transformation and variation that result in increasing complexity of the system and increasingly refined variants (Gestsdóttir & Lerner, 2008; Overton, 2006). As Demetriou, Mouyi, and Spanoudis (2010) state,

> The relations between the general and the specialized processes are complex and bidirectional. On the one hand, general processes set the limits for the construction, operation, and development of the domain-specific systems. On the other hand, specialized processes provide the frame and raw material for the functioning of general processes. (pp. 322)

This relational solution clarifies the *de facto* situation that much of the research in developmental science currently takes place at one or the other pole of the whole, and the solution encourages an integrated vision for future study.

At this point the six defining features of developmental change processes and the relational developmental system will be examined in detail.

Organization of Processes: System

Developmental change entails change in the form, organization, or structure of a system. In the case of ontogenesis, the system is the living organism, whereas subsystems consist of cognitive, affective, and motivational (i.e., psychological) processes together with their biological correlates. Embryological changes constitute some of the clearest and most concrete examples of transformational or morphological change (Edelman, 1992; Gottlieb, 1992).

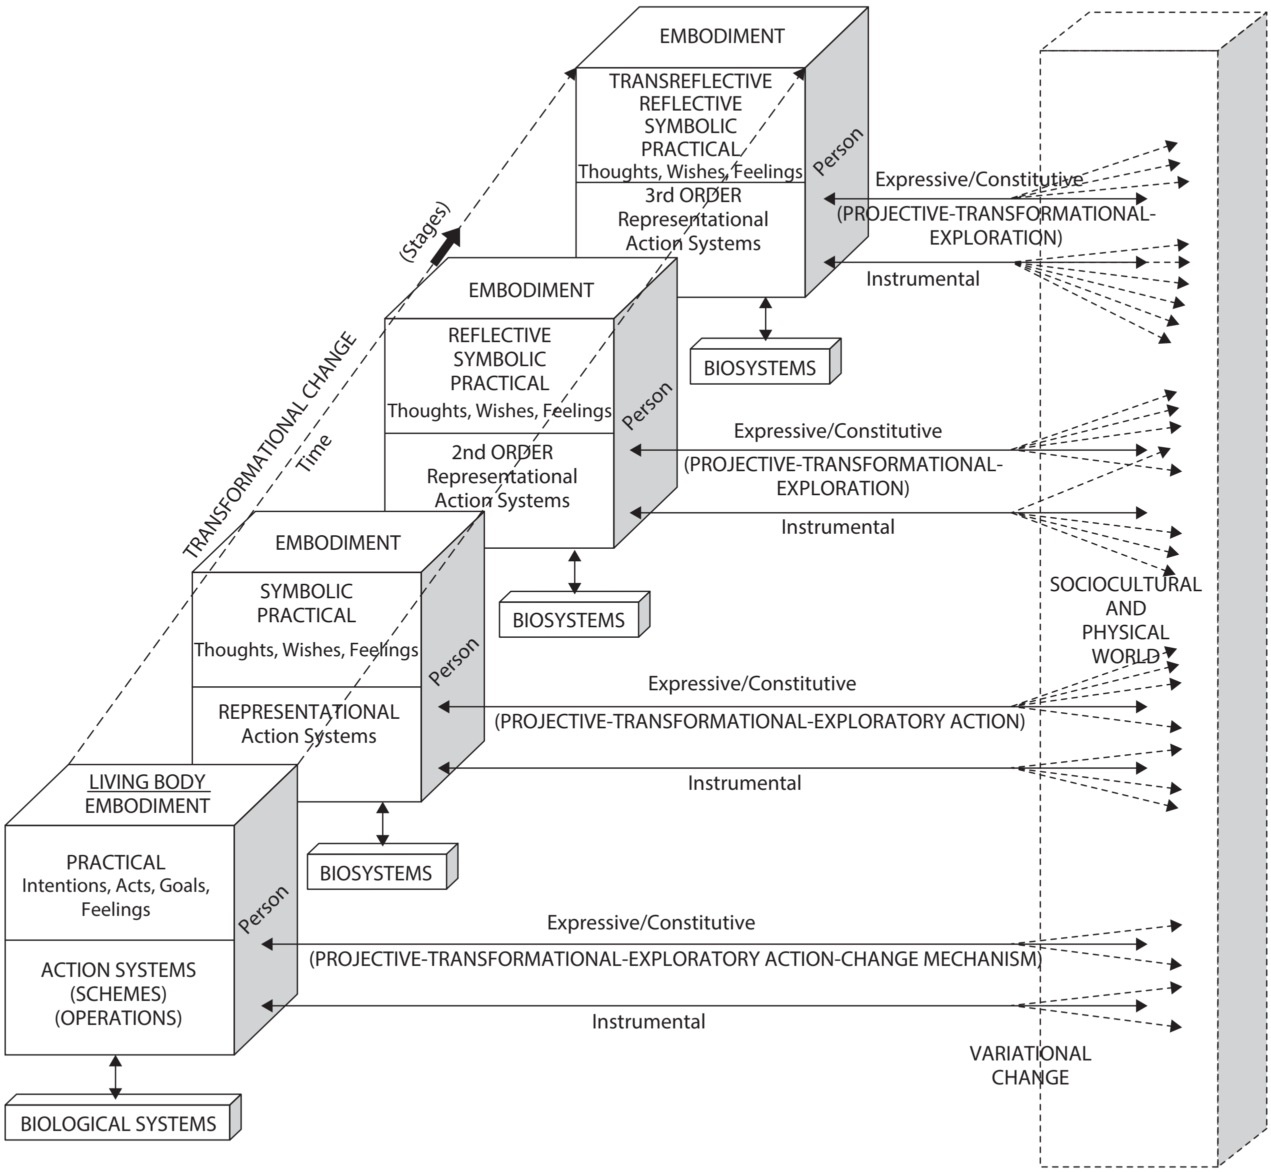

Figure 2.10 Synthesis of transformational and variational developmental change. Acts (expressive/constitutive/instrumental) emerge from embodied systems, aim at completion-satisfaction. Blocking of satisfaction results in variational acts, which feedback to system leading to transformational change. Bottom half of cubes at left represent *subpersonal system* concepts; top half of cubes represent *psychological* concepts.

Through processes of differentiation and reintegration, movement occurs from the single-celled zygote to the highly organized functioning systems of the 9-month fetus. Some cognitive and social-emotional phenomena of human ontogenesis have also been conceptualized as reflecting transformational change.

For example, sensorimotor action undergoes a sequence of transformations to become symbolic thought, and further transformations lead to a reflective symbolic thought exhibiting novel logical characteristics (see Mascolo & Fischer, 2010, Chapter 4, this *Handbook*, this volume; Sokol, Hammond, Kuebli, & Sweetman, Chapter 8, this *Handbook*, this volume). Memory may reflect transformational changes moving developmentally from recognition memory to recall memory. The sense of self and identity (Chandler, Lalonde, Sokol, & Hallett, 2003; Damon & Hart, 1988) has been portrayed by some as moving through a sequence of transformations. Emotions have been understood as differentiations from an initial relatively global affective matrix (Sroufe, 1979). Physical changes, such as changes in locomotion, have also been conceptualized as transformational changes (Thelen & Smith, 2006). Again, it requires emphasis that all of this transformational change occurs in the context of the variational changes in the system's actions

Developmental change implies an entity that is changed. Under the dominance of the Cartesian-Split-Mechanistic paradigm—when developmental science could be conceived as a *discipline assuming substance rather than process as its ontological* base—the entity changed was simply observable behavior. At the core of neo-positivism and behaviorism, and strict Contextualism, observed behavior and its associations with biological and environmental variables formed the bedrock and exclusive context of inquiry. As a consequence, within these metatheoretical frames, it was possible to identify developmental change with variational behavioral change that was not relationally connected to any organization of processes. In fact, it was, and to a significant extent continues to be, an era in which the gold standard of developmental explanation was to find the *mechanism* (i.e., causal force) producing the behavior under consideration.

As developmental science has moved to a more relational stance—becoming a *process rather than a substance discipline*—it is the living, inherently active, open, self-creating, self-organizing, and self-regulating system of processes that constitutes the entity changed. *System* has been defined in various ways. For example, van Geert (2003) offers "any collection of phenomena, components, variables" (p. 655). However, this conception and other "collection" or aggregate-like definitions are inconsistent with holism and, consequently, inconsistent with Relational-Developmental-Systems. A more adequate relational definition of system is "a whole which functions as a whole by virtue of the interdependence of its parts" (Overton, 1975, p. 73). Thus, a system is by its nature a set of organized processes and this set is organized holistically. Further, the relational developmental system is an adaptive system. Here *adaptation* refers to how the system acts in the context of changing environments—*perturbations* in systems language, or *affordances*, assets, *resources*—so as to increase its probability of survival; not in the sense of *adjusting* to an environment. Adaptive systems are defined in contrast with *determined systems*. In determined systems, the relation between inputs and outputs are exactly and reproducibly connected. For example, an automobile is a determined system. When the driver presses the accelerator or turns the steering wheel, both driver and passenger expect the auto to speed up or turn. All components of the auto must be fully determined to achieve this collective response. And determined systems are linear in the sense that small inputs result in small outputs; large inputs in large outputs—thus, outputs are predictable. In adaptive systems, the parts follow simple rules, whereas the behavior of the whole system is not determined; it is probabilistic because it is a function of all of the timing of the relations among the interpenetrating events, including nonnormative events.

As an inherently active system, *the system acts*, and its acts, have the following characteristics: (a) acts and their variation express the underlying organization of the system (i.e., any act is *expressive*); (b) acts function as the means for communicating within the sociocultural world, while changing and being changed by both the sociocultural and the physical world (i.e., any act is *communicative/instrumental*); and (c) *acts constitute the basic change process* that, through coaction with the world, results in system's transformation. It is *the relational developmental system itself* that organizes and regulates itself through complex and multidirectional relational coactions with its biological, socio-cultural, and physical environmental subsystems (see Figure 2.10).

Embodiment

All acts are embodied acts, and consequently the general case is that it is not simply acts, but rather it is *embodied action* that *constitutes the fundamental process for all development change* (i.e., the *sufficient condition* of development). Embodiment represents the relationally interpenetrating processes among person, biology, and culture. It is the claim that perception, thinking, feelings, desires—*the way we behave, experience, and live the world*—is contextualized by our being *active agents* with this *particular kind of body* (Overton, 1994a, 1994b, 2008; Taylor, 1995). The kind of body we have is a constitutive precondition for having the kind of behaviors, experiences, and meanings that we have. Embodiment includes not merely the physical structures of the body but *the body as a form of lived experience, actively engaged with the world of sociocultural and physical objects*. The *body as form* references the biological standpoint, the *body as lived experience* references the psychological subject standpoint, and the *body actively engaged with the world* represents the sociocultural standpoint. Within a process-relational context, embodiment is a concept that bridges and joins in a unified whole these several research points of synthesis discussed earlier (see Figure 2.9).

Order and Sequence

The overt or observable embodied acts of a relational developmental system exhibit variations (e.g., there are many ways to reach for and grasp a cup), and these variations produce sequences. These behavioral sequences are *contingent* (i.e., under changed conditions can be different). However, change in the form or organization of the system itself exhibits a *necessary order* and *universal sequence* (e.g., the development of human *grasping*). Any complex living system is an adaptive system, and any adaptive system, if it is to survive and thrive, necessarily moves from lesser to greater levels of complexity. The transformations from zygote to embryo to fetus, to neonate, for example, are not contingent (although they entail contingent variable acts); they are universal, and could not be otherwise. Similarly, the transformation of a system characterized by sensorimotor functioning to a system characterized by complex reflective thought represents a necessary and universal ordered sequence.

Directionality

Any notion of order implies a *direction* to the change. That is, any ordered system implies an *orientation toward a goal* or end state (termed *attractors*, or *equilibria* in dynamic systems; Molenaar and Nesselroade, Chapter 17, this *Handbook*, this volume; Witherington, Chapter 3, this *Handbook*, this volume). The notion of a goal orientation (*telos*) has often befuddled and even frightened those developmental scientists who continue to be held in the grasp of the Cartesian-Split-Mechanistic approach. To talk of a *telos* seems to raise the worry of admitting a discredited teleology into the science. This fear is based on competing metatheoretical assumptions and conceptual confusions. One conceptual confusion concerns subjective versus objective teleology. Subjective teleology involves *subjectively* held *purposes, aims*, or *goals* (e.g., "I intend to become a better person") and is irrelevant to the definition of developmental change. Objective teleology, in contrast, involves the construction of principles or rules designed to explain (Aristotle's final explanation)—in the sense of making intelligible—phenomena under investigation (e.g., "the development of X moves from lack of differentiation to more equilibrated levels of differentiation and hierarchic integration"). The rule so constructed conceptually "finds" or "discovers" or "identifies" the sequential order and the end state. Any position that seriously embraces the Process-Relational and Relational-Developmental-Systems approach necessarily accepts both goal directedness and the fact that the specific goal articulated is a theoretical concept—not a slice of physical nature, nor the positing of an *entelechy*—designed to illuminate the nature of the developmental change under study.

It is simply a conceptual confusion to argue that adequate descriptions are more important than the positing of end points (e.g., Sugarman, 1987), or similarly to suggest a movement away from end points and toward "a more neutral, person-time-and-situation-geared conception of development" (Demetriou & Raftopoulos, 2004, p. 91). There is no "neutral" standpoint, and no description could possibly occur without a positing of endpoints. The question here is what one would possibly describe if one did not understand development as tending toward some specified end? If one wishes to describe/explain the course of acquiring language, then adult language is, of necessity, the end point toward which development moves. No "description" of the language of the child would be possible without this ideal end point. In a similar fashion, if one wishes to describe/explain the transformational development of reasoning, or thought, or problem solving, or personality, or anything, a conceptual end point must serve as the ideal ultimate model.

A related feature of this confusion over the positing of developmental end point arises from the mistaken notion that positing a goal or endpoint necessarily leads to an "adultomorphic perspective [that] forces one to view earlier behaviors and functions as immature versions of adult functions" (Marcovitch & Lewkowicz, 2004, p. 113). Central to this argument is its faulty assumption that all developmental change, including transformational change, is additive (linear, strict continuity) and, conversely, the failure to recognize that in relational developmental systems, nonlinearity (nonadditivity; discontinuity) is frequently the rule. For example, Piaget's interest in examining the development of the reasoning process from a Relational-Developmental-Systems perspective resulted in his identifying deductive propositional reasoning as the end point of inquiry; whether this was a good idea or a poor idea is irrelevant to the current argument. What is relevant is that Piaget described several quite different forms of reasoning (e.g., preoperational and concrete operational) that function as discontinuous precursors to this adult form, and these early forms are not simply immature versions of the adult function. Rather, they are qualitatively distinct forms of reasoning.

A final conceptual confusion is the notion—abroad for many years—that focusing on sequences and positing endpoints introduces rigidity and denies the *relativity plasticity* of development. This notion is quickly debunked by recognizing that the concept of *equifinality* (i.e., that there are multiple means to the same end) is a core concept of the relational developmental systems. Although each level of organization of the system is a part of the normative sequence moving toward a normative end, there are multiple means or action paths to each system level.

The centrality of an understanding of developmental processes of transformational/variational change—including the relational developmental system, embodiment, order, sequence, and directional characteristics—is meaningful only to the extent that the understanding of developmental science and scientific method in general have advanced beyond the Cartesian-Split-Mechanistic paradigm. It will be recalled from an earlier discussion, that this paradigm includes what has traditionally been termed *Newtonian mechanical explanation* according to which scientific explanation, and, hence, science itself, was ultimately reduced to the search for individual and additive observable forces that were taken as efficient *causes or mechanisms*. In the Process-Relational and Relational-Developmental-Systems paradigm, as mentioned earlier, any search for efficient causes or mechanical mechanisms is rejected. These are replaced by the identification of dynamic action *patterns*—both synchronously as actual action events and diachronically as organized, sequential, directional, relational developmental systems. This identification of action patterns and the processes they entail is logically prior to the identification of necessary conditions and resources for development. It is in fact the specific relational developmental system under investigation that defines both conditions and resources. To consider *genes*, *neurons*, *cultural objects*, *parents*, *peers*, or *neighborhoods* to be sets of additive mechanical causes that drive development is to miss the point that these are all resources and conditions that the relational developmental system itself uses to develop. It is the relational developmental system itself that is the cause of development—if we must use the word *cause*—and this system enacts development by engaging in a multitude of complex relational actions with these resources and conditions.

From a Cartesian perspective, these complex actions have been termed *interactions*, but that term is totally inadequate to describing the relational interpenetrations of coacting part processes that operate as the relational developmental system. In order to capture both the merging (or *fusion*; Greenberg & Tobach, 1984) of parts into a single identity, while maintaining their individual identity as differentiations, the terms *interpenetration* (merging) and *coaction* (←→) (Gottlieb et al., 2006) must be substituted in place of *interaction*, except in those cases that refer to a simple additive combination of elements, such as statistical interactions. At times—perhaps unfortunately—a relational process notion of causality as *reciprocal bi- or multidirectional* (←→) or circular (positive and negative feedback loops) are introduced. However, it is *imperative* that it be clearly understood that these bear no relation to mechanical efficient or material causes.[7]

Epigenesis and Emergence

The concept of *epigenesis* was originally introduced in biology by Waddington (Van Speybroeck, 2002) as a counter to the idea of *preformation* in the explanation of the appearance of increasingly organized complexity from a relatively undifferentiated egg to a highly differentiated organism. Although epigenesis has a long history with several twists and turns (see Lickliter & Honeycutt, 2010, Chapter 5, this *Handbook*, this volume), today, conceptualized relationally as *probabilistic epigenesis* (Gottlieb, 1992), the concept designates a *holistic* approach to understanding developmental complexity. *Probabilistic epigenesis* is the principle that the role played by any part process of a relational developmental system—gene, cell, organ, organism, physical environment, culture—is a function of all of the interpenetrating and coacting part processes of the system. It is through complex relational bidirectional and multidirectional reciprocal interpenetrating actions among the coacting part processes that the system moves to levels of increasingly organized complexity. Thus, epigenesis identifies the system as being completely *contextualized* and *situated; time and*

[7] An example of the confusion that results from the failure to make this distinction appears in the writings of Pigliucci and Müller (2010a) and Müller (2010). In discussions of new trends in evolution, these authors acknowledge the centrality of systems concepts, but simultaneously describe this as “a shift towards a causal-mechanistic approach . . . a shift . . . to a causal-mechanistic theory” (Pigliucci & Müller, 2010a, p. 12), and a “turn towards the mechanistic explanation of phenotypic change” (Müller, 2010, p. 309). There is a profound difference between the claim that there has been a trend away from correlational approaches, and the claim that there has been a trend away from correlational approaches and to *mechanistic* causal approaches.

place matter (Elder, 1998; Elder, Shanahan, & Jennings, Chapter 2, this *Handbook,* Volume 4). The contextualization of the system is important because it points to the necessity of exploring contextual processes as a part of the overall developmental research enterprise (Bronfenbrenner & Morris, 2006).

Epigenesis also points to a closely related feature of transformational/variational developmental change: *emergence*. Change in complexity results in the *emergence of system novelty*. As forms change, they become increasingly complex. This increased complexity is a complexity of pattern rather than a linear additive complication of elements. The butterfly emerges from the caterpillar through the differentiation and reintegration of organization, the frog from the tadpole, the plant from the seed, the organism from the zygote. In an identical fashion, higher order psychological structures emerge from lower order structures; also in an identical fashion, new patterns of organization exhibit novel characteristics that cannot be reduced to (i.e., completely explained by) or predicted from earlier forms. This impossibility of reduction asserts what Witherington refers to as ontological or *strong emergence* (Witherington, 2011; see also Blachowicz, 2012). The novel properties that emerge are termed *systemic*, indicating that they are properties of the whole system and not properties of any individual part process. This emergence of novelty is commonly referred to as *qualitative* change in the sense that it is change that cannot be represented as purely additive.

Similarly, reference to *discontinuity* in development is simply the recognition of emergent novelty, and qualitative change of a system (Overton & Reese, 1981). Concepts of *stages, phases*, and *levels* of development are theoretical concepts, which within a Process-Relational and Relational-Developmental-Systems paradigm reference transformational change together with the associated emergent novelty, qualitative change, and discontinuity. Each of the classic grand developmental theories of the 20th century—Piaget (1967), Vygotsky (1978), Werner (1958), and Erikson (1968)—acknowledged the centrality of nonlinearity and emergence: Piaget and Werner via their ideas of development proceeding through phases of differentiation and reintegration; Erikson through his epigenetic principle of development; Vygotsky in his argument that development is not "the gradual accumulation of separate changes . . . [but] a complex dialectical process characterized by . . . qualitative transformations of one form into another [with an] intertwining of external and internal factors" (1978, p. 73). Systemic emergence is not limited to homogeneous stages such as those offered by the grand theories. Mascolo and Fischer (2010) for example, in discussing *skill theory* describe development as an "emergent developmental web":

> The developmental web represents development in terms of a series of partially distinct pathways that, depending on developmental circumstances, move in different diverging or converging directions. Higher order psychological structures emerge from the integration or coordination of lower-level structures that develop along partially distinct trajectories. The splitting and converging of developmental trajectories is not something that can be specified or predicted a priori. (p. 163; see also Fischer & Bidell, 2006; Mascolo & Fischer, Chapter 4, this *Handbook*, this volume).

Relative Permanence and Irreversibility

A final feature of transformational change of a system is that it is not circular, transitory, or willy-nilly reversible. Transformational change particularly—system change—is relatively permanent, relatively irreversible. This eliminates sleep, digestion, going to the movies, and any behaviors that are readily extinguishable from the list of transformational changes. Although this attribute is generally a straightforward feature of transformational change, it raises an issue with respect to life-span development. If it were found empirically that there were declines in middle or late adulthood in behaviors associated with transformational systems (e.g., if the form of thinking deteriorated or regressed to an earlier form), would this change be considered something other than development? Would it be necessary to introduce two radically different processes into our life-span understanding such as *development* on the one hand and *aging* on the other? Not necessarily. The modifier *relatively* partially addresses this issue. And it might be possible to conceptualize the late adult years as having their own order, sequence, epigenesis, and permanence well into the late adult years (see Overton, 2010)

The description of the nature of the Relational-Developmental-System's active complex organism, along with the description and analysis of six other defining features of the Process-Relational system and developmental processes, essentially completes the task set out at the beginning of this chapter: A rethinking of the traditional Cartesian-Split-Mechanistic research paradigm and the offer of an alternative Process-Relational and Relational-Developmental-Systems paradigm.

WHEN VOCABULARY MATTERS

Although the main goal of the chapter has been achieved, there remains the knowledge that, even as we change sets of basic categories, we are often, as Searle (1992) suggested, still captives of the Cartesian vocabulary we have inherited and, as mentioned earlier in this chapter, the "vocabulary is not innocent, because implicit in the vocabulary are a surprising number of theoretical claims" (p. 31). In this final section, I describe some of the Cartesian vocabulary terms and their alternatives.

Avoiding *Stimulus*, *Response*, *Elicit*, *Evoke*, and Even *Behavior* and *Interaction*

As suggested earlier in the chapter, one taking an active organism (system of organized processes) approach should avoid, except in very limited cases, the terms *stimulus, reinforcement, response, elicit,* and *evoke. Affordance (opportunity to act), resources,* and *asset* should be substituted for both stimulus and reinforcement, and *activity* (at the biological level) and *action* or *act* (applied to the psychological level, entailing intention or goal directedness) should be used to replace *response* and *behavior*. As also described earlier, the term *interaction* should be eliminated from our scientific vocabulary—again, except in very limited cases—and replaced with *coaction*.

An example of assuming the Process-Relational category system, but being stuck in the Cartesian vocabulary is found in a discussion in which Greenberg (2014) describes Zing-Yang Kuo's (1967) work with chick embryos as an illustration of the significance of activity and action in development. As Greenberg (2014) correctly points out, Kuo's investigations discovered that the pecking activity of the newly hatched chick was not the product of some genetic determinism, but rather the outcome of the embryonic chick's spontaneous activity prior to hatching. However, from a Relational-Developmental-Systems perspective, the embryonic activity itself was not, in fact, the product "of something that was *happening to* it [the embryonic chick]" (Greenberg, 2014, p. 2; emphasis added). The embryonic activity was actually something *the chick was doing*. That is, the organized system (embryonic chick) qua organized system is inherently active and, although this organized active system can be described with respect to part–part relations (i.e., "because of the musculature of the head, as it rose and fell, the beak would open and close . . . and the reflexive action of peristalsis would . . . [lead] the embryo to swallow" Greenberg, 2014, p. 2), these relations in no way nullify the centrality of the chick's inherent activity in the overall process.

The Meaning of *Experience*

The active organism characterization also affects the meaning of the term *experience*. The conventional Cartesian meaning of experience is an event or object (stimulus) that is split off from and antecedent to the activity/action of the organism. However, as William James (1912) pointed out, "experience" is a "double-barreled" (p. 10) concept and, as John Dewey (1925/1958) elaborated, "It includes what men do and suffer, what they strive for . . . and endure, and also how men act and are acted upon" (p. 8). The Cartesian understanding of experience was exclusively on "how men [sic] are acted upon," a split-off concept that entailed efficient causal forces (stimuli—endogenous or exogenous) that were taken to explain behavior and development. As a consequence, from the Cartesian perspective it was reasonable to split off nature from nurture (experience).

The process-relational active organism position focuses on the individual, on "how men [sic] act." Experience is the action of observing, manipulating, exploring, symbolizing, languaging. Affectively, the feel of the action is the *feeling of experience*. Thus, one does not have a "frightening experience," one has an experience (an action) that feels frightening. Further, the object of an action is the *object of experience*. Thus, for example, one does not "experience a bright light," one has the experience (an action) of a bright light (the object of experience). This latter example illustrates how perception can be understood as an active process (see, e.g., Noë, 2004).

Within the process-relational frame, embodied organized activity or action is the primary definition of experience. Thus, at the microscopic and macroscopic level, all development is the result of, and all action is identified as, *experience* (i.e., embodied organized action). Hence, there is no such thing as *nature versus nurture*, and there is no such thing as *nativism versus empiricism*, there are only the organized embodied activities and actions of the system (experience), whether these operate on a biological, psychological, or cultural level of organization.

It is, for example, not the case that "early perceptual and behavioral asymmetrical biases *can provide experiences* relevant to the formation of . . . nascent sensorimotor systems" (Michel, 2014, p. 37; emphasis added); "rather, it is that the experiences entailed by early perceptual and activity asymmetrical biases constitute the basis for the formation of . . . nascent sensorimotor systems." Similarly, we do not "inherit . . . our . . . experiences" (Michel 2014, p. 42); rather, experience (embodied activities and actions) constitutes the fundamental processes that make inheritance possible.

The Elimination of *Innate* and *Maturation*

Taken seriously, the Relational-Developmental-System characterization of the living organism and its development renders other Cartesian-inspired concepts meaningless and/or scientifically counterproductive; foremost among these being the concepts *innate* and *maturation*. Unless used in its strict sense (i.e., present at birth), and it rarely is used this way, *innate* implies that a characteristic is acquired through a split-off encapsulated evolutionary or biological process, independent of experience. But as illustrated in the discussions by Greenberg (2014) and Michel (2014) (see also Bateson, Chapter 6, this *Handbook*, this volume; Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume), and as outlined earlier, developmental psychobiology has already demonstrated that any characteristic is the outcome of a long and continuous epigenesis entailing embodied activities and actions (experiences), beginning at conception and continuing through prenatal and postnatal phases of development, as well as across the life span. Thus, for example, various action patterns present at birth, including the nascent form of hand-use preference, have a long experiential history, as is nicely demonstrated in detail by Michel (2014).

The concept *maturation* is analogous to *innate*, for here, too, an appeal is made to a split-off encapsulated biological determinism, independent of experience. Maturation was popular many years ago, even among some of the most advanced patriarchs of relational thought For example, Piaget (1970) discussed one of the three "classical factors of development" as being "maturation" (p. 719), and Schneirla (1957) differentiated maturation and experience by maintaining that "*maturation* connotes processes contributed through growth and differentiation" (p. 102). However, in today's relational approaches, the concept *maturation*, like the concept *innate,* functions as a blind spot choking off, conceptually and empirically, a full understanding of development through the coactions of biology ←→ person ←→ environment in the context of processes of epigenesis.

The Elimination of *Mechanism*

It will be recalled from the earlier discussion of *cause* that in mechanistic philosophy cause is *always* defined in terms of some *force that produces a change* (i.e., an efficient or material cause) (Bunge, 1979). In that discussion it was suggested that the term *cause* be eliminated in favor of *explanation*, or else carefully defined each time it is used. From a Process-Relational and Relational-Developmental-Systems perspective *cause* would never be used as we already know that the relational developmental system is the sufficient condition of its own development.

The term *mechanism* is a mechanistic term designating the *force* of mechanical explanation. For example, according to the mechanistic philosopher Glennan (2002) a mechanism refers to "an interaction of parts, where the interactions are occasions on which a change in a property of one part *brings about a change* in a property of another part" (p. S344; emphasis added), while another group of mechanistic philosophers (Machamer, Darden, & Craver, 2000) drop the "interactions" and refer to mechanisms as "entities and activities *producing* regular changes (p. 3; emphasis added). In fact, these philosophers and others have been active in promoting a "new mechanistic" movement in the sciences. As Tabery (2004) has noted:

> The search for and discovery of mechanisms in the sciences abounds. Whether it is geology or molecular biology, biochemistry, or cosmology, what is taken to be a causal explanation often consists of the description of a mechanism. The last two decades have seen a return to the philosophical analysis of the concept of a mechanism, but these efforts have predominantly evaluated the use of mechanical explanations in specific sciences. . . . Recently, . . . Stuart Glennan and the team of Peter Machamer, Lindley Darden, and Carl Craver . . . have attempted to assess the concept of a mechanism more generally. (p. 2)

Now it should be clear that *mechanism* has no place in a Process-Relational ontology because external split-off forces do not produce changes, the becoming and the fading away. The term *process*, in fact, fits very well in any location someone might be tempted by the ghost of Cartesian ontology past to use the term *mechanism*.

There is a certain ironic twist to the "New Mechanist" understanding of mechanism. Bechtel and Abrahamsen (2005) now define *mechanism* as:

> a structure performing a function in virtue of its component parts, component operations, and their organization. The orchestrated functioning of the mechanism, manifested in patterns of change over time in properties of its [*organization*,] parts and operations, is responsible for one or more phenomena. (p. 423)

The irony is that, except for my needing to insert the term *organization* in this definition, it would have been quite an acceptable definition of *process*, but as such it would lose all meaning associated with its mechanistic philosophical base category of an exogenous force. This quote, therefore, is an example of conceptual incoherence, and the worst kind of incoherent eclecticism; asserting a set of ontological and epistemological principles, and then defining core concepts that are incoherent with respect to those principles.

CONCLUSIONS

The broadest and most important conclusion to be drawn from this chapter is that *concepts matter*, and to echo again Robert Horgan's (2001) statement that "all the empiricism in the world can't salvage a bad idea" (p. 27). Developmental science is an empirical science, but *empirical* refers to being based on experience, and concepts are a part of the warp and woof of experience. It was, in fact, under a split-off Cartesian *concept laden* philosophical *doctrine* termed *empiricism* that we were led to a *conceptual understanding* that empirical science entails only pristine observations and experiments; clearly a conceptual incoherence worthy of analysis.

Today science generally acknowledges that concepts and methods go hand in hand; they form an indissociable relation (see Nesselroade & Molenaar, 2010; Overton, 2014). However, the ghost of empiricism, which itself is an epistemological tentacle of the Cartesian-Split-Mechanistic worldview, continues like an invisible hand to haunt the halls of academia, funding agencies, and publication boards. In a sense this effect is highly irrational. There is now more than enough evidence—piles and piles of data—demonstrating, as exemplified in the opening pages of this chapter, that in the field of developmental science and in other scientific fields, including physics, biology, anthropology, sociology, and cultural psychology, this paradigm simply is not working any longer; it is not successfully participating in the problem solving function of science. In another sense, the continuing impact of the unseen hand of the Cartesian paradigm is rational: It follows the rule articulated long ago by Thomas Kuhn that a research paradigm "is declared invalid only if an *alternative candidate is available* to take its place. . . . The decision to *reject one paradigm is* always simultaneously *the decision to accept another*" (Kuhn, 1970, p. 77; emphasis added).

In this chapter, I try to make visible the usually unseen hand of the Cartesian-Split-Mechanistic paradigm and offer an alternative candidate to take its place, the Process-Relational and Relational-Developmental-Systems paradigm. I believe that this alternative better explains the wealth of new data in various developmental science subfields addressing issues of inheritance, evolution, cognition, affect, moral values, and the sociocultural context; that it resolves problems that have existed for decades and decades (e.g., nature-nurture, subject-object, continuity-discontinuity); and that it offers directions for future scientific productivity. This paradigm is not a theory, but relational developmental systems theories have been derived from it; this paradigm is not a methodology, but it has a methodology associated with it and methods have been constructed within its framework; this paradigm is not an actual entity, but the actual entity that is the object of developmental science inquiry is the *relational developmental system*.

CONCLUSION: IN SEARCH OF UNIFIED METATHEORETICAL GROUND 103
REFERENCES 106

The focal question facing developmental science remains the question of process: *How* do new forms, functions and levels of organization arise in development from precursor forms, functions, and levels? Throughout the field's history, answers to this question have frequently invoked arguments by design: An aspect of the developing organism—for example, its phylogenetically entrained genetic code—or of the organism's contextual surround—for example, socialization practices, cultural institutions, or other structural regularities of the world into which the organism is born—harbors preexistent "information" for the developmental construction of the organism, information that prefigures the very processes that actually engender development (Oyama, 1985). In arguments by design, developmental process involves little more than the transmission of information from various, autonomous parts of the organism-environment system to the organism as a whole (Witherington & Heying, 2013). Such answers to the question of process, in Oyama's (1985) words, reflect a "preoccupation with organisms as material objects whose design and functioning must be imparted to them" (p. 12) and effectively sidestep the very question they purport to answer by marginalizing—if not eliminating altogether—the constructive, formative activity of process itself and the true novelty to which this activity gives rise.

I sincerely thank Shirley Heying for her help in preparing this manuscript and I thank Jane Jackson for quantitative guidance.

An alternative answer to the question of process arrives in what Overton (2013, Chapter 2, this *Handbook*, this volume) has termed the *Relational-Developmental-Systems paradigm*. Emblematic of *relationalism* or *relational metatheory* (Overton, 2006, 2010), this paradigm embeds the development of structure and function precisely within the constructive activity of process by invoking the dynamic, interpenetrating *relations* among various intra- and extraorganismic components—not the components themselves or the information housed in them—as the formative source of truly emergent, developmental change (Lerner, 1978, 2002). Over the past three decades, amid renewed commitment in developmental science to antireductionist, process-focused conceptions of development, numerous relationally oriented approaches have emerged as potential mid-range metatheories for developmental science, from Sameroff's (1983) transactional approach and Ford and Lerner's (1992; Lerner, 2002, 2006) developmental systems approach—modified to a "relational developmental systems approach" (see Overton & Lerner, 2012)—to Gottlieb's (1992; Gottlieb, Wahlsten, & Lickliter, 2006) developmental psychobiological systems view and Bronfenbrenner's (2005; Bronfenbrenner & Morris, 2006) bioecological model. Of all these approaches, however, few have enjoyed quite the level of prominence and impact in the field within the past 20 years as the dynamic systems (DS) approach to development (Hollenstein, 2011). Two prior *Handbook of Child Psychology* chapters (Thelen & Smith, 1998, 2006), numerous edited volumes (e.g., Fogel, King, & Shanker, 2008; Kunnen, 2012; Lewis & Granic, 2000), and a plethora of empirical applications across a wide variety of content domains (e.g., Bassano & van Geert, 2007; Camras, Lambrecht, & Michel, 1996; Lewis, 2005; Schutte & Spencer, 2002; Snapp-Childs & Corbetta, 2009; van der Maas & Molenaar, 1992) all testify to the DS approach's broad-based appeal, an appeal borne in no small measure from the approach's comprehensive research agenda.

Running the gamut from specific analytic techniques to overarching metatheoretical treatments, the DS approach to development covers all levels of the research process. Analytically, the DS approach weds the mathematics of nonlinear dynamics to the study of developmental phenomena, highlighting the centrality of *nonlinearity* for understanding processes of change; whereas traditional linear models of change assume that "outcomes are proportional to inputs in a straightforward manner," nonlinear models assume that "change is not proportional to inputs. Large inputs sometimes produce small results, and a small input at the right time can produce a dramatic result" (Guastello & Liebovitch, 2009, p. 1). At one level, then, the DS approach to development represents a set of geometric modeling techniques and analytic tools for formally charting stability and change in nonlinear systems (Abraham & Shaw, 1992; van der Maas & Raijmakers, 2009; van Geert, 1997a). However, the DS approach is also a methodological agenda for developmental science that emphasizes the study of intraindividual variability through frequent sampling of individuals (or individual systems) across time, both on microgenetic and ontogenetic scales (Nesselroade & Molenaar, 2010; Newell & Molenaar, 1998; Thelen & Smith, 1994; van Geert & van Dijk, 2002). At the conceptual level, the DS approach articulates a set of principles for understanding developmental process such as self-organization, emergence, multicausality, and soft assembly (Lewis, 2000a; Thelen & Smith, 1994). At the level of theory, the DS approach supports different theoretical treatments of real- and developmental-time phenomena such as Spencer, Schöner, and colleagues' dynamic field theory of embodied cognition (e.g., Schöner & Thelen, 2006; Spencer, Perone, & Johnson, 2009; Thelen, Schöner, Scheier, & Smith, 2001) and Fogel et al.'s (1992) social process theory of emotional development in social context. Finally, as an overarching worldview or metatheory, the DS approach elaborates a set of guiding ontological and epistemological assumptions regarding the nature of development and what constitutes legitimate explanatory and causal frames for understanding developmental process (Granic & Hollenstein, 2003; Spencer et al., 2006; Spencer, Dineva, & Schöner, 2009; Thelen & Smith, 1994).

In its comprehensiveness, the DS approach is uniquely positioned among modern Relational-Developmental-Systems approaches to serve as a guiding model for developmental science, especially given its concrete and unified grounding in the mathematics of nonlinear dynamics. Yet despite its basic analytic unification, the DS approach is beset by long-standing disagreement among its proponents over what phenomena constitute legitimate objects of study and explanation in dynamic analysis (Lewis, 2000a; Thelen & Smith, 1994; van der Maas, 1995; van Geert & Steenbeek, 2005). With respect to this question, van Geert and Steenbeek (2005) have formally demarcated two distinct stances: their own "Groningen approach" and the "Bloomington approach." Proponents of the Groningen approach freely admit psychological constructs such as object permanence and theory of mind into their dynamic analyses as more macroscopic levels of action patterning. In contrast, for proponents of the

Bloomington approach—such as Thelen and Smith, as well as Spencer—many psychological constructs cannot serve as legitimate variables for dynamic systems analysis; only variables grounded in the real-time dynamics of specific activity in context count as viable source material.

What does this disagreement suggest about the conceptual coherence of the DS approach? Is the disagreement simply a reflection of surface-level differences among varied articulations of an otherwise ontologically unified approach? Or does it reflect a more fundamental metatheoretical rift among proponents of the approach? Van Geert and Steenbeek (2005) avoided characterizing disparity between their approach and the Bloomington approach as anything more than a difference of degree or emphasis, arguing that the Groningen approach's admittance of all manner of organizational properties and levels of abstraction into the mix of dynamic modeling should be read in purely pragmatic terms rather than as an endorsement of the "mental" status of these constructs. In fact, they suggested that ultimately "these variables and dimensions will have to be brought back to the working of a so far unknown short-term dynamics that incorporates the embodied acting person that Esther Thelen brought in to the study of human development" (pp. 436–437), emphasizing the bottom-line unity of the two DS stances (see also Thelen & Bates, 2003). However, even the most cursory examination of the typical narratives employed to capture the historical significance of the DS approach reveals two qualitatively distinct vantage points from which to view the approach, calling into question the approach's deep unity.

THE DYNAMIC SYSTEMS APPROACH: A TALE OF TWO NARRATIVES

For DS proponents such as van Geert (1998a, 1998b; van Geert & Fischer, 2009), van der Maas (1995, 1998; van der Maas & Raijmakers, 2009), and Lewis (1997, 2011a, 2011b), the DS approach fundamentally aligns with the constructivist philosophy of Piaget and establishes mathematical formalizations for the general developmental processes articulated in Piaget's, Vygotsky's, and Werner's (among others) classic systems approaches to psychological development (Lewis & Granic, 1999a; van Geert, 2000). The narrative that surfaces in the writings of these DS proponents, in other words, is one that historically frames the DS approach as a *return to* and *elaboration of* the relational, dynamic thinking already evident in Continental-European developmental psychology circles during the first decades of the past century. From Piaget's central focus on self-organization in open systems (Garcia, 1992) and on how novel forms emerge (Chapman, 1988; van Geert, 1998b) to the idiographic, microgenetic focus of the Würzburg school, elaborated in Werner (1956) and Vygotsky's (1987) own microgenetic work (Diriwächter, 2009; Wagoner, 2009), to Stern's (1900) call for person-centered, intraindividual-focused research (Lamiell, 2009), reflected in contemporary developmental science in the methodological work of Nesselroade and Molenaar (2010), the pervading climate in pre–World War II Europe conceptually prefigured the central tenets of the DS approach, absent only the analytic tools of nonlinear dynamics (Toomela, 2009; van Geert, 1998b).

Van Geert (1998b) characterized this early period in the field's history as "developmental-science-in-the-making" and specifically highlighted its thoroughgoing process orientation: "What is most striking in the works of the founders is that they believed that the reason for or the causes of development are *inside the developmental process*" (pp. 143–144). By the mid-20th century, as developmental psychology grew increasingly analytic in its orientation, the field's initial process orientation had become recast through the lens of a more rigid independent-dependent variable orientation, grounded in associationist models of antecedent-consequent relations. Isolable variables, not integrated systems, came to occupy center stage, and researchers sought to exert greater statistical control and representativeness of results through increasing focus on large sample, normative group data, time tables for developmental acquisitions, and the independent variables that impact such acquisitions (Toomela, 2009; van Geert, 1998b). For van Geert (1998a, 2004), the DS approach not only revives and confers mathematical legitimacy on the field's classic systems accounts of psychological development but also promotes the synthesis of these classic process orientations by "bridging the gaps between related theories and . . . bringing the central, common elements to the fore" (p. 635). For van der Maas and Raijmakers (2009), the DS approach is "a theory-free approach, in the same way that statistical methods are largely theory-free approaches" (p. 302); as a consequence, this narrative frames the novelty of the DS approach not in conceptual or metatheoretical terms but principally in terms of the analytic tools available under its aegis.

A fundamentally different narrative—reflected in the *Handbook of Child Psychology*'s two prior treatments of the DS approach—arises from DS proponents such as Thelen and Smith (1994, 1998, 2006), and Spencer

(Spencer et al., 2006; Spencer, Dineva, et al., 2009; Spencer, Perone, & Buss, 2011). For these DS proponents, many of the central tenets characteristic of Piaget's, Werner's, and Vygotsky's classic systems approaches fail to adequately capture actual developmental process, largely through what Thelen and Smith (1994) regard as the substitution of static portrayals of global order for the truly dynamic variability of local, real-time interaction. Thelen and Smith (1994, 1998) specifically repudiated Piaget's "grand sweep" approach: the characterization of development as an orderly, irreversible sequence of qualitatively distinct and increasingly abstract levels of psychological organization yielding a fundamental directionality teleologically framed in terms of end points toward which organisms develop. By their explicit denial of the explanatory legitimacy of structure, sequence, and directionality in Piaget's approach to development, Thelen and Smith effectively positioned the structuralist traditions of pre–World War II European developmental psychology as ontologically incompatible with the DS process orientation. Along similar lines, Spencer et al. (2011) have argued that Piaget's framework, like those of nativism and cognitive/information processing, is fundamentally at odds with what they called the "systems metatheory" (p. 261) and its "new grand theory of development" (Spencer et al., 2006, p. 1533) in the form of the DS approach.

The DS approach as *new metatheory* and overarching conceptualization for developmental science offers as its historical progenitors the embryological and psychobiological traditions of Waddington (1957), Schneirla (1957), and Kuo (1967) and the ecological and field theory traditions of Gibson (1979) and Lewin (1946), rather than the classic systems approaches of developmental psychology per se (Thelen & Smith, 1998, 2006). By elevating those traditions that focus on anatomical, morphological, and behavioral analyses over those traditions that focus on psychological analyses and "higher-order" structural explanations, proponents of the DS approach as new metatheory establish a historical narrative ontologically grounded in "concrete" rather than "abstract" levels of organization (this despite the fact that at least some of the historical progenitors whom Thelen, Smith, and Spencer elevate [e.g., Schneirla] explicitly repudiated the notion that *any* level of system organization, from the biological to the psychological to the sociocultural, was ontologically foundational). Within this historical narrative, the DS approach actively rejects both the "mentalistic assumptions" (Thelen & Smith, 2006, p. 268) of classic systems approaches in developmental psychology—in keeping with a Gibsonian heritage—and the reductionist assumptions of mechanistic approaches to development—such as nativism and empiricism (Spencer, Blumberg, et al., 2009)—which assign privileged formative status to certain elements of a system over others. Development, instead, is couched in terms of the concrete, here-and-now specifics of multiply determined, embodied activities, softly assembled to confront the unique properties of individual contexts across time (Spencer et al., 2006; Thelen & Smith, 1994).

Does the DS approach to development establish a new metatheoretical framework for developmental science that leaves behind the structuralism of classic systems approaches, as Thelen, Smith, and Spencer's narrative suggests? Or does the DS approach mark a return to and elaboration of that very structuralism and its concomitant process orientation, as van Geert, van der Maas, and Lewis's narrative suggests? Something more than just surface-level disagreement fuels these two qualitatively distinct narratives. A much more substantial *worldview* division exists *within the DS approach*, bearing directly on the framing of the approach's conceptual principles, such as self-organization and emergence, and on its basic conceptualization of developmental process (Witherington, 2007, 2011; Witherington & Margett, 2011). The purpose of this chapter is to examine the DS approach to development in light of this deep-seated metatheoretical division and to articulate the two fundamentally divergent ontological stances that different proponents of the approach adopt with respect to the very nature of explanation in developmental science.

As this chapter argues, the ontological stance of one DS approach—embodied in the narrative espoused by van Geert, van der Maas, and Lewis—promotes an *inclusive*, explanatorily pluralistic framework within which to study development and operates fully within the Relational-Developmental-Systems paradigm (Overton, 2013, Chapter 2, this *Handbook*, this volume) through its synthesis of organismic and contextualist worldviews. In contrast, the ontological stance of a second DS approach—embodied in the narrative espoused by Thelen and Smith and by Spencer—promotes an *exclusive*, explanatorily monistic framework within which to study development and reinvokes the specters of foundationalism and reductionism, establishing it as a Cartesian-Split-Mechanistic paradigm (Overton, 2013) through the radical contextualist worldview it espouses. In essence, when viewed through the lens of its inclusive vantage point, the DS approach sits at the forefront of the Relational-Developmental-Systems movement in developmental science. But when viewed through the lens of its exclusive vantage point, the DS approach threatens to undermine relationalism by furthering the very split metatheoretical framework it purports to transcend (Overton, 1998; Witherington, 2011).

This chapter begins with an examination of two key historical influences on the DS approach to development: von Bertalanffy's general systems theory and nonlinear dynamical systems theory. It next discusses alternative possibilities for the integration of these multidisciplinary influences as the backdrop for current ontological divergence among DS proponents. What follows is a delineation of the DS approach, its principles, and its overarching conceptualization of development from the perspective of both its inclusive and exclusive metatheoretical stances, with specific focus devoted to the work of Lewis, van Geert, Thelen and Smith, and Spencer. Finally, the chapter concludes by framing ontological division in the DS approach to development more broadly in terms of the Relational-Developmental-Systems and Cartesian-Split-Mechanistic paradigms.

HISTORICAL FOUNDATIONS FOR THE DYNAMIC SYSTEMS APPROACH: GENERAL SYSTEMS THEORY AND NONLINEAR DYNAMICS

Protean are the historical roots of the DS approach to development, as the preceding narratives attest. Arguably the most prominent and influential historical rendering of the intellectual traditions that positively inform the approach arrived in Thelen and Smith's (1998, 2006) two prior *Handbook* chapters, and as previously illustrated, their account of the approach's historical significance deviates in significant ways from that of van Geert (1998b) and others, for whom "Piaget *was* an early DS theorist" (Lewis, 2011b). Nonetheless, all DS proponents routinely acknowledge the central role of von Bertalanffy's general systems theory in the shaping of the DS approach to development. And as definitions for the DS approach uniformly appeal to the application of nonlinear dynamics principles to the phenomena of development, nonlinear dynamical systems theory similarly occupies pride of place among DS proponents in the approach's origins (Thelen & Smith, 1998, 2006). This chapter selectively focuses on von Bertalanffy's general systems theory and nonlinear dynamical systems theory as setting the historical precedent for the DS approach to development, both because of their multidisciplinary focus and because of their unquestionable status as core sources of influence for the approach.

Von Bertalanffy's General Systems Theory

Despite its translation, "general system theory" is not a theory—the English word fails to adequately capture the broadened meaning of the German *theorie* in *allgemeine systemtheorie* (von Bertalanffy, 1975, foreword by Ervin Laszlo). It instead is a perspective, a metatheoretical approach, for understanding systems, with a system being any set of interacting components or parts that, through the interdependence of their relations to one another, constitutes an organized whole or totality. As a metatheory, general system theory (GST) moves scientific endeavor beyond the mechanistic orientation of conventional physics—what von Bertalanffy, like Pepper (1942), called *mechanism*—in which all phenomena are modeled after machines and analytically decomposable into a foundational set of elemental parts and forces (Overton, Chapter 2, this *Handbook*, this volume; Reese & Overton, 1970; von Bertalanffy, 1933, 1968b). In place of this mechanistic stance, GST promotes a science of *organization* and *wholeness* and establishes broad, multidisciplinary principles for characterizing the organizations (structures, forms, or patterns) of different kinds of systems irrespective of their specific content, be it physical, biological, or social (Overton, 1975; Sameroff, 1983; von Bertalanffy, 1933, 1968a, 1975).

At the core of GST rests von Bertalanffy's (1933) particular focus on living systems and the irreducible organizational qualities—such as purposiveness, self-maintenance, and goal-seeking—required to understand them. Viewing life as irreducible in itself, however, does little to distinguish von Bertalanffy's systems approach. After all, vitalism, the long-standing rival to mechanism's reductionist stance, similarly conceived of life's higher-order organization in terms irreducible to the inorganic physicochemical world of conventional physics. Yet von Bertalanffy's GST was as much a reaction against vitalism as it was a reaction against mechanism—and not just because vitalism explained living phenomena through an appeal to immaterial, transcendent factors, such as entelechies, that were resistant to investigation within the traditional purview of natural science. Both mechanism and vitalism, von Bertalanffy argued, shared a common metatheoretical root: their adherence to the materialism and determinism of conventional physics (von Bertalanffy, 1933, 1975). In effect, both mechanism and vitalism presupposed the foundationalism of mechanism's worldview, namely that the universe is composed of bedrock elements—particles and forces—independent and isolable from one another, which, by themselves and in linear combination, constitute the "ultimate building blocks of reality" (von Bertalanffy, 1975, p. 71). Vitalism merely added a transcendent factor to the mix. And as von Bertalanffy (1933, 1975) highlighted, this transcendent factor, though unresolvable to physicochemical materials and forces in the natural world, nonetheless operated within the same antecedent-consequent causal framework applied to physicochemical forces: that of *efficient causality*.

Efficient causes are the classic, push-from-behind forces of causality—the initiating or propelling forces typically characterized as temporal exchanges of energy *from an antecedent to a consequent*—that have served as the hallmark of scientific orthodoxy since the 17th century (Bates, 1979; Emmeche, Koppe, & Stjernfelt, 2000). Efficient causes can involve both extra- and intraorganismic antecedents: in post-Humean terms, they are any concrete event or circumstance that reliably precedes a phenomenon, thereby explaining it (Lear, 1988). Examples of efficient causes in the context of psychology include explaining behavior by means of inertial forces and muscle interactions, physiological or neurological processes, or particular stimulus events or environmental factors. Though vitalism regarded its vital "guiding forces" (von Bertalanffy, 1933, p. 44) as immaterial, these forces nonetheless were framed as temporal antecedents for the establishment and maintenance of living phenomena. They conferred a life "essence" on the otherwise lifeless, machine-like matter of the physicochemical world, much as the kinetic energy of one billiard ball is imparted to another by spatiotemporal contact. As antecedents, they sat apart from the matter on which they acted and imbued this matter with life through what amounted to a transfer of energy. In other words, vitalism reified its transcendent forces, "hypostasizing the concepts necessary for the teleological description of vital processes into active natural factors or entelechies" (von Bertalanffy, 1933, p. 14) and creating, in the process, "soul-like factors—little hobgoblins as it were—hovering in the cell or the organism" (von Bertalanffy, 1968a, p. 89). Life had been explained through recourse to a life-giving, efficient causal force independent of the matter it enlivened.

For von Bertalanffy, the problem with vitalism lay as much in this unquestioning endorsement of mechanism's *explanatory monism*—efficient causality and only efficient causality constitutes explanation—as in its appeal to immaterial factors. Through the call to "expand physics to include life phenomena rather than reduce biology to conventional physics" (von Bertalanffy, 1975, p. 117), von Bertalanffy sought to overhaul the very frameworks of foundationalism and efficient causality on which both mechanism and vitalism relied. In his GST, there exists no material bedrock of foundational elements for constructing all organizational complexity; rather, "organization runs right through all levels of reality and science" (von Bertalanffy, 1968b, p. 34). Parts and processes at any level of analysis necessarily presuppose a system—an organized whole—within which they are embedded, requiring in von Bertalanffy's (1968b) words "an *expansion of categories*, models and theory" (p. 37) beyond those of conventional physics.

GST's call for category expansion involved nothing less than a paradigmatic reorientation in scientific endeavor. For in embracing wholeness and organization as fundamental categories of scientific thought, von Bertalanffy had called for an ontological expansion of the very nature of scientific explanation itself, an expansion beyond its exclusively mechanistic framing in terms of antecedent-consequent relations via efficient causality. He called for science to employ the organization of systems—the unitary structure of the whole—as a form of explanation *in its own right*.

The System as Cause: Moving Beyond Antecedent-Consequent Relations

Von Bertalanffy (1933) heralded the *organization* of physicochemical materials and processes—not some new organizing force/process or substance existing beyond the realm of the physicochemical—as the key to distinguishing living from nonliving phenomena. To understand life, he argued, "the most exact knowledge of its ingredient materials and processes does not suffice. We can only speak of such an understanding when we know the laws which govern the organization of these materials and processes" (pp. 49–50). For von Bertalanffy, decomposing a living system into its components/materials and into the processes that interrelate those components can only go so far in explaining the activity and nature of the system, even if all processes are rendered completely. Without also understanding the *configurational wholeness* or *organization* of these component parts and processes—what von Bertalanffy (1933) called "organic description in the realm of the organic" (p. 15)—the qualities that comprise the system qua system remain elusive. But what does examination of the system qua system—of its wholeness—add to a complete accounting of the dynamic interrelations that obtain among the components that comprise the system? After all, isn't the wholeness or organization of a system definable precisely *in terms of* those dynamic interrelations, *as* arising bottom-up from process dynamics? How does organization in itself add significantly to process explanations in science?

Recall that, by dint of its argument against foundationalism, GST conceptualizes processes as always embedded within an organizational framework. Organization, far from being built on a foundational level of process, comprises the very nature of process; in von Bertalanffy's (1975) words, "all that can be said about the processes in question depends on the form of these processes" (p. 70). Though processes—the interactions among components in a system—yield new levels of organization in a system, these processes always operate within the context of an existing level of organization, an organization that necessarily constrains the very nature of the processes themselves. At every level of analysis, then, from micro to macro, process is organized. Because all organization is process and all process is organization—with neither foundational to the other—an understanding of system process must always be embedded within an understanding of system structure, and vice versa (von Bertalanffy, 1933, 1968a). Though indivisible, organization and process nonetheless offer different vantage points for understanding the same phenomenon; in this way, organization offers a unique form of explanation, distinct from that offered via the vantage point of dynamic processes themselves.

When, in fact, we as scientists examine the indissociable unity of organized process from the *bottom-up* vantage point of dynamic process, we establish a context of *temporal precedence*. Mapping the relations that characterize a system's component parts necessarily invokes a temporal dimension of analysis in terms of antecedent-consequent relations. As soon as we begin to investigate any given process, we position our lens of inquiry toward events that unfold over time, wherein a single interaction or set of interactions give rise to a product. This antecedent-consequent framing holds true even when models of dynamic process appreciate the reciprocal nature of relation among a system's components. In living systems, for example, where the component parts are "internally" related such that the identity of each component part depends on its relation to other component parts (Kitchener, 1982; Lerner, 1978; von Bertalanffy, 1968a), each part-to-part interaction involves simultaneous influence between the components (e.g., component A is affecting, while simultaneously being affected by, component B, and vice versa). Under these conditions, absolutist notions of antecedent and consequent, cause and effect at the part-to-part level disappear, because any given component can be both cause and effect (Ford & Lerner, 1992). Because the whole is multiply determined—with each part of the whole a necessary but insufficient interactant in the joint production of the whole—efficient cause becomes distributed across all of the parts that make up the whole such that each part equally influences the emergence of the whole without determining it (Turvey, Shaw, & Mace, 1978). Nonetheless, the products to which these part-part relations give rise—the wholes arising in the parts-to-whole relation—are still framed as a consequent relative to the push-from-behind, antecedent forces of part-part relations when adopting a bottom-up vantage point.

When, however, scientists examine the indissociable unity of organized process from the *top-down* vantage point of organization, they establish a context of *atemporal embeddedness*. This form of explanation is akin to the manner in which the ground in a figure-ground relation conditions the meaning of the figure embedded within it. For von Bertalanffy (1968a), organization captured the *singular*, *instantaneous* totality of the system as a whole: "While we can conceive of a sum as being composed gradually, a system as total of parts and interactions has to be conceived of as being composed instantly" (p. 55). Conceiving of a system in instantaneous terms requires a form of explanation that invokes the atemporal embeddedness of structural explanation rather than the temporal precedence of antecedent-consequent, functional explanation. Wholeness thus captures what a temporal charting of lower-order process dynamics cannot: the structural *totality* of relations that comprise a system. Systems, as wholes, *constrain* in whole-to-parts fashion the very nature of their components and the relations that can occur among those components (Deacon, 2012; Juarrero, 1999). They impart meaning to and provide a structural, topological precondition for understanding those processes, not as an antecedent to a consequent defined in temporal terms but as a critical explanatory backdrop or framework—a ground—against which the temporally unfolding local dynamics of the system—the figure—must be understood (Overton, 1975; Thompson, 2007).

Von Bertalanffy's treatment of system organization—its form and teleology—as an explanatory vantage point in its own right recalls the *formal* and *final* causes of Aristotle's classic pluralistic explanatory framework (Jurich & Myers-Bowman, 1998; Overton, 1975; von Bertalanffy, 1968a). Unlike the temporal antecedent or propelling force explanations captured through efficient cause, formal and final causes—or better for the modern reader, formal and final explanations—are atemporal, organizational levels of explanation that lend *meaning* to the temporal, cause-effect sequences of efficient cause (Juarrero, 1999; Rychlak, 1988). Whereas efficient cause necessarily presupposes a temporal context, formal and final explanations invoke abstraction itself as a means of partial explanation, without recourse to the flow of time (Emmeche et al., 2000; Rychlak, 1988). Formal explanations abstract a pattern—a form, structure, organization—from the particular, real-time dynamic content of a phenomenon, and that pattern functions as a partial explanation for the phenomenon. Final explanations abstract a function, future-end, or purpose from the particular, real-time dynamic content of a phenomenon to explain the phenomenon. This abstracted patterning—both formal and teleological—has explanatory value because it "introduces order and organization into the domain under investigation" (Overton, 1991, p. 220), rendering the domain intelligible and providing a meaningful, holistic context within which to investigate the real-time dynamics of process.

As psychologists, when we appeal to constructs such as emotions, cognitive scripts, and personality structures—constructs that capture organismic functioning as a whole, across specific actions and contexts—or to a particular stage or developmental level of organization, we are essentially invoking formal explanations for understanding real-time organismic activity in context. When we appeal to goals and intentions—and, more generally, to the function served by an action, conscious or otherwise—or when we posit ideal endpoints and directional sequences of organizational change, like Werner's (1957) orthogenetic principle (i.e., whenever there is development it proceeds from an initial state of globality and lack of differentiation to states of increasing differentiation, articulation, and hierarchical integration), we are essentially invoking final explanations for understanding real-time organismic activity in context. What constitutes higher-order form/organization and what constitutes lower-order dynamic content depends on one's level of analysis and perspective; for a molecular biologist, cells as organized wholes comprise the formal explanation for understanding the real-time activity and interrelations of their constituent components, for example, DNA, RNA, proteins. However, the orthodox approach of modern science, with its exclusive adherence to efficient cause, views formal and final levels of explanation as temporary heuristics devoid of any true explanatory power and only rendered as legitimate forms of explanation when reduced to or reframed in terms of an efficient cause (Overton, 1991). By the orthodox approach, explanation counts only when filtered through the narrow lens of efficient cause.

Such scientific orthodoxy effectively encourages the reification of formal and final explanatory modes. Abstractions—like goals, mental schema, or personality structures—thus routinely become conceptualized as particular objects or things in their own right, antecedent forces relative to some consequent such as the real-time behavior of the organism. Just as proponents of vitalism explained living organization by reifying organization as a guiding force, causally antecedent to the living organization it explained, psychologists frequently reframe as efficient causes what should be considered formal and final explanations in their efforts to account for real-time activity in context, structurally reifying these organizational qualities of the whole as concrete parts of the system. This results in the incorrect framing of formal and final explanation in terms of antecedent "forces" that initiate consequent activity—activity from which they are, in fact, abstracted—as when, in developmental circles, Piagetian object permanence is framed as an antecedent force, which causes infants to engage in exhaustive search rather than as an organizational constraint that imparts meaning to infants' exploratory efforts (Lourenco & Machado, 1996; Rychlak, 1988).

Reification of formal and final explanation constitutes a fundamental category mistake (Ryle, 1949). Whereas efficient cause serves to contextualize—in bottom-up fashion—our understanding of an organism's specific activity in terms of the events and conditions that temporally and regularly precede that activity, formal and final explanations are not meant to identify the antecedent circumstances for such activity or to account for its variable content. Instead, formal and final explanations serve to contextualize—in top-down fashion—our understanding of an organism's specific activity in terms of the organization and directional purpose which that activity evinces as a whole (Overton, 1991; Tolman, 1991). In Aristotle's pluralistic framework, formal, final, efficient, and material cause (i.e., explaining a phenomenon by means of articulating the material substrate underlying the phenomenon) all represent unique, equally legitimate perspectives or vantage points for understanding phenomena. None of these vantage points offers sufficient explanation by itself, but all are necessary to fully understand any phenomenon, with no one perspective privileged as an explanatory gold standard relative to any other.

In keeping with the general spirit of Aristotle's explanatory pluralism, GST explicitly articulates what von Bertalanffy (1968a, 1968b, 1975) called a *perspectivist* philosophy to counter the absolutism of mechanism and its foundationalist enterprise. For GST, perspective conditions all understanding, no one perspective constitutes "ultimate truth or ultimate reality" (von Bertalanffy, 1968b, p. 67), and fuller understanding requires alternate perspectives on the same whole, given the inherent limitation and approximation of any given perspective. GST's perspectivism mirrors the ontological stance of relational metatheory: an inclusive framework within which classic polarities such as structure and function, process and pattern, are recognized as distinct, alternative, yet equally legitimate perspectives taken toward the same whole, each being contextualized with respect to the other and neither assuming an absolute foundational status (Overton, 2006, 2010, Chapter 2, this *Handbook,* this volume). In describing his perspectivist philosophy, von Bertalanffy (1968a) left no doubt as to its relational, dialectical underpinnings:

> The same object is quite different if envisaged from different viewpoints. The same table is to the physicist an aggregate of electrons, protons, and neutrons, to the chemist a composition of certain organic compounds, to the biologist a complex of wood cells, to the art historian a baroque object, to the economist a utility of certain money value, etc. All these perspectives are of equal status, and none can claim more absolute value than the other . . . ultimate reality is a unity of opposites; any statement holds from a certain viewpoint only, has only relative validity, and must be supplemented by antithetic statements from opposite points of view. (pp. 236, 248)

As previously outlined, GST established its own "unity of opposites" for understanding systems in the form of two alternative yet complementary perspectives/vantage points for viewing system functioning: an atemporal, organizational focus that targeted the wholeness of dynamic process and a temporal, process focus that targeted the dynamics of wholeness. With this general introduction in place, the chapter turns to an elaboration of each of these vantage points to illustrate the inclusive, explanatory pluralism that von Bertalanffy's GST embodies—a pluralism with critical implications for understanding ontological splits in the DS approach to development.

The Wholeness of Dynamics: The View From Above

For von Bertalanffy (1960, 1968a), the key distinction between living and nonliving phenomena resolved to two organizational criteria: the openness of the system to its environmental surround and the system's self maintenance of wholeness. With respect to the first of these criteria, von Bertalanffy established a broad contrast between two forms of system: open and closed. *Closed systems* are those that populate the world of conventional physics (von Bertalanffy, 1950, 1975). Such systems—exemplified in the form of the spring-driven clock—embody orthodox science's mechanistic orientation: The system as a whole reduces to its elemental components and the linear relations that obtain among them (Overton, 1975). Time-reversible and deterministic (Prigogine & Stengers, 1984) closed systems involve no exchange of matter with their surrounding environment. The only directionality in such systems is completely definable in terms of the second law of thermodynamics: The inexorable movement toward states of maximum entropy and maximum probability, or equilibrium, in which differences in the system are leveled, resulting in uniform, homogenous distribution of matter and energy from which no work can be obtained (von Bertalanffy, 1950).

Open systems, however, involve exchange of both matter and energy with their surrounding environment, yielding a continual dissolution and generation of the component parts that comprise the system. In the midst of this continual exchange with their surround, open systems can assume states of stability in which the system as a whole remains constant (von Bertalanffy, 1950). At all levels of the living hierarchy, from cells to living organisms generally and persons specifically, such higher-order stability subsuming continuous exchange of lower-order components is evident: Cells remain cells organizationally despite ceaseless exchange of their chemical constituents just as organisms remain organisms organizationally despite ceaseless exchange of their material components (e.g., cells, proteins). Unlike the true equilibrium of closed systems—borne of irreversible entropic breakdown—the stable states of open systems are characterized by *disequilibrium*, "maintained in distance from true equilibrium" (von Bertalanffy,1968a, p. 142) and permitting the capacity for work. Directionality in open systems thus involves movement toward states of increasing improbability and decreasing entropy (negative entropy): states of organization, heterogeneity, and complexity (von Bertalanffy, 1950, 1968a).

Von Bertalanffy (1950, 1968a) coined the term *Fliessgleichgewicht*, or steady state, to characterize these dynamic states of disequilibrium: constant and "time-independent" at the level of the whole, yet ceaseless flow and turnover at the level of the material and energetic components that comprise the whole. In the context of *living open systems*, von Bertalanffy (1933) further insisted that steady states require a teleological framing:

> All vital processes are so organized that they are *directed to* the maintenance, production, or restoration of the wholeness of the organism . . . the physic-chemical description of the vital processes does not exhaust them. They must also be considered from the standpoint of their significance for the maintenance of the organism. (pp. 8–9; emphasis added)

In other words, living systems *self-maintain*, preserving their own macroscopic organization in the face of microscopic flux; their parts and processes—the continual, local dynamics of the system—are only fully explicable when considered as being for the sake of the whole, ordered in such a way as to serve the maintenance of the system's organization itself (von Bertalanffy, 1968a, 1975). In von Bertalanffy's (1975) words, "the self-preservation of living systems requires and presupposes an ordering of their processes" (p. 118).

By the same token, the system as a whole is only organized by virtue of its ceaseless dynamic flux, able to maintain itself only "by a continual import and export of matter which is built up and broken down" (von Bertalanffy, 1975, p. 109). Nonetheless, von Bertalanffy stressed that the lower-order dynamics of the system cannot by themselves account for the nature of those open systems that are *living* systems. The very patterning of the processes that comprise the living system—the system's organization of process—"guarantees the maintenance, restoration, or reproduction of the system. This is the main difference between the processes going on in a living system and the reactions taking place in inert material or in a decaying corpse" (von Bertalanffy, 1975, pp. 97–98). In their self-maintenance, living systems constitute *active systems*, never at rest, with autonomous activity being primary to the very organization of the living system and establishing the continuous ground against which all open exchange between the living system and its surround is understood (von Bertalanffy, 1968a).

Von Bertalanffy's emphasis on living systems as self-maintaining finds elaboration in the work of Maturana and Varela and colleagues on *autopoiesis*, a core organizational feature of life from cells to the organism as a whole (Maturana, 1978; Maturana & Poerksen, 2004; Maturana & Varela, 1980; Varela, 1979; Weber & Varela, 2002). In most *physicochemical* dissipative systems—nonliving, physical systems that, as dissipative structures, remain energetically and materially open to their surround, taking in molecules high in free energy and low in entropy while dissipating high entropy energy back in to the environment (Prigogine & Stengers, 1984)—the emergence and maintenance of spontaneous organization and pattern depend on boundary conditions *external* to the system itself. Without exogenously controlled conditions, such organization in these open systems disappears (Juarrero, 2009; Ruiz-Mirazo & Moreno, 2004). Some physicochemical systems, like the candle flame, exhibit a form of organizational *self-maintenance* in that they can promote their own order within narrowly constrained environmental circumstances but are limited in not being able to "maintain the property of being self-maintenant" (Allen & Bickhard, 2011, p. 108; Bickhard, 2009). Living dissipative systems, or *autopoietic* systems, in contrast—which Bickhard (2009) terms *recursively self-maintenant*—evidence autonomous generation and maintenance of organization by generating the very boundary conditions required for creation and maintenance of their *self*-organization (Ruiz-Mirazo & Moreno, 2004). *Autopoietic systems, in other words, construct themselves*.

The generation of organization in typical physicochemical dissipative systems requires no autonomous activity on the part of the system for its explanation of emergent patterning, because organization in such systems is essentially assembled from without. However, in autopoietic systems, the system's organizational integrity, within which the local dynamics of the system are contextualized, is a necessary component of explanation for the system's patterning. The autopoietic system *qua system* produces the very components that give rise to it, establishing its own self-maintaining processes through its incessant exchange of energy and matter with its surround (Thompson, 2007; Weber & Varela, 2002). Thermodynamically open, autopoietic systems establish *organizational closure* in that they metabolically maintain their organization in the face of continuous turnover and renewal of their material and energetic constituents (Jonas, 1966; Moreno & Umerez, 2000; Varela, 1979; Weber & Varela, 2002). Autopoietic systems thus actively regulate the very external boundary conditions that produce them—by regulating the flow of energy and matter—thereby incorporating external boundary conditions into their own dynamics (Juarrero, 2009; Thompson, 2007).

The living cell exemplifies autopoiesis, functioning as a self-producing, metabolic system in which "every molecular reaction in the system is generated by the very same system that those molecular reactions produce" (Thompson, 2007, p. 92; Varela, 1979). The cell dynamically and continuously constructs its own membrane

—the semipermeable boundary that establishes self-other distinction, the divide between itself and its surround—through metabolic processes that exist and operate only by means of the membrane they construct (Thompson, 2007). Thus, the products of cellular process are necessary conditions for the enactment of the process itself (Juarrero-Roque, 1985). Such systems cannot be adequately explained through sole reliance on the temporal dynamics of efficient cause, for, as Kant (1790/2007) classically established, something that organizes itself is a "natural purpose," which means that it is "both cause and effect of itself" (p. 199). Autopoiesis, in keeping with von Bertalanffy's organizational focus, requires the framing of living phenomena in final causal, teleological terms, wherein "purposiveness" or "that for the sake of which" provides a key component of scientific explanation.

Von Bertalanffy's writings on the wholeness of dynamics did not confine themselves simply to *synchronic* articulations of organization and purpose—the organic unity that formally and functionally characterizes a system's real-time dynamics at any given point in time. Understanding system organization for von Bertalanffy (1933) additionally required a historical dimension of embeddedness, in which the meaning of current organization is only fully explicable through its relative positioning in a structural sequence of organizational forms, yielding a teleological frame at the level of developmental time. Von Bertalanffy's forays into these issues of *diachronic* organization, though less detailed than his work on synchronic organization, add a level of developmental organization to GST's emphasis on the wholeness of dynamics (Overton, 1975).

Diachronic Organization: The Organism's Development as Organized Emergence

Development begins and ends in wholeness; in von Bertalanffy's (1933) words, "the developing germ is to be conceived as a unitary system" and "the primary unity and wholeness of the individual prevails in all stages of life" (p. 179). For von Bertalanffy, changes in development fundamentally mapped onto a sequence of transformations in the organizational nature of the developing system's wholeness. Specifically, he argued that "organisms assume ever more improbable states of higher organization and order" (von Bertalanffy, 1975, p. 117) characterized by what he described as a tendency toward maximal organization: "so long as an organic system has not yet reached the maximum organization possible to it, it tends toward it" (von Bertalanffy, 1933, p. 186). In this, von Bertalanffy appealed to the fundamental *directionality* of development as an explanatory framework within which specific levels of organization during development were meaningfully embedded (Overton, 1975). System wholeness at any given point in time (the synchronic structure of the system) is itself part of a larger system wholeness abstracted across the history of organizational transformations in the system (the diachronic structure of the system) and is only fully explicable when framed in terms of that larger system wholeness. Through this focus on the structuring of development as a whole, von Bertalanffy (1933, 1968a, 1975) promoted a final explanatory framework for understanding development that mirrored the orthodox principles of directionality and sequence in development formalized in the classic embryological writings of von Baer (see Gottlieb, 1992) and given psychological extension through the classic systems approaches of Piaget (1971, 1985), Werner (1957), and Vygotsky (1978).

GST frames the directionality of living systems' development in terms of two complementary principles: differentiation and progressive mechanization (von Bertalanffy, 1968a, 1975). In contrast to mechanistic portrayals of development—as an assemblage of complex structures from the combination and association of basic, foundational elements—GST's approach to development establishes *differentiation as its primary organizational principle*: "The organization of biological wholes is built up by differentiation of an original whole which segregates into parts.... Progress is possible only by passing from a state of undifferentiated wholeness to differentiation of parts" (von Bertalanffy, 1968a, pp. 69–70). Development as differentiation involves directional transition from an initial, homogenous whole, diffuse in its organization—what von Bertalanffy (1968a) termed "an undifferentiated absolute of self and environment" (p. 212)—to increasingly heterogeneous wholes characterized by distinctly definable yet intercoordinated parts.

As development in the living system proceeds via differentiation, new levels of differentiated wholeness are marked by greater specialization of the system's parts, and the system becomes increasingly amenable to mechanized, closed system descriptions, even though the system as a whole always remains thermodynamically open to its surround. Once parts of the system assume distinct specializations, these parts—now as wholes in their own right—start functioning in increased, though never complete, autonomy from one another and from the larger system as a whole, with certain parts coming to predominate the activity of the whole. Von Bertalanffy (1960) termed this developmental trend *progressive mechanization*, wherein systems become more efficient but at the price of their equipotentiality and thoroughgoing interdependence: "ontogenetically . . . we find a transition from less mechanized and more regulable states to more mechanized and less regulable ones" (p. 17).

In highlighting the wholeness of dynamics vantage point, von Bertalanffy argued both for the ontological legitimacy of formal and final explanation and for the epistemological necessity of establishing an organizational framework of explanation to constrain investigation of a system's dynamic process. With respect to the process dynamics themselves—the temporal unfolding of interpenetrating relations among the component parts of a system—von Bertalanffy offered relatively few specifics but in no way undervalued the *dynamics of wholeness* as an equally important vantage point for understanding systems. As emphatic as he was in stressing the organization of process, von Bertalanffy was equally emphatic in stressing the process of organization, for "the primary order of organic processes must be sought in the processes themselves" (von Bertalanffy, 1960, p. 17).

The Dynamics of Wholeness: The View From Below

Characterizing systems from the vantage point of their dynamic processes, von Bertalanffy distinguished between *primary* and *secondary* regulations. Primary regulations form a base level of "dynamic" interaction among components of a system, involving what von Bertalanffy (1968a) described as a "free interplay of forces and mutual interaction between components" (p. 161). Given their incessant build-up and break-down of material constituents, open systems *both* incorporate molecules high in free energy and low in entropy from their environment *and* expel high entropy energy back into the environment, allowing for new levels of organization to emerge in the system by counteracting the irreversible increases in entropy that necessarily take place within the boundaries of any system (Brent, 1978; Prigogine & Stengers, 1984; von Bertalanffy, 1968a, 1975). As metabolic outgrowths of this ceaseless interchange of material and energy, primary regulations among the system's components lead the system toward new levels of organization, or *steady states* (von Bertalanffy, 1968a). These regulations govern all interrelations of system components in the early stages of development and remain the process ground for living system organization as a whole throughout the system's life span (von Bertalanffy, 1968a).

As systems undergo differentiation, more structurally constrained processes called *secondary* regulations—"controlled by fixed arrangements, especially of the feedback type" (von Bertalanffy, 1968a, p. 44)—arise from primary regulations. Secondary regulations map onto the feedback-based control mechanisms of cybernetics approaches and embody for von Bertalanffy "the Cartesian machine model of the organism, unidirectional causality and closed systems" (p. 163). Critically, secondary regulations always operate within the wider context of primary regulations, on which they energetically depend. Whereas primary regulations showcase the nonlinear, reciprocal, internal relations among components of a system—relations that transcend unidirectional notions of antecedent to consequent causality by framing systems in multiply determined terms via *distributed* efficient causality—secondary regulations showcase the orthodox antecedent-consequent, linear, and ultimately summative relations among system components that mark the progressive mechanization that systems exhibit with increased differentiation and specialization.

Von Bertalanffy (1968a) stressed the centrality of primary regulations over the more scientifically orthodox, mechanistic processes of secondary regulations, which, though important in their own right, were always a more locally constrained derivative of dynamic processes of interaction:

> The basis of the open system model is the dynamic interaction of its components. The basis of the cybernetic model is the feedback cycle. . . . The open systems model in kinetic and thermodynamic formulation does not talk about information. On the other hand a feedback system is closed thermodynamically and kinetically; it has no metabolism. . . . An open system may "actively" tend toward a state of higher organization, i.e. it may pass from a lower to a higher state of order owing to conditions in the system. A feedback mechanism can "reactively" reach a state of higher organization owing to "learning," i.e., information fed into the system. (p. 150)

When von Bertalanffy's grand accounting of *General Systems Theory* was published in 1968—just a few years before his death—the quantitative study of secondary regulations, through subdisciplines of GST such as cybernetics, had been flourishing for years. His own attempts to mathematically capture and systematically explore the nature of primary regulations, however, proved far less tractable.

To study systems from the vantage point of their dynamic relations, von Bertalanffy (1968a) clearly recognized both the need to map changing relations across time among multiple values or quantities (instantiating different components of the system as a whole) and the complexity involved in doing so mathematically. He wrote of systems that "the prototype of their description is a set of simultaneous differential equations which are nonlinear in the general case" (p. 19). In this, von Betalanffy left no doubt as to the critical function of *nonlinearity* in the temporal dynamics of primary regulations. However, nonlinear differential equations are not amenable to traditional closed-form, analytical solutions, and von Bertalanffy apparently knew little of the topological, qualitative mathematics—first developed by Poincare in the 19th century—available to study nonlinear systems (Gottman, Swanson, & Murray, 1999; Gottman, Swanson, & Swanson, 2002). He viewed the mathematical modeling of a system via multiple nonlinear differential equations as ideal but "impossible" (von Bertalanffy, 1968a, p. 20), with practicality dictating for von Bertalanffy the need to render by means of linear approximations the differential equations he employed for modeling purposes (Gottman et al., 1999).

Thus, although von Bertalanffy (1968a, 1975) pointed to the dynamic interactions of primary regulations as crucial processes through which organization arises in systems, his mathematical applications yielded little elaboration of the "dynamics" themselves and of how the development of higher levels of organization is made possible through such dynamics. During von Bertalanffy's lifetime, however, major advances in the mathematical understanding of nonlinear systems were already underway in the physical sciences, paving the way for what has come to be known as nonlinear dynamical systems theory (Gleick, 1987; Guastello, 1997; Molenaar & Raijmakers, 1998). Alongside von Bertalanffy's GST, nonlinear dynamical systems theory establishes—both in nomenclature and technique—the guiding conceptual framework for the DS approach to development. Encompassing many specific research foci, such as catastrophe theory (Thom, 1975), chaos theory (Barton, 1994; Gleick, 1987), far-from-equilibrium thermodynamics (Prigogine & Stengers, 1984), and synergetics (Haken, 1996), the study of nonlinear dynamics critically informs the *dynamics of wholeness* vantage point with precisely the kind of mathematical formalization that von Bertalanffy had considered "impossible" to achieve.

NONLINEAR DYNAMICS: MATHEMATICALLY FORMALIZING THE DYNAMICS OF WHOLENESS

In systems close to equilibrium—and thus amenable to description via classical thermodynamics—levels of flow process, or fluctuations, are minimal and can be accounted for through traditional linear equations (Capra, 1996; Juarrero, 1999). However, open systems, as von Bertalanffy (1950) described them, are "maintained in distance from true equilibrium" (von Bertalanffy, 1968a, p. 142) and exhibit order by means of incessant exchange of material and energy. Fluctuations in these far-from-equilibrium, dissipative systems increase both in variability and magnitude and, unlike those of close-to-equilibrium systems, involve complex temporal dynamics that can only be adequately modeled through *nonlinear* differential (and difference) equations (Barton, 1994; Prigogine & Stengers, 1984). This holds true for all manner of far-from-equilibrium systems, from the physicochemical systems of whirlpools and hurricanes to the autopoietic systems of living organisms and the physical and psychological levels of organization that they construct throughout their development.

Under certain thermodynamic conditions of exchange between far-from-equilibrium systems and their surrounds, flow processes yield stable regimes of organization, which can be maintained as long as these fluctuations remain within a given range. In the realm of development, for example, individual persons are characterized by stable organization over extended time periods in the form of a given stage or level of developmental organization so long as the ceaseless fluctuation and variability of their ongoing exchange with the world remains bounded within a certain range. But beyond certain thresholds of value, the same interplay of flow processes amplifies to render unstable the system's current level of organization, "compelling it to evolve toward a new regime" (Prigogine & Stengers, 1984, p. 141). Thus, in far-from-equilibrium systems, fluctuations serve as the process source for both instability and increasing levels of system stability and complexity; via positive feedback loops, microscopic flow processes become amplified, destabilizing the system at a macroscopic level but also opening up new possibilities for macro-level order (Prigogine & Stengers, 1984). Again, with respect to development, when the intrinsic variability and fluctuation that characterize an individual's active engagement with her or his world amplify beyond certain thresholds, a developmental transition occurs as that individual's previously stable level of developmental organization becomes unstable and gives way to new possibilities for developmental organization, as in, for example, the transition from sensorimotor to preoperational forms of intelligence or from unidimensional to multidimensional systems of thought.

By the late 1950s, the introduction of high-speed computers coupled with the visual graphical techniques of Poincare's topological approach had established the means to "probe the complex interior of nonlinear equations" (Briggs & Peat, 1989, p. 23), ushering in a new mathematics of complexity for capturing the fluctuation dynamics of far-from-equilibrium systems (Capra, 1996). This new mathematics of complexity established constructs and techniques for the study of change across a wide range of disciplines and phenomena—from the inorganic to the organic—giving birth to the multidisciplinary approach of nonlinear dynamical systems theory (NDS) (Guastello & Liebovitch, 2009). As a mathematical theory, NDS has revolutionized both the way we as scientists study the dynamics of process and the way we understand those dynamics, with nonlinearity, variability, and the importance of local conditions assuming center stage in the quest to reveal how organization arises in nature, without any set of instructions or prescription (Guastello & Liebovitch, 2009; van der Maas, 1998). In other words, to understand the dynamics of those broad and reliable developmental transitions in individuals' functioning—from one stable level of developmental organization to another—we as scientists must immerse ourselves in the intraindividual "performance" variability that we witness across real time as specific individuals continuously act in specific contexts.

The two sections that follow provide a "broad stroke," simplified overview of both the quantitative and qualitative mathematical tools and concepts with which NDS works (the analytic details of which are beyond both the scope of this chapter and the ken of its author). These tools and concepts provide a unifying framework for describing and understanding change in all its complexity, grounded in the importance of variability and nonlinearity. They reveal that incremental, quantitative change in an iterated set of equation variables can suddenly coalesce to shift the equation's solution to qualitatively new levels of patterning irreducible to any variable in the set; thus, the ceaseless, ever-present microfluctuations of systems, under far-from-equilibrium conditions, spontaneously yield new system qualities, driving the system to new (i.e., emergent) levels of macroscopic order.

The Quantitative Mathematics of Spontaneous Emergence

Examining the wholeness of systems—both synchronically (i.e., atemporally) and diachronically (i.e., developmentally)—from the standpoint of their dynamics requires immersion in the ever-present *motions* of systems, their ceaseless variability over both real and developmental time, during periods of organizational stability as well as transformation (Kelso, 2000). System organization during periods of developmental stasis consists of stable relations among the continuous motions of the system's components. For example, take a cognitive system consisting of attentional, motivational, and memory components: despite continual fluctuations and variability in the functioning of the components themselves, the cognitive system remains organizationally stable so long as the relations that obtain among these three component processes remain stable. Developmental transformations in system organization are characterized by fluctuations at the level of the relations themselves (e.g., a change in the nature of relations among the attentional, motivational, and memory components of the cognitive system). This leads to new, stable sets of relations among component motions, reflecting a new level of developmental organization in the system. Modeling the dynamics of a system at any point in its development involves temporally interrelating *rates of change* among the motions of the system's components—that is, the variables of the system. Mathematically, this is achieved through the use of equations of motion—such as differential equations—which, by tracking the short-term dynamics of the system, can establish longer-range forecasts for future states and transition points in the system (Abraham & Shaw, 1992; Hirsch, 1984).

Recall that a linear relation is one in which output is proportional to input, offering straightforward prediction as in the relation between how many times a clock is wound and how long that clock will operate (Friedenberg, 2009). More specifically, in a linear relation occurring between the changing quantities of two variables, both variables change at the same rate. Plotting one variable in relation to the other produces a line, the slope of which remains the same for all values of each variable, as Figure 3.1a illustrates. Thus, how much one variable, y, changes in

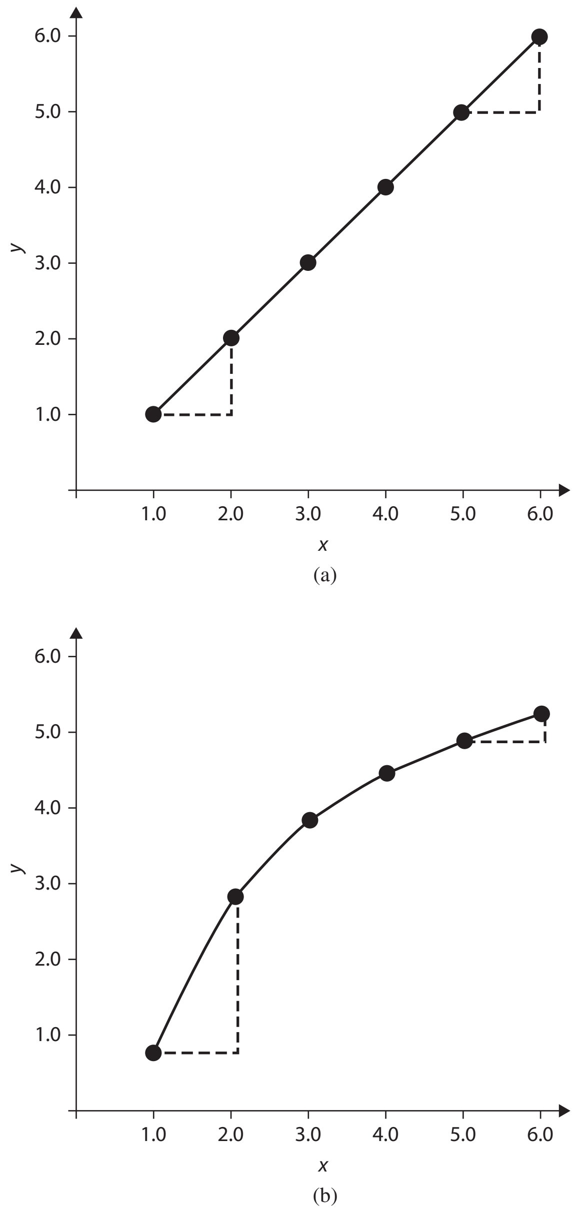

Figure 3.1 Examples of (a) a linear relation and (b) a nonlinear relation between variables *x* and *y*. Note that in (a), any two intervals of change in variable *x* (e.g., from 1 to 2 or from 5 to 6) are always associated with the same interval of change in variable *y*. In (b), however, different intervals of change in variable *y* accompany the same intervals of change in variable *x*.

relation to another variable, *x*, remains the same no matter what value of *x* is considered. From the perspective of changes in *x* leading to change in an outcome *y*, the effect of a change in *x* on *y* does not vary with the value of *x*—each wind of the clock yields a given length of time for its operation, and more winds yield proportionally longer operation.

In the realm of nonlinear relations, however, how much *y* changes in relation to *x does* vary as a function of what value of *x* is considered, meaning that nonlinear relations deal with *variable* rates of change. As Figure 3.1b illustrates, a nonlinear relation between two variables yields a curve, the slope of which changes point by point—for the same increment of change in *x*, change in *y* can vary dramatically. Weather patterns—where small changes in atmospheric conditions can suddenly lead to disproportionately large effects in weather output, making long-term prediction impossible—classically depict what it means for a relation to be nonlinear. Unlike equations depicting a linear relation between variables, nonlinear equations feature one or more variables either multiplied by itself or raised to a higher power; in other words, variables interact with, or feed back to, themselves in nonlinear functions. Relations of nonlinearity thus characterize variables that are "internally" related (Kitchener, 1982): the rate of change in one variable itself varies as a function of another variable's rate of change, and vice versa, magnified across a multitude of interdependent variables in complex systems. Or, in Gleick's (1987) words, "Nonlinearity means that the act of playing the game has a way of changing the rules.... Analyzing the behavior of a nonlinear equation ... is like walking through a maze whose walls rearrange themselves with each step you take" (p. 24).

Describing the slope of a curve for a nonlinear relation means being able to assess variable rates of change on the curve at any given point—the instantaneous velocity of the curve, modeled through a differential equation. By means of the method of differentiation, exact values for the rate of change in *y* as a function of *x* can be derived. Though all differential equations deal with how the rates of change among variables interrelate, not all differential equations are considered nonlinear. Those differential equations for which the function and its rate of change, or derivative, remain at a power of 1 are called linear differential equations. Linear differential equations are appropriate for systems whose components are varying in their rates of change relative to one another but for which the pattern of changes emerging from these varying rates of change can itself be modeled in terms of a functional relation that remains stable across time. In other words, the rate of change of the functional relation that is modeled in a linear differential equation is *itself* constant, even though the variables that comprise the relation are varying in their rates of change relative to one another.

By way of illustrating this property of linear differential equations in more general terms, take, as a highly simplified example, how y varies in relation to x in the function $y = x^2$. When $x = 1$, $y = 1$; $x = 2$, $y = 4$; $x = 3$, $y = 9$; $x = 4$, $y = 16$; $x = 5$, $y = 25$, and so on, as Figure 3.2a illustrates. Whereas each new x value differs from the previous value by 1—a constant rate of difference—each new y value differs from the previous value by varying quantities: first by 3, then by 5, then by 7, then by 9, and so on, a variable rate of difference. Thus, each of these variables exhibits different rates of change relative to one another, producing the curve of Figure 3.2a. Yet the *difference of the differences* between each value of y itself is constant, moving from 3 to 5, then from 5 to 7, then from 7 to 9, and so forth: It is always 2. Plotting the difference of the differences for y—a constant rate of change of 2—against the differences for x—a constant rate of change of 1—yields a straight line, or a linear relation, as Figure 3.2b illustrates. This demonstrates that a proportional functional relation still underlies the varying rates of change that x and y exhibit relative to one another.

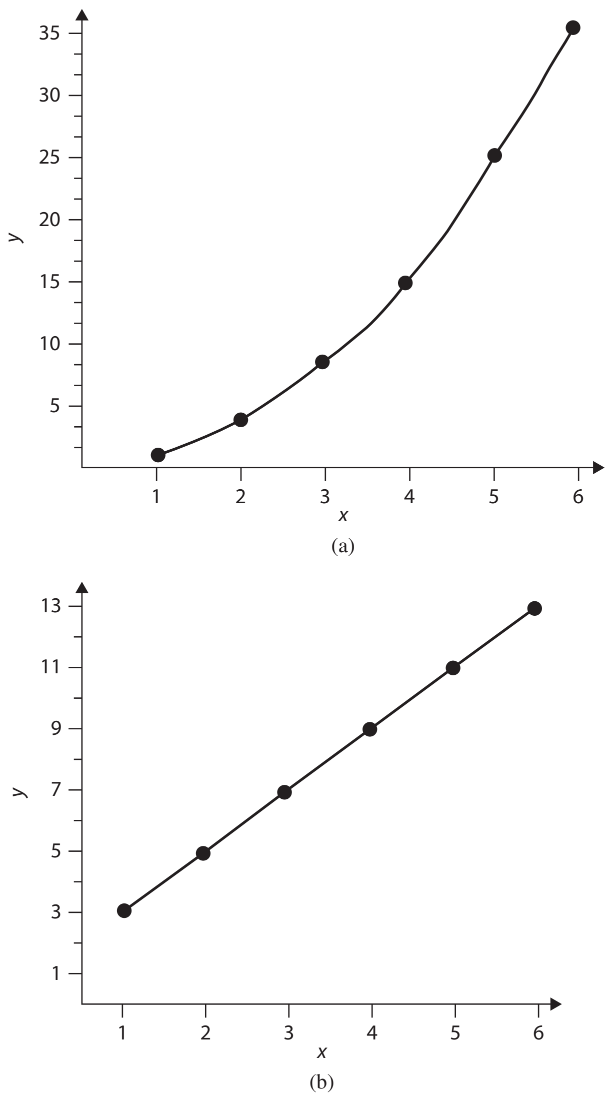

Figure 3.2 Graph (a) charts the equation $y = x^2$ and depicts the different intervals of change in variable y that accompany the same intervals of change in variable x. Though each new y value differs from the previous value by varying quantities across the same intervals of change in x, the difference of these differences is constant. Graph (b) demonstrates that a linear relation emerges from plotting the differences for x values against the difference of the differences for y values.

Nonlinear differential equations, however, are those for which the function and/or its derivative are multiplied by themselves or raised to a higher power. The rate of change in the functional relations that are modeled by these equations varies over time, just as the variables that comprise the relation vary in their rates of change relative to one another. Such equations, in other words, map change in the functional relation that itself captures varying rates of change among variables. This is precisely what is required to model the dynamics of organizational transformation in the *development* of a system, e.g., the transition from one stage or level of developmental organization (representing a given set of nonlinear relations among the system's components) to a new stage (representing a new set of nonlinear relations among the system's components). A common method for beginning to solve differential equations—and one that more adequately conveys what is going on in the modeling use of these equations—involves converting them into their discrete-time analogue: the difference equation. Difference equations are defined in terms of a recursive sequence of states such that each time state of the equation—its state at $t + 1$—is a function of its preceding time state, t, with this function being nonlinear for nonlinear difference equations (Kaplan & Glass, 1995). In other words, these equations operate through a process of *iteration*, of clear relevance to the modeling of developmental phenomena: the product of the equation's initial run—describing the instantaneous state of the system at $t + 1$—feeds back to the equation as a new initial state with which to produce a description of the instantaneous state of the system at $t + 2$, and so on (Guastello & Liebovitch, 2009; van Geert & Steenbeek, 2005).

Thus, the function modeled in the difference equation is repeatedly applied to itself by using the output from one iteration of the equation as input for the next iteration, yielding both negative and positive feedback loops (Briggs & Peat, 1989; Capra, 1996). Negative feedback loops serve a regulatory or maintenance function, decreasing the rate of a process as the magnitude of its product increases. The way in which thermostats control heaters through temperature monitoring—shutting off the heater when room temperature reaches a certain level—provides a classic example of a negative feedback loop. Positive feedback loops, in contrast, serve an amplificatory function, increasing the rate of a process as the magnitude of its product increases and creating the conditions for system growth. The deafening, screeching sound produced when a microphone is held too close to a loud speaker/amplifier—which essentially results in feeding the output of the amplifier back to the amplifier as input—provides a classic example of a positive feedback loop (Briggs & Peat, 1989). Both types of feedback loop play critical roles in far-from-equilibrium systems and the nonlinear differential/difference equations used to model them, but positive feedback processes, as detailed later, are especially central to understanding the dynamics of system instability and transformation (Ford & Lerner, 1992; Juarrero, 1999; Prigogine & Stengers, 1984).

Remarkably, a single nonlinear difference equation, through successive iterations, can capture various, qualitatively distinct states of the developing system across time: stable, repetitive patterning of variable motions, amplified periods of flux where output patterning breaks down altogether, and reconfigured patterning of variable motions (May, 1976). Defying conventional wisdom, even the most simple and deterministic of these equations can model highly complex stability and change in systems—with exact prediction often breaking down after many iterations of the equation, demonstrating that both ordered pattern and turbulent, chaotic instability arise from the same quantitative dynamics of motion (Abraham & Shaw, 1992; Briggs & Peat, 1989).

A widely cited mathematical example of such "complexity from simplicity" originates in the logistic equation $f(x) = rx(1 - x)$, first formulated by Verhulst in the mid-19th century as a model of population growth and extensively analyzed in the mid-20th century, reflected in May's (1976) systematic and integrative review. Converting this differential equation to its discrete-time analogue—the nonlinear difference equation $x_{n+1} = r(1 - x_n)\, x_n$—and mapping successive iterations of the difference equation reveal astonishing results, as Figure 3.3 depicts with x initially set at .5 and with values of r, a constant, gradually raised from 2.4 to 4.0. Bear in mind that the figure depicts for each value of r what solutions to the equation look like after multiple iterations (over 100) have ensued. At any given value of r lower than 3, the equation yields a series of oscillations with each successive iteration, but after

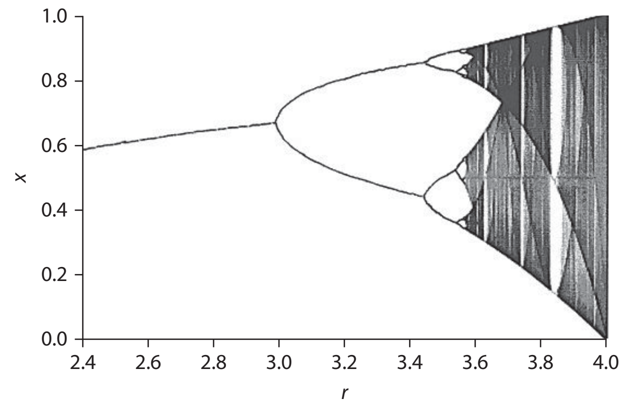

Figure 3.3 Bifurcation diagram for the logistic equation $x_{n+1} = r(1 - x_n)\, x_n$, revealing period-doubling transitions that eventually give way to chaos with x initially set at .5 and r raised from 2.4 to 4.0.

multiple iterations these oscillations eventually dampen around a single point of convergence, which is referred to as an *attractor*. As r is pushed closer and closer to a value of 3, larger oscillations arise with each new level of r but still eventually settle to reveal a stable point of convergence for each new level (Briggs & Peat, 1989). However, when the value of r eventually reaches 3.0, subsequent iterations of the equation now yield oscillatory patterns that eventually settle into not one but two stable cycles of convergence. As the value of r reaches 3.4495, subsequent iterations yield not two but four stable cycles, or "cycles within cycles" (Guastello & Liebovitch, 2009, p. 15). Each stable periodic cycle continues to double with quantitative increases in r—from a stable cycle, for example, of Period 4 to Period 8 when r reaches 3.5441 and again to Period 16 when r reaches 3.5644 (Kaplan & Glass, 1995). Eventually, when r reaches 3.5699, subsequent iterations no longer settle into stable periodic cycles but instead reveal the a periodic instability of chaos, where the activity of the system never repeats itself yet remains bounded (Guastello & Liebovitch, 2009), exhibiting "islands of order in a sea of randomness" (Briggs & Peat, 1989, p. 62) and making quantitative prediction impossible. Moving to even higher values of r results in the reemergence of stable periodic cycles from chaotic conditions, suggesting that "the route to chaos can simultaneously be a route to order" (Briggs & Peat, 1989, p. 64).

Both stable patterns of convergence and unstable, amplified fluctuations arise from the same positive and negative feedback dynamics of this equation. Within certain parameters of the equation, oscillatory patterns—fluctuations—are repeatedly dampened, only to amplify out of control within other equation parameters. Conditions of fluctuation amplification, in turn, set in motion system instability, out of which emerge new levels of order in the system, via the establishment of new relations among system components (Kossmann & Bullrich, 1997; Prigogine & Stengers, 1984). From the vantage point of the dynamics of wholeness, the bottom-up process dynamics of the system engender both transformation and organizational stability in development. The iterative results of this simple, deterministic equation further demonstrate that a continuous change in just one constant parameter of the equation—quantitatively identical to previous changes in that same parameter—can result at a certain threshold in qualitatively different and varied patterning for the output, or solution, of the equation. In other words, a *nonspecific* change in one component of a system, bereft of any "prescriptive information" or a set of formative instructions for what new forms will emerge, can nonetheless precipitate the system as a whole to establish new levels of organization (Molenaar & Raijmakers, 2000; Zanone, Kelso, & Jeka, 1993). Thelen, Fisher, and Ridley-Johnson (1984) provide a classic developmental example of this in their demonstration that quantitative changes in muscle-to-fat ratio prompt the context-specific "disappearance" of stepping movements in the early months of infancy.

All of this mathematically highlights the centrality of nonlinearity in the dynamics of wholeness: major, system-wide changes in organization can follow from small, nonspecific changes in one parameter of a system just as, conversely, a major change in one parameter of a system may have little to no system-wide impact on overall organization. Consider, for example, a quality that nonlinear systems evidence during periods of increased fluctuation and instability: sensitive dependence on initial conditions, or the "butterfly effect," whereby "two states differing by imperceptible amounts may eventually evolve into two considerably different states" (Lorenz, 1963, p. 133). In modeling fluid convection with three simplified nonlinear differential equations, Lorenz (1963) classically demonstrated that virtually identical initial values for the variables of the equations did not guarantee virtually identical trajectories of change after extensive iterations of the equations. Rather, altering by an infinitesimal amount the initial value established for even just one of the variables resulted in a trajectory of change that departed substantially from the same set of equations absent the infinitesimal alteration. Thus, even the most insignificant of differences can make a difference, especially as systems move toward instability, prompting Lorenz to assert that "prediction of the sufficiently distant future is impossible by any method" (p. 141). In particular, *numerical prediction becomes impossible* under the *unstable*—that is, easily susceptible to disturbance—and *aperiodic*—that is without regular cycles of repetition—conditions of system chaos (Kellert, 1993). As a routine and theoretically fundamental feature of both the living and nonliving worlds, sensitive dependence on initial conditions highlights the deep-seated inadequacy of traditional Cartesian-Mechanistic science for capturing natural phenomena of change in even the most rudimentary of open systems. Conceptualizing the natural world in clockwork terms—composed of linear, additive relations among isolable elements that can, with precise enough measurement, yield accurate, long-term prediction—is simply no longer tenable in the face of nonlinearity's ubiquity in natural systems (Gleick, 1987; Kellert, 1993).

Given the variety and complexity of patterning derivable from a single, deterministic equation, nonlinear functions rarely resolve to a single solution; instead, these equations yield "a pattern of solutions" (Barton, 1994, p. 6). Understanding this pattern of solutions in NDS takes place through the visual, *qualitative* techniques of geometrical modeling, the mathematical roots of which lie in Poincare's innovations for capturing the overall *shape* of a system's plotted motions (Abraham & Shaw, 1992; Hirsch, 1984). Gleick (1987) vividly describes the utility of these qualitative mathematics in terms of:

> The possibility of using a shape to help visualize the whole range of behaviors of a system. For a simple system, the shape might be some kind of curved surface; for a complicated system, a manifold of many dimensions. A single point on such a surface represents the state of a system at an instant frozen in time. As a system progresses through time, the point moves, tracing an orbit across this surface.... Shapes that look roughly the same give roughly the same kinds of behavior. If you can visualize the shape, you can understand the system. (p. 47)

Studying the geometry of a system's dynamics—its movement through an abstract mathematical space—establishes a holistic means for mathematically understanding system organization and its transformation. It allows for the abstraction of invariant patterning from the multitude of interdependent rates of change that characterize the motions of a system's components in relation to one another, even when local prediction of component motions breaks down.

The Qualitative Mathematics of Spontaneous Emergence

Equations of motion for system change can be topologically framed in terms of a *state* or *phase space*—a "geometric model for the set of all idealized states" of a system over time (Abraham & Shaw, 1992, p. 15). This multidimensional space is comprised of *at least* two axes, or dimensions, with every axis of the space corresponding to a variable employed in the equation(s) of motion. Each axis, in other words, captures a component of the system whose dynamics are being modeled. If the system of interest is emotion, for example, a state space for this system could consist of four separate axes corresponding to appraisal, goal, action tendency, and situational/contextual components. If the system of interest is the organism taken as a psychological whole, a state space could involve three axes of psychological functioning: cognitive, conative, and emotional. Or if the system of interest is a parent-child dyad, a state space might simply involve two axes: child and parent affect. The nature of the components themselves—and the axes that comprise the state space—depends on the questions being asked and the theoretical assumptions guiding one's characterization of the system, for as Kunnen and van Geert (2012b) note, systems (and the components that comprise them) "do not simply exist out there . . . we define them ourselves" (p. 19).

Every point within a state space marks a unique intersection among all of the variables that define the axes for the space; thus, every point on the state space reflects a possible instantaneous state of the system as a whole. In the case of a state space for the emotion system, each point in space could represent a current state of emotional experience or behavioral activity. When the changing states of a system are plotted, trajectories connecting successive points in the space demarcate temporal change in the states of the system, for example fluctuations in emotional activity across real-time. Through differentiation, not only can the instantaneous velocity of these specific trajectories at any point be established but also a broader velocity vector field that predicts tendencies for change of the system at different points in the state space can be constructed (Abraham & Shaw, 1992).

For a concrete and highly simplified example, take a state space that models the movement of a pendulum subject to friction and air resistance (e.g., Abraham & Shaw, 1992). Such a state space requires two axes—a standard Cartesian coordinate system—to plot the angle of elevation for the pendulum's bob against its rate of rotation. Figure 3.4a depicts an example of a movement trajectory for the pendulum, with each point of the trajectory representing an instantaneous state of the pendulum and with the trajectory connecting these points depicting change in the state of the pendulum over time. From the vantage point of its state space depiction, the movement of the pendulum resembles a spiral winding down to rest at the zero point of the two axes. In fact, when different points in the state space are chosen as starting points for the oscillation of the pendulum, the pendulum's trajectory will always assume the form of a spiral, inevitably coming to rest at the zero point of the space.

Unless a system is completely random in its state generation, it will not visit all portions of its state space (Juarrero, 1999). Instead, for any given system, certain regions of state space are more likely to be occupied than others; the system seems actively drawn or attracted to certain areas and repelled by others. As mentioned earlier, those portions of a state space toward which the trajectories of a system converge are called *attractors*. With reference to the example of an emotion system state space, attractors would correspond to stable patterns of emotional activity that, for any given level of developmental organization, establish an individual's characteristic emotion tendency repertoire. The effectiveness of an attractor in drawing system trajectories toward it depends on its range of influence within the state space—its *basin* of attraction. The wider the attractor basin, the more pull it has. In the pendulum example, the zero point of the state space constitutes the single attractor for this simple system, and the region surrounding the zero point comprises the attractor's basin. State spaces designed to model complex systems will routinely consist of multiple basins of attraction, reflecting multiple patterns of behavioral or state stability within the system, (e.g., qualitatively distinct and stable patterns of emotional activity for an individual, such as fear, anger, jealousy, happiness). Within the region of any given attractor, particular rules of motion apply, lending the attractor its particular geometric shape (e.g., the spiral characterizing the pendulum swing [Guastello & Liebovitch, 2009]). Attractors thus mark states of system stability—the dynamic states of disequilibrium that constitute steady states. They are the patterns into which the system settles after transient fluctuations are dampened: the asymptotically stable solutions to differential equations (Abraham & Shaw, 1992; Hirsch, 1984).

All regions of the state space that lie outside the basins of its attractors are called *separatrices* (Abraham & Shaw, 1992). Separatrices are those portions of a state space

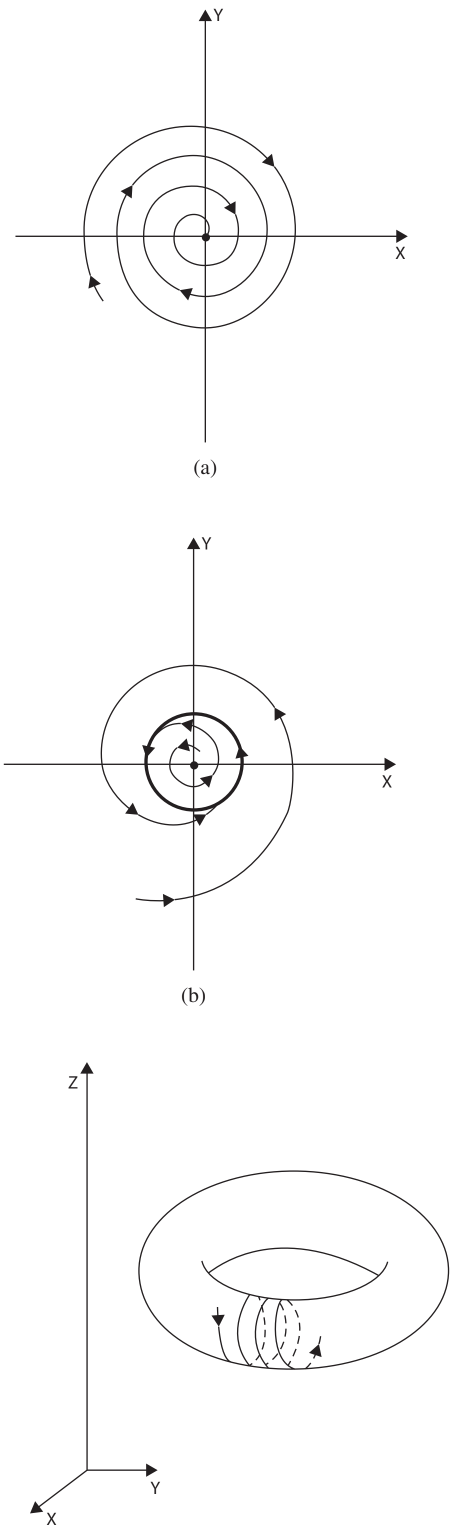

Figure 3.4 Examples of three types of attractor: fixed-point (a), limit-cycle (b), and toroidal (c). (a) and (b) specifically plot the angle of elevation for a pendulum (the *x* axis) against its rate of rotation (the *y* axis).

from which trajectories of a system diverge; movement of the system within these regions "is deflected away from the epicenter" of the separatrix, which is why these regions are also termed *repellors* (Guastello & Liebovitch, 2009, p. 10). System activity within separatrices, unlike that within attractors, is marked by instability—these regions are structurally unstable, in contrast to the structural stability of attractor regions. For example, in the emotion system state space of an easygoing individual who routinely "goes with the flow," hostile anger patterning might constitute a separatrix region of emotional activity. In what has become a common topographical metaphor, state spaces can be thought of in terms of an evolving landscape of hills and valleys, in which the hills represent separatrices and the valleys represent attractors (e.g., Briggs & Peat, 1989; Thelen & Smith, 1994, 1998, 2006). A spherical rock—representing the instantaneous state of a system—situated on any given hill of this landscape is easily displaced and will fall downward toward the valleys of the landscape. The steeper the hill, the more easily displaced the rock. Once the rock ends up in a valley, it will be relatively resistant to displacement from the valley, with deeper valleys more thoroughly constraining displacement of the rock. Given that state spaces, as abstract mathematical concepts, can conceivably assume any number of dimensions, Briggs and Peat (1989) reframed this metaphor in terms of "hills and valleys of energy. Systems in nature are attracted to energy valleys and move away from energy hills" (p. 36). The complete landscape/state space of a system, replete with its attractors, basins, and separatrices, establishes the system's *phase portrait* and "provides a global overview of the modes of behavior of the system" (Mosekilde, Aracil, & Allen, 1988, p. 21).

Attractors in a state space fall under one of four broad classes: fixed-point, limit cycle, toroidal, and chaotic. In a *fixed-point attractor*, all trajectories converge on a single point, as the pendulum in Figure 3.4a illustrates. Although all trajectories terminate on a fixed point within this class of attractors, different patterns can arise in movement trajectories within the attractor basin; for example, the spiral patterning of a pendulum's movement differs in its dynamics from a fixed-point attractor in which all trajectories *directly* converge to a single point (Guastello & Liebovitch, 2009). Of all classes of attractors, only those of the fixed-point class can operate in linear systems (Mosekilde et al., 1988). Their relative simplicity notwithstanding, fixed-point attractors have proven successful in modeling many forms of nervous system activity (Schöner, 2009). In a *limit cycle*, or *periodic*, *attractor*, trajectories converge not on a single point but on a cyclic path, oscillating around an epicenter. Trajectories within the cyclic path move outward from the epicenter of the cycle to the cycle itself just as trajectories outside the cycle are attracted to the cycle, not to its epicenter (Abraham & Shaw, 1992; Guastello & Liebovitch, 2009). The movement of a clock pendulum as depicted in Figure 3.4b—swinging at a steady rate and counteracting air resistance and friction due to the energy bursts it receives from its mechanical components—stands as a simple example of a limit cycle.

The coupling of two limit cycles creates interdependent oscillatory patterning—"a limit cycle that is cycling along two axes rather than one" (Guastello & Liebovitch, 2009, p. 11)—and results in the class of attractors known as *toroidal,* or *quasi-periodic*. Topologically, the torus attractor involves a curved-surface manifold, doughnut-like in shape, as Figure 3.4c illustrates. If, for example, the oscillatory patterns of two pendulums became interlocked with one another, one pendulum cycle would be embedded in another pendulum cycle, "as if cycle A is swept around in a circle by cycle B" (Briggs & Peat, 1989, p. 39). Both limit cycle attractors and their more complex extensions—toroidal attractors—readily capture oscillatory phenomena in living systems and have been classically employed in the study of brain dynamics (e.g., Kelso & Tognoli, 2009; Thatcher, 1998) and motor activity, coordination and its development (e.g., Fitzpatrick, 1998; Kelso, 1995; Thelen & Smith, 2006; Turvey, 1990), among other areas.

Attractors at their most geometrically complex involve *chaotic* motion, seemingly random when examined quantitatively at the level of local detail and prediction but actually highly patterned when viewed as a qualitative whole. The state values for systems in the midst of a chaotic attractor are numerically unpredictable and extremely sensitive to initial conditions yet remain within a bounded area of activity (Guastello & Liebovitch, 2009; Kellert, 1993; Mosekilde et al., 1988). Within this bounded area, motion trajectories "asymptotically approach almost every location in the thickened surface" (Abraham & Shaw, 1992, p. 294), making these attractors resistant to absolute quantitative prediction yet fully deterministic mathematically speaking. One of the most famous chaotic attractors is the Lorenz attractor, pictured in Figure 3.5 and generated from his three equations for convection (Lorenz, 1963). In keeping with previous pendulum examples, chaotic patterns of motion can also arise in the simplest of coupled oscillatory systems, as when two pendulums are *attached* to one another—pivot to

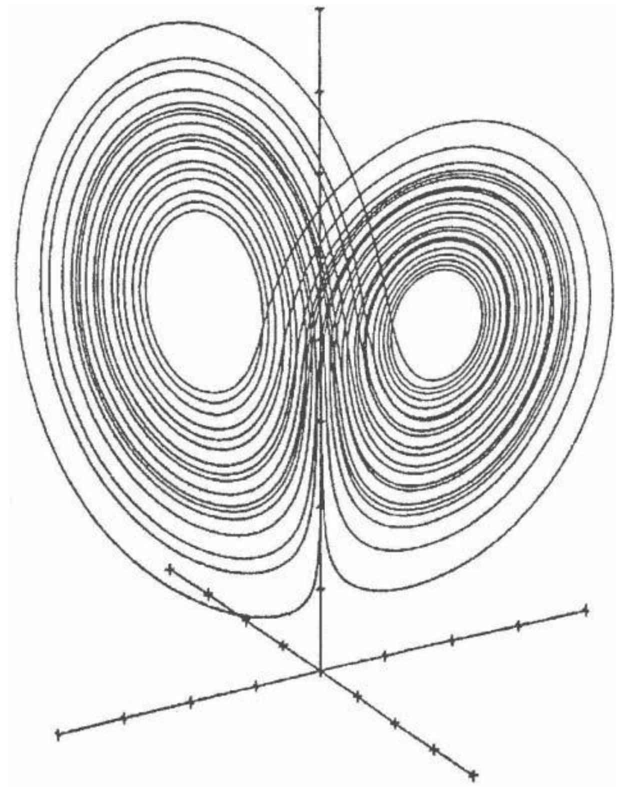

Figure 3.5 Example of a chaotic attractor, specifically the Lorenz attractor generated from his three equations for convection.

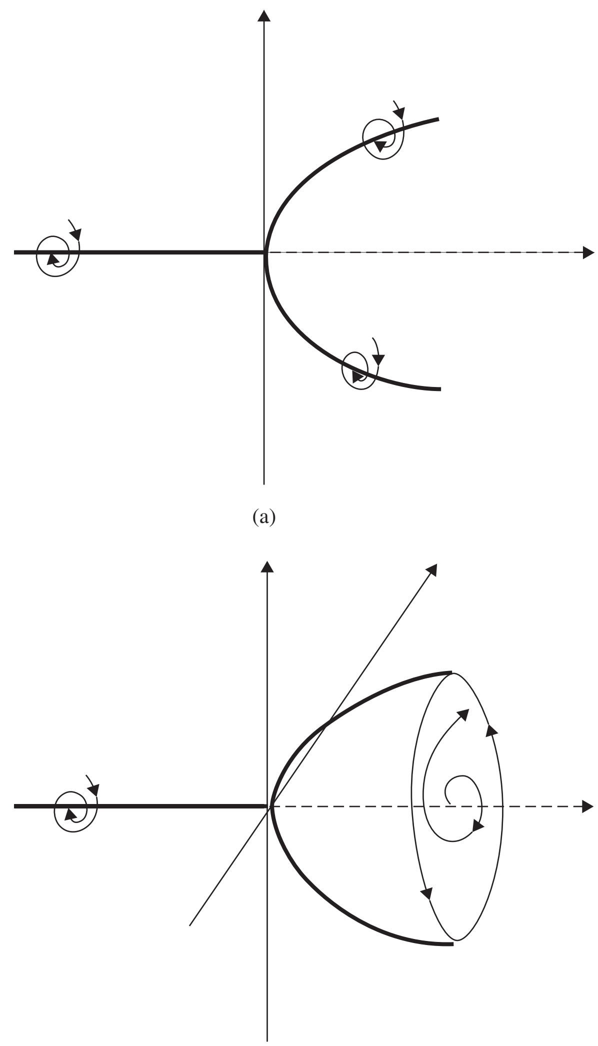
bob—and allowed to oscillate freely. Modeling neural activity in terms of chaotic attractors remains one of many prominent areas of scientific endeavor within the realm of living systems to employ principles of chaos, though such efforts are not without controversy (e.g., Durstewitz & Deco, 2007; Minelli, 2009; Skarda & Freeman, 1987; Tsuda, 2001).

Under conditions of system stability, the local, qualitative patterning of any given attractor—its broad class type and specific geometric patterning—persists despite quantitative alterations to the attractor, such as increases in its strength of pull or widening of its basin of influence. Similarly, the organizational stability that marks the system as a whole—during any given period of developmental stasis, for example—globally manifests itself in the topographical invariance of the system's phase portrait (Juarrero, 1999). In other words, a *phase portrait* consisting of stable topographical relations over time among a series of attractors and separatrices can correspond to a particular stage or level of developmental organization in an individual's developmental history. During such qualitative stability at the level of the system as a whole, the overall attractor and separatrix layout of the landscape remains configurationally intact, both in the midst of system activity moving from one attractor to another as a function of specific "task demands" and despite persistent *quantitative* alteration in the system's landscape, that is, its hills steepening and narrowing or its valleys deepening and widening. This relates to context-general, organizational characterizations of a system persisting in the midst of inherent fluctuation in the content of that system's activity across time and context; for example, the general organizational properties of the emotion system for a particular level of developmental organization persist whereas real-time emotional activity fluctuates both *between* local, stable patterns available to the system (moving from fear to anger to happiness, etc.) and *within* these stable patterns (intensity and duration changes, ease of elicitation changes, etc.). Thus, both locally and globally, the state space maintains its qualitative patterning in the face of flux during periods of system stability.

When, however, systems become unstable, either locally at the attractor level or globally at the state space level, *qualitative shifts* in the dynamics of the phase portrait arise, called *bifurcations*, yielding *new* levels of attractors and, by extension, state space organization. These bifurcations, in other words, can capture qualitative shifts from one stage or developmental level of stable organization in the system to another (via transitional periods of increased intrasystem variability). For example, consider the qualitative shift in infant emotional functioning from impulsiveness to wariness in the second half of the infant's first year of life. At the level of an infant's emotion system state space, this shift can be viewed in terms of the emergence of a new attractor corresponding to fearfulness between 7 and 9 months. This new attractor both adds a new valley of attraction to and reconfigures the existing topography of the attractor and separatrix landscape that characterized the largely impulsive character of infant overall emotional functioning at 4 to 6 months.

With respect to how bifurcations arise, recall that the graduated scaling of a certain parameter in nonlinear, deterministic equations can give rise to a dramatic reconfiguration for the output, or solution, of the equations. Such a parameter is known as a *control parameter*. Bifurcations in system dynamics manifest themselves under precisely those circumstances in which a control parameter moves beyond a critical threshold value for the maintenance of stability in a system, precipitating the *emergence* of new patterning in the system, both locally and globally (Guastello & Liebovitch, 2009). For example, self-produced movement experience could be construed as a control parameter for the transition from impulsiveness to wariness in infant emotional development, at least with respect to the emergence of fear of heights: converging evidence demonstrates that after a few weeks of accumulation in self-produced movement experience, infants begin to systematically avoid drop-offs (e.g., Campos et al., 2000; Thelen, 2000).

Different forms of bifurcation have been identified. Two of the most prominent forms are the *pitchfork* and the *Hopf*. Figure 3.6a illustrates a pitchfork bifurcation, in which two



(a)

(b)

Figure 3.6 Examples of two types of bifurcation: pitchfork (a) and Hopf (b). In (a), a fixed-point attractor bifurcates into two separate fixed-point attractors divided by a separatrix region. In (b), a fixed-point attractor bifurcates into a limit cycle attractor.

stable attractors—a bistable solution to system dynamics divided by a separatrix region of instability—emerge from a single stable attractor (Kelso, 1995). As a result of the bifurcation, what once was a stable region of attraction becomes a region of instability, flanked, in turn, by two, newly emergent regions of stability. Figure 3.6b depicts a Hopf bifurcation—"the complex equivalent of the pitchfork" (Kelso, 1995, p. 85)—consisting of the transformation of a fixed-point attractor into a limit cycle attractor when the critical threshold for a given control parameter is reached (Guastello & Liebovitch, 2009). Both forms of bifurcation can be thought of in terms of processes of differentiation in development; for example, the hypothesized differentiation of specific emotion patterns of anger and sadness from an undifferentiated pattern of distress. A complex variation on the simple Hopf bifurcation emerges from the logistic equation whose successive iterations were modeled in Figure 3.3. Figure 3.3, in fact, presents a bifurcation diagram illustrating the *period-doubling*, or *Feigenbaum*, *bifurcation* in which a system's dynamics undergo qualitative reorganization from fixed-attractor to limit cycles to chaos—in the midst of which new limit cycles emerge—all as a single control parameter gradually increases in value (Abraham & Shaw, 1992; Guastello & Liebovitch, 2009; Kelso, 1995).

Of the many types of bifurcation, perhaps the most primary is the *saddle-node*, or *fold bifurcation* in which fixed-point attractors are spontaneously created or annihilated in a state space (Thompson & Stewart, 1986). For example, a decrease in the value of a control parameter may result in an existent fixed-point attractor moving ever closer to the repellor point of the separatrix, which exists at the edge of the attractor's basin. When the attractor arrives at this boundary point, the attractor, its basin, and the separatrix are simultaneously destroyed. With an increase in the value of the same control parameter, the attractor and its separatrix spontaneously emerge (Abraham & Shaw, 1992; Thompson & Stewart, 1986). Fold bifurcations and their two control parameter complement—the cusp bifurcation—are foundational to the branch of bifurcation study known as catastrophe theory (Thom, 1975; Zeeman, 1977). *Catastrophe theory* has enjoyed successful application to the study of development in areas ranging from Piagetian stage transitions in the development of conservation (van der Maas & Molenaar, 1992) to the transition in motor development from reaching without grasping to reaching coordinated with grasping (Wimmers, Savelsbergh, Beek, & Hopkins, 1998).

The Continuity of Dynamic Process

The complementary quantitative and qualitative mathematics of NDS have revealed that surprising *nonlinear* complexity is available to even the most simple and deterministic of systems. In turn, these mathematical formalizations of the *dynamics* of wholeness highlight the continuity that exists in dynamic process across varied levels of complexity in the organization of real-world phenomena. Mirroring GST's call for the expansion of physics to include life phenomena and for the recognition that "organization runs right through all levels of reality and science" (von Bertalanffy, 1968b, p. 34), NDS calls for the acceptance of nonlinearity as more rule than exception at all levels of reality and science. And as previously indicated, NDS has established common principles of spatiotemporal stability and change for capturing the dynamics in any and all systems to which nonlinearity applies, from the inorganic to the organic, from the physical to the psychological (Kaiser, 2000).

Few examples have captured the nonlinear complexity evident in the most unsuspected of real-world phenomena quite as well as the chemical reaction known as the Belousov-Zhabotinskii reaction, discovered in the late 1950s. Under particular conditions of chemical concentration and temperature, random fluctuations in a glass dish mixture of malonic acid, bromate ions and a catalyst (cerium, manganese, or ferroin) amplify through autocatalytic feedback to produce remarkable macroscopic order, consisting of pockets of concentric circular and rotating spiral patterning that expand to fill the entire dish before eventually decaying (Madore & Freedman, 1987; Prigogine & Stengers, 1984). The complexity that arises under these inorganic chemical conditions bears more than a passing resemblance to the emergence of higher order morphogenetic patterning in living systems, as Madore and Freedman (1987) suggest:

> The spontaneous origin of forms within the Belousov-Zhabotinskii reaction, the subsequent growth and stability of the patterns, and the ever-increasing complexity of the structures (new ones are still being reported) are all more characteristic of living creatures than of simple chemical reactions. But simple they are. Without detracting from the beauty and the importance of these reactions, the mystery of their growth and development has been revealed by some of the simplest of computer simulations. (p. 254)

The inorganic physicochemical world, in fact, is replete with examples of spontaneous pattern formation, or *self-organization*. One need look no further than the hexagonally shaped convection cells that emerge when a shallow layer of liquid is heated or the cloud formations that materialize overhead under conditions of air saturation.

That such complexity can emerge within such simple, inorganic systems of relations—and be modeled by straightforward, deterministic equations—vividly illustrates how the complexity of organic developmental form could arise from the same basic iterative dynamics that mark any physicochemical system pushed toward far-from-equilibrium thermodynamic conditions. In fact, applications of nonlinear dynamics to the study of morphogenesis and developmental biology were already prominent in some of NDS's foundational work (e.g., Thom's [1975] catastrophe theory and Prigogine's [Prigogine & Stengers, 1984] far-from-equilibrium thermodynamics [Molenaar & Raijmakers, 2000]). What could be more natural but to extend principles of nonlinear dynamics to psychological development? Such an extension ushered in the formal birth of the DS approach to development (Thelen, 1992).

THE DYNAMIC SYSTEMS APPROACH TO DEVELOPMENT: GENERAL CONSIDERATIONS

The DS approach to development conceptually and analytically targets the question of *how* in development: How do new levels of system organization arise from previous levels of organization (Lewis, 2000a; Thelen & Smith, 1994; van Geert & Steenbeek, 2005)? *Self-organization*—the core idea behind the DS approach—provides the conceptual framework for answering this question. Undergirding this conceptual framework are (a) a focus on emergent form rather than preexistent design, and (b) a focus on the relations among components of a system, rather than the components themselves, as the source of developing form in a system. In effect, self-organization marks the process by which new levels of organization—new, irreducible patterns or wholes—spontaneously emerge in a system through coactions among the very components that comprise the system (Kelso, 2000; Lewis, 2000a; Lewis & Granic, 1999a). Spontaneous emergence means that the newly emergent organization of the system arises without design, without being prefigured in any of its components (Thelen & Smith, 1994). More specifically, stability and organization at the macrolevel of a system arise from and are constantly maintained by the ever-present microlevel variability and dynamics of the system (i.e., the internal relations among the components that comprise the system). Through the recursive nature of open systems—whereby system activity constantly feeds back to itself, both positively and negatively—the dynamics of microlevel variability can, under certain conditions, amplify to the point of rendering the system organizationally unstable, establishing in turn conditions for new levels of cooperation among the components of the system to emerge and fashion new macrolevels of stable organization. More complex levels of organization in development thus arise in genuinely novel fashion from the nonlinear interactions that obtain among the simpler component parts of the system, with such self-organization made thermodynamically possible through open systems under far-from-equilibrium conditions.

As a function of its grounding in the mathematical constructs and tools of NDS, the DS approach to development offers a unifying nomenclature and cadre of modeling techniques for analytically capturing self-organization in developmental process—the temporal dynamics of emergence in living, developing systems. Its lineage thus traces directly and unambiguously to the quantitative and qualitative mathematics that constitute the multidisciplinary study of nonlinear dynamics, and although applying NDS's principles of pattern formation in physicochemical systems to the realm of complex organic *behavior* and *development* is far from a simple, straightforward exercise (Kelso, 2000), the ingredients for such an application are well established through NDS. However, the broader *systems* lineage of the DS approach remains much more elusive and relatively ill-defined in DS writings. Apart from subscribing to the most general and rudimentary of systems tenets (i.e., that wholes are irreducible to the additive sum of their parts and that relations among components of a system, not the components themselves, are central to the understanding of the emergent order in systems), how does the DS approach to development map onto and/or extend the *organizational*, explanatory tenets of von Bertalanffy's GST?

The novelty of the DS approach arrives primarily in its central focus on the dimension of time, specifically the real-time, local dynamics of change that engender both developmental stability and transformation (Granic, 2005; Thelen & Smith, 1994). For many of DS's proponents, this temporal focus, coupled with an equally critical appreciation for within-system variability (e.g., psychological intraindividual variability) as the source of transformative system change, stand in marked contrast to the overweening emphasis on organizational invariance and maintenance of stability around which von Bertalanffy's GST centrally revolves (Aslin, 1993; Granic, 2005; Granic & Hollenstein, 2003). Moreover, charges pertaining to GST's *metaphorical* status and the need to move "beyond metaphor" to real-time, concrete action in context (Thelen, 1992, p. 191) routinely surface in DS accounts, particularly with respect to the "theoretically vacuous" (Beek, Hopkins, & Molenaar, 1993, p. 499) and "empirically bereft" (Granic, 2005, p. 388) standing of GST's developmental process conceptualization (Lewis & Granic, 1999a). This, in turn, begs two questions: What constitutes the metaphor of GST, and what role does metaphor play in the explanatory framework of the DS approach?

Is GST's atemporal, organizational focus—its *wholeness of dynamics* perspective—the metaphor beyond which the DS approach moves in its thoroughgoing temporal embeddedness? If so, what does moving beyond this metaphor entail? In the eyes of DS proponents, does the metaphor of GST serve an explanatory purpose in its own right, or is it merely a heuristic placeholder for the "true" explanation offered through the study of real-time variability and dynamics? These questions bear directly on how the DS approach to development conceptually integrates its GST and NDS lineages. How, in other words, does the broad, multidisciplinary metatheory of von Bertalanffy's general systems approach align with the equally broad, multidisciplinary mathematics of nonlinear dynamics to establish the new landscape of the dynamic systems approach for developmental science?

ALIGNING GENERAL SYSTEMS THEORY AND NONLINEAR DYNAMICS: AN INCLUSIVE APPROACH

Framing NDS as a conceptual and analytical elaboration of the *dynamics of wholeness* side of GST, as this chapter has done, presents one possibility for aligning the multidisciplinary forerunners of the DS approach to development. Such an alignment underlies the *inclusive DS approach* to development as articulated in the writings of Lewis, van Geert, and van der Maas. In this vein, the broad *perspectivism* of von Bertalnaffy's GST fosters precisely the sort of explanatory pluralism within which the more specific mathematical pluralism of NDS can comfortably reside. By means of its perspectivist philosophy, GST values both the temporal dynamics and the atemporal organization of phenomena as equally legitimate lines of sight from which to understand system functioning. Process and organization, activity and structure, go hand in hand at all levels of analysis, as two sides of the same coin (van Gulick, 1993). Von Bertalanffy (1933, 1975) stressed unequivocally that understanding systems and their development can never arrive through a reduction of all organization and pattern to process but must instead involve the dissolution of *foundationalism* and, consequently, a broadening of the notion of process to conceptually envelop organization. Like Piaget and other developmentalists operating within pre–World War II Continental-European circles of psychology, von Bertalanffy endorsed a *holistic structuralism* in which structure is both founded in constructive activity and constitutive of that very activity (Overton, 1975; Toomela, 2009). In Overton's (1975) words:

> The ideas of holistic structuralism then are based on the views of the universe as activity. From this perspective the organization or structure of the phenomena is not reducible to something else but, instead, it is a representation of the flux of everyday particulars. Structure is a *primitive construct* in the sense that it is given as a basic explanatory construct. (p. 66)

Subsumed under the explanatory auspices of GST's holistic structuralism, NDS offers what von Bertalanffy, in attempting to articulate the dynamics of wholeness vantage point of GST, could not: elaboration of self-organization in systems (i.e., how higher-order pattern arises through lower-order fluctuations and the nonlinearity of relations among the components that comprise a system). NDS highlights the importance of iterative processes and variability as keys to creative potential in nature through examination of both nonlinear equations of motion and qualitative topographical frameworks for modeling system stability and change over time. It stresses the importance of formal mathematical explanation, by which organization becomes temporally defined in terms of the real-time dynamics of fluctuation and motion. GST, in turn, stresses the importance of atemporal organizational explanation—the formal and final explanatory backdrops—by which higher-order abstractions organizationally constrain and meaningfully define the dynamics of specific temporal relations.

ALIGNING GENERAL SYSTEMS THEORY AND NONLINEAR DYNAMICS: AN EXCLUSIVE APPROACH

A different means of aligning GST and NDS is revealed through the *exclusive DS approach* to development, articulated most prominently by Thelen and Smith in their seminal 1994 book as well as their prior *Handbook of*

Child Psychology chapters. Adopting an explanatory monism, Thelen and Smith privilege the here-and-now of real-time, task-specific activity over all other levels of analysis; for them, "the cornerstone of a dynamic theory of development is this emergent nature of behavior assembled in *real time*" (Thelen & Smith, 1994, p. 73). Their explanatory privileging of real-time dynamic process means that *organization*—the global order and pattern abstracted from the real-time particularities of specific actions in specific contexts—is only something *to be explained*, a product of process, not a kind of explanation in its own right (Witherington, 2007, 2011; Witherington & Margett, 2011). Thelen and Smith (1994) write that "order is . . . created in the process of action" (p. 63), that "form is a product of process" (Thelen & Smith, 2006, p. 271), that "no knowledge exists that is divorced from the constituent dynamics of the task itself" (Thelen et al., 2001, p. 76). Explanation for Thelen and Smith, as well as for Spencer, is limited exclusively to temporally based mechanisms, concretely grounded in real-time activity dynamics. Because structures (forms, organizations), as abstractions, cannot explain according to Thelen and Smith's criterion, structural explanation cannot serve as true explanation from the standpoint of an exclusive DS approach (Witherington & Heying, 2013).

The antistructuralist stance of the exclusive DS approach thus mandates a different outlook on the relation between GST and NDS, one in which the study of nonlinear dynamics serves to *redefine* and *reconfigure* in temporal, dynamic terms the atemporal, organizational abstractions of von Bertalanffy's general systems approach. The exclusive DS approach to development dispenses with the idea of alternate, complementary lines of sight in favor of privileging temporal explanation and the dynamics of wholeness vantage point. This suggests that the organizational focus of GST—the wholeness of dynamics—cannot be explanatory in its own right; it cannot serve as a legitimate, meaningful vantage point of explanation but ultimately must be explained by means of the real-time dynamics of activity, the dynamics of wholeness. The behavior of any system "is always assembled in time," thus the only way to understand such behavior is through an analysis of its embeddedness within time, as "patterns assembled for task-specific purposes" (Thelen & Smith, 2006, pp. 278, 284). The global order of the system—its holistic structure—merely exists as a "momentary *product* of a dynamic system, not a dissociable cause [i.e., explanation] of action" (Thelen & Smith, 1998, p. 617). In this reframing, the system itself becomes only an object of study, not also a subject of explanation—via formal and final explanation—in its own right.

INCLUSIVE AND EXCLUSIVE APPROACHES TO DYNAMIC SYSTEMS COMPARED

At its core, the metatheoretical divide between inclusive and exclusive versions of the DS approach to development revolves around whether to frame the temporal dynamics of NDS within the broader explanatory context of holistic structuralism, as evinced in von Bertalanffy's GST. This question, in turn, conditions what constitutes legitimate explanation within the DS approach. Is a system's organization or global order—its pattern, structure, form—explanatory in its own right or merely a transient, epiphenomenal byproduct of local process dynamics? Is form abstracted from the here-and-now as integral to explanation as real-time contextual factors? Is process explanatorily foundational to organization, or is all process necessarily organized, just as all organization is necessarily a process? Are the sequencing and directionality of development mere appearance or necessary components of developmental explanation? Inclusive and exclusive variants of the DS approach offer ontologically incompatible answers to these questions, despite being unified through adherence to the principle of self-organization and the mathematics of NDS. Owing to its grounding in both the organizational explanation of GST and the dynamical explanation of NDS, the *inclusive DS approach*: (a) fully admits higher-order, emergent form into its explanatory framework; (b) embraces an explanatory pluralism encompassing not just efficient and material cause but formal and final explanation; (c) considers developmental time as emergent from but irreducible to real time; (d) regards the process of self-organization in both bottom-up and top-down terms, which, as will soon be discussed, entails full adherence to the principle of *circular causality*. For the inclusive DS approach, organization and process (i.e., structure and function) are two sides of the same explanatory coin, conferring equally legitimate perspectives on the same whole; both top-down organizational constraint and bottom-up dynamic construction are vital to understanding the development of complex systems, at all levels of organizational abstraction.

The *exclusive DS approach*, in contrast—owing to its recasting of the organizational "heuristics" of GST in terms of the dynamical explanation of NDS: (a) rejects higher-order, emergent forms as explanatory in any real sense; (b) embraces an explanatory monism in wedding its analysis exclusively to activities in the context of the here-and-now; (c) reduces developmental time to real time; (d) treats as illusory the orderly, directional flow of development viewed in macroscopic terms; (e) regards the process of self-organization in primarily bottom-up terms. For the exclusive DS approach, process is foundational to organization, in unidirectional fashion; organization is the epiphenomenal byproduct of process, establishing bottom-up dynamic construction as the *fundamental* level of explanation for understanding change in all far-from-equilibrium systems (Witherington, 2007, 2011).

The essence of this overarching ontological difference in DS frameworks is aptly captured in a well-established conceptual distinction prominent in modern philosophical discussions of emergence: the distinction between *epistemological*, or "weak," emergence and *ontological*, or "strong," emergence (Bedau, 1997; Silberstein & McGreever, 1999; Witherington, 2011). Both epistemological and ontological approaches to emergence treat higher-order forms arising in systems as neither fully predictable from nor fully expressible in terms of the lower-order components of the system (Silberstein & McGreever, 1999). Both also acknowledge the genuine irreducibility of emergent form such that something new—some new property of a system—comes into being, having not previously existed in or been prefigured by any of the parts that comprise the system. For advocates of an epistemological approach to emergence (e.g., Spencer et al., 2011; Thelen et al., 2001; Thelen & Smith, 1994), however, higher-order form—though irreducible to lower-order form—*causally reduces* to the lower-order, local process dynamics that engender it, maintain it, and into which it falls out of being. In other words, emergent pattern may not be reducible to other patterns but *is* ultimately reducible to the processes that gave rise to it, meaning that a strict, ontological distinction exists between causal processes and emergent products (Clayton, 2006; Gregersen, 2006; Silberstein & McGreever, 1999). The forces or laws that govern new emergent forms operate solely at lower levels of explanation, the level of local here-and-now process, of real-time dynamics in the physicochemical world; all causality involves micro- to macrolevel determination, not the reverse.

Advocates of an *ontological* conceptualization of emergence (e.g., Kunnen & van Geert, 2012a; Lewis, 2000b; van der Maas, 1995), in contrast, fully embrace the *causal irreducibility* of emergent form. Rather than privileging a bottom-up, microdeterministic view of cause, these advocates affirm both bottom-up, microlevel determinism and top-down, macrolevel determinism (Silberstein, 2006; Sperry, 1986). Top-down, *whole-to-parts* determinism, however, involves a fundamentally different mode of causal explanation than its bottom-up counterpart. Advocates of ontological emergence uniformly reject the notion of *efficient,* temporal causality from an independent higher level to a lower one. In effect, conceptualizing the vertically downward influence of higher-order wholes on their lower-order constituents in terms of the antecedent-consequent, force-like process orientation of efficient causality—distributed or otherwise—essentially amounts to a revival of vitalism (Campbell, 1974; Emmeche et al., 2000; Juarrero, 1999; Sperry, 1986). Instead, the top-down, macrolevel determinism of ontological emergence involves a *downward* or *systematic causation*, in which systems qua systems constrain the properties of their lower-order components and the interactions of those components with one another (Campbell, 1974; O'Connor, 1994; Silberstein, 2006). Systematic causation does not operate by generating new physicochemical "forces" or by altering existing forces but by *topologically constraining* the distributed, efficient causal interactions among the system's components (El-Hani & Pereira, 2000; Moreno, 2008). In other words, consistent with von Bertalanffy's treatment of system organization, systematic causation invokes formal and final explanations (El-Hani & Pereira, 2000; Emmeche et al., 2000; Juarrero, 1999). Through systematic causation, a system's organization—the unitary structure of the whole—constitutes a subject of explanation in its own right by establishing an *organizational* (i.e., formal) explanatory grounding for the very part-part relations that give rise to it. Macrolevel patterns are just as causally real as the microlevel dynamics that give rise to them.

In ontological emergence accounts, the explanatory causality of a system's organization rests in its top-down constraint. Constraint involves a lessening of variability, a narrowing of degrees of freedom, and as such plays a critical role in explanation by virtue of establishing limitations for what kinds of bottom-up processes are available to a given system; thus, the nature of local interactions cannot be fully understood divorced from the organizational whole in which these interactions are embedded (Deacon, 2012; Juarrero, 1999; Murphy, 2009; Thompson, 2007). Constraint—a negative property—refers to absence rather than presence. As Deacon (2012) articulated:

> The concept of constraint does not treat organization as though it is something added to a process or to an ensemble of elements. It is not something over and above these constituents and their relationships [*sic*] to one another. And yet it neither demotes organization to mere descriptive status nor does it confuse organization with the specifics of the components and their particular singular relationships [*sic*] to one another. Constraints are what is not there but could have been, irrespective of whether this is registered by any act of observation. (p. 192)

Constraints establish the causal power of a system by restricting its options for change and thereby promoting specific degrees of freedom under which the causal power of the system operates. In Deacon's words, "it is precisely by virtue of what is not enabled, but could otherwise have occurred, that a change can be forced.... whenever new constraints are generated, a specific capacity to do work is also generated" (p. 198). The system as a whole cannot be fully understood through decomposition into temporally sequenced part-to-part relations. It must also be simultaneously understood as a totality, in its own terms, by means of its organization and invariant ordering across the particularities of specific time and context (Witherington, 2011).

By espousing systematic causation via top-down constraint, ontological emergence approaches establish an inclusive, pluralistic approach to explanation, akin to GST, and endow the emergent organization of a system—its structure, form, pattern—with its own distinct kind of causal significance (Campbell, 1974; Silberstein, 2006; Silberstein & McGreever, 1999). In the process, these approaches evidence a strong commitment to the notion that multiple levels or orders of reality coexist, separate yet interdependent, in contrast to the exclusivist framework endorsed by sole reliance on epistemological emergence and the privileging of microdetermination (Bickhard & Campbell, 2000; Emmeche et al., 2000). Adherence to levels of organization undermines reductionist notions of a fundamental reality: cultural, social, and psychological levels of organization are as equally real as the physicochemical levels of organization on which they are built (Bickhard, 2008; Bickhard & Campbell, 2000). Reality assumes both a vertical and a horizontal dimension, both in terms of pattern and in terms of process (Witherington & Heying, 2013). In fact, the explanatory pluralism of ontological emergence approaches frames system behavior simultaneously in terms of its antecedent and material conditions and in terms of its higher-order patterning, the forms and functions of the behavior abstracted from the particularities of its specific content in context. This breaks down the arbitrary divide between process and pattern, cause and effect. Emmeche et al. (2000) explain that "upward and downward causes are not temporally distinct (the lower level does not cease to make up the higher one while this is assumed to 'cause back').... The same phenomena are at the same time cause and effect for each other" (p. 21). Bottom-up and top-down causes offer different but simultaneous levels of explanation, with neither level privileged either temporally or ontologically (Ellis, 2009).

In brief, epistemological emergence conceptualizes emergence exclusively in terms of the bottom-up generation of higher-order pattern from lower-order, local processes—processes to which the higher-order pattern causally reduces. Ontological emergence, however, conceptualizes emergence more broadly by invoking both local-to-global and global-to-local causality via the interdependence and interpenetration of micro and macro levels of reality, wherein "part and whole co-emerge and mutually specify each other" (Thompson, 2007, p. 38). Mapping these two conceptualizations of emergence onto the ontologically distinct stances of the DS approach to development is both straightforward and revealing: An inclusive DS approach embraces ontological emergence, whereas an exclusive DS approach embraces epistemological emergence (Witherington, 2011). What follows offers further delineation for each of these two DS approaches to development with an eye toward instantiating their ontological differences through the work and writings of their leading proponents.

THE INCLUSIVE DYNAMIC SYSTEMS APPROACH TO DEVELOPMENT: ALL IS ORGANIZED PROCESS

Illustrating the inclusive DS approach to development are the conceptual frameworks of Lewis and van Geert, two of

DS's most prominent adherents whose extensive theoretical writings vividly articulate the explanatory pluralism endemic to the inclusive narrative for the approach. Nearly 20 years ago, however, van der Maas (1995) was one of the first DS proponents to capture the heart of metatheoretical divide between an inclusive and exclusive DS approach in his trenchant critique of Thelen and Smith's (1994) antistructuralist stance:

> In spite of their rejection of reductionism, to me this is a reductionist view. The rejection of reductionism is only correct if structures influence the local processes that created them and initiate other local processes. . . . This is what self-organization is about. *The local processes are not more real than the emergent structures. One reason for this statement is that the local processes themselves are macroscopic structures of lower order local processes*. (pp. 631–632; *italics* added)

By asserting the ontological reality and causal irreducibility of higher-order wholes, van der Maas was advocating the admittance of structure into the explanatory efforts of a DS approach to development. Rejecting Thelen and Smith's absolutist stance toward process as foundational reality, van der Maas embraced what amounts to the perspectivism of von Bertalanffy's GST: All process is itself an organization (structure) and all organization is itself a process (function). Whether a phenomenon is construed in organizational/structural or dynamic/process-oriented terms depends on the perspective adopted toward the phenomenon (Witherington & Heying, 2013), for as van der Maas argued, no ontological dividing line exists between what constitutes process and what constitutes structure. Reframing this in the language of parts and wholes reveals a classic systems principle: Every part of a system is simultaneously a whole relative to its own lower-order parts, just as every system whole is simultaneously a part of a larger system whole (Sameroff, 1983).

This view of self-organization as structure-process reciprocity—not simply the privileging of process over structure through exclusive reliance on bottom-up dynamic construction of organization—stands as the cornerstone of an inclusive DS approach to development. It also happens to be reflected in a central principle from one of NDS's intellectual progenitors, the field of synergetics (Haken, 1977, 1996). That principle is *circular causality*, and no DS proponent has done more to explicitly uphold the centrality of this principle for understanding development through the DS approach than Lewis, to whose work the chapter now turns.

Lewis and the Centrality of Circular Causality

Grounded in a neo-Piagetian context, Lewis, even in his early forays into DS thinking (e.g., Lewis, 1994, 1995), emphasized the DS approach as a framework within which both microscopic dynamics and macroscopic structure, experientially specific trajectories of individual variation and stable diachronic organizational change, can reside as alternate, explanatorily compatible perspectives on the same whole. His work has taken particular aim at the interrelations among different levels of system organization—from relations between real- and developmental-time scales in cognition-emotion coupling to those between neurobiological and psychological levels of analysis—but always with an eye toward framing these vertical interrelations in *both* parts-to-whole *and* whole-to-parts terms (e.g., Lewis, 2000b, 2005; Lewis & Ferrari, 2001).

For Lewis, capturing the complexity of emergence in self-organizing systems entails *fully reciprocal bidirectional* (←→) relations both within and across levels of organization in systems and their development. These relations are manifested in two basic "directions of influence between scales of self-organization" (Lewis, 2002, p. 186). Lower-order interactions among components of a system yield higher-order forms, both at the scale of real-time self-organization by generating temporary, short-term emergent forms (e.g., organized, task-specific activity) and at the scale of developmental-time self-organization, by generating longer persisting, stable levels of organismic organization (e.g., stages of development). But just as critical to understanding development is the directional influence of these higher-order wholes—both those that emerge at short-time scales and those that characterize long-standing periods of developmental organization—on their lower-order components (Lewis, 2001, 2002).

The relational reciprocal bidirectional (←→) nature of influence in self-organizing systems revolves around two forms of process explanation: *reciprocal* and *circular causality* (Lewis, 2000b), depicted in Figure 3.7. Reciprocal causality simply reflects the bottom-up perspective of influence wherein lower-order components of a system nonlinearly coact with one another in part-to-part fashion to dynamically construct higher-order, macroscopic organization, (i.e., parts-to-whole influence). Circular causality broadens reciprocal causality by assigning explanatory status to *both* bottom-up and top-down processes, with full recognition of the different but simultaneous levels of explanation involved in each (e.g., temporal

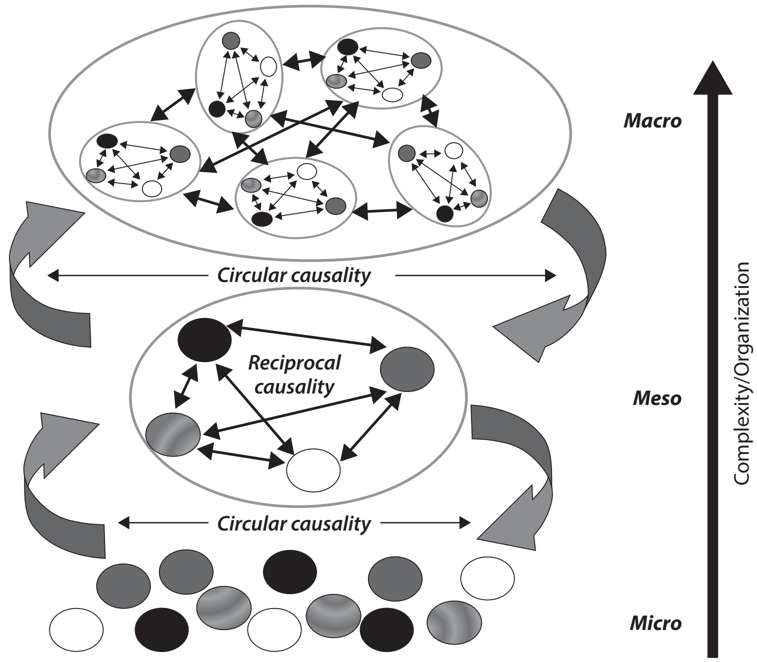


Figure 3.7 Illustration of reciprocal and circular causality, demonstrating both bottom-up dynamic construction and top-down organizational constraint.

precedence *and* atemporal embeddedness). In Lewis' (2005) words, circular causality means that "a coherent, higher-order form or function *causes* a particular pattern of coupling among lower-order elements, while this pattern simultaneously *causes* the higher-order form" (p. 174). Complementing the parts-to-whole perspective of bottom-up processes, top-down processes introduce hierarchy and higher-order form into explanation. As *systematic causes*, these whole-to-parts relations operate in terms of constraint: the system as higher-order, organizational whole conditions or constrains the degrees of freedom within which its local dynamics—the reciprocal causality of part-to-part relations—can operate (Haken, 1996; Juarrero, 1999; Kelso & Engstrom, 2006). In developing systems, this extends to what Lewis has called *cascading constraints* (Lewis, 1997), whereby the system's current organization constrains subsequent possibilities for organization in development such that "later assemblies must be compatible with the orderliness already laid down by earlier ones" (Lewis, 2000b, p. 40).

Lewis' adherence to the explanatory pluralism of circular causality is exemplified in his psychological model of emotional self-organization (Lewis, 1995, 2000b, 2005; Lewis & Granic, 1999b; see also Hollenstein, Lichtwarck-Aschoff, & Potworowski, 2013, for an extension of this model to the domain of socio-emotional flexibility). Articulated at three time scales of self-organization, the model delineates (1) the real-time, microdevelopmental emergence of emotion episodes over seconds and minutes, (2) the consolidation of mesodevelopmental mood patterning that can last hours, days, or weeks, and (3) the macrodevelopmental self-organization of personality structures that remain stable for months and years (Lewis, 2000b). With respect to the microdevelopmental self-organization of emotion episodes, Lewis has posited some form of "trigger"—such as a sensory event, a memory, or a change in arousal—as the initiation point for an emotion episode through its perturbation of the emotion system. This, in turn, sets in motion a process of "self-amplifying interaction among appraisal and emotion elements" (Lewis, 2005, p. 176), which eventually yields a higher-order patterning for the emotion system that Lewis (2000b; Lewis & Granic, 1999b) has termed an *emotional interpretation* (EI). Specifically, various cognitive appraisal components—concepts, expectations, images, plans—begin to couple or synchronize with one another around interaction with an emotional feeling state—"a global, non-reducible affective state . . . elicited by a specific class of situations related to the organism's goals" (Lewis & Granic, 1999b, p. 689)—via recursive, positive feedback loops, marking a phase of reciprocal amplification among these components. By the same token, reciprocal bidirectional causal relations among the cognitive and emotional components constrain one another via negative feedback loops (Lewis, 2005). The higher-order, irreducible whole (the EI) that emerges from these distributed, iterative causal relations constitutes a real-time intention for engaging the world. Whenever this temporary, organizational coherence of components—this particular EI—emerges in the context of a future perturbance of the system, it enjoys increasing stability in an individual's emotion system repertoire and comes to represent a behavioral attractor in that individual's state space, the topography of which routinely consists of multiple EI attractors at any given point in development.

Lewis has emphasized that emergent EIs themselves "cause the lower-order coordination of cognitive and affective elements that (circularly) cause those intentions" (Lewis, 2000b, p. 44), explaining the coupling of lower-order components through whole-to-parts constraint. The constraint that EIs establish for the entrainment of their cognitive and emotional constituents is invoked at the microdevelopmental level of real-time, temporary activity-in-context. Higher-order organizations of *moods* characterize emotional self-organization at the mesodevelopmental scale of hours, days, and weeks and constrain the microdevelopmental EIs from which they emerge. Moods constrain as temporary modifications of the *topography* of an individual's entire state space. Whereas EIs, as intentions, dissipate once action is taken, moods arise when actions in the service of the intention fail to satisfy the intention, leading to the preservation of organizational patterning in interpretation and emotion over an extended period of time. Moods reflect a longer-term emotional interpretation tendency, or a *global intentional orientation*, within which the real-time emergence of EIs is embedded, thereby constraining such real-time emergence (Lewis, 2000b, 2002). This means that real-time "interpretations of events no longer start from 'zero'" (Lewis, 2000b, p. 48) but instead are constrained by a modified state space topography that biases the system, "a temporary constriction of the state space, representing a cognitive-emotional bias: attractors are strengthened for some EIs and weakened or absent for others, and trajectories between states are more limited" (Lewis & Ferrari, 2001, p. 186).

Thus, real-time EIs give rise to more global mood orientations over longer time scales, just as mood orientations themselves constrain the real-time process of EI emergence. However, in their time scale of stability, moods only involve temporary reconfigurations of an individual's state space, leading to biased orientations at the time scale of hours, days, and weeks. Macrodevelopmental time scales of organizational stability at the level of months and years involve more firmly entrenched topographical changes in the state space, built up from the mesodevelopmental level of moods, which "not only modify the cognitive-emotional state space temporarily but lay down permanent changes if they recur sufficiently often" (Lewis, 2000b, p. 57). Lewis has characterized this long-term organizational stability as personality—or continuity in sense of self—reflecting a stable, cross-situational manner by which individuals intentionally engage their worlds. In circular causal fashion, macrodevelopmental organizational qualities constrain the mesodevelopmental emergence of moods, which constrain the cognitive-emotion relations of real-time, microdevelopment: "Thus, it is the nesting of mood in personality that constrains EIs in real time, and their joint effects curtail the variance available for making sense of and feeling about the world" (Lewis & Ferrari, 2001, p. 189).

Throughout Lewis' writings on emotional self-organization and cognition-emotion interplay—both at the psychological and the neurophysiological levels—his articulations of the DS approach have relied on "hierarchically nested self-organizing processes, by which the emergent products at each level assemble themselves according to complementarities among their elements and constraints from above and below" (Lewis & Ferrari, 2001, p. 189). From the concreteness of activity in the here-and-now to the abstraction of structures stably maintained in developmental time, higher-order forms *organizationally constrain* the coupling of lower-order components, which themselves give rise to the higher-order pattern through real-time, bottom-up processes of dynamic construction. Developmental-time *organized process* both emerges from real-time *organized process* and constrains in circular causal fashion the very real-time organized dynamics that gave rise to it (Witherington, 2011). Lewis' inclusive DS approach to development is as committed to the ever-present hierarchy of organization within which dynamic, local process is embedded as it is to the dynamic construction of new levels of organization through the real-time particularities of specific actions in context, demonstrating his approach's grounding in the ontological reality and explanatory significance of higher-order form—both synchronic and diachronic—not just lower-order dynamic process.

Lewis' inclusive focus on structural constraint translates directly to his empirical work and methodological innovation. Methodologically, Lewis and his colleagues have developed and successfully applied a technique for graphically realizing preferred behavioral states (attractors) that is suitable for categorical or ordinal data and amenable to more traditional analytic strategies in psychology: *the state space grid* (e.g., Granic, Hollenstein, Dishion, & Patterson, 2003; Hollenstein, 2013; Hollenstein & Lewis, 2006; Lewis, Lamey, & Douglas, 1999; Martin, Fabes, Hanish, & Hollenstein, 2005). State space grids consist of two ordinal or categorical variables measured in time-locked fashion over a real-time, microdevelopmental period for a given system, such as an individual child or a single dyad. These variables produce a two-dimensional cell matrix for the system, juxtaposing, for example, five intensity levels of infant distress expressions with five levels of infant gazing activity to create a 25-cell state space grid of possible behavioral states (Lewis et al., 1999). Measurements of attractor strength within the state space grid may involve simple frequency counts for visits to regions of the space, assessments of how quickly attractors that have been occupied are again occupied, or analyses of the probability that cell activity outside of the attractor areas at time 1 will fall into the attractor area at time 2 (DiDonato, England, Martin, & Amazeen, 2013). Individual systems studied longitudinally generate state space grids for each longitudinal sampling point and allow for the charting of changes in cell values across grids, revealing potential qualitative transitions in system organization over developmental time (e.g., Lewis, Zimmerman, Hollenstein, & Lamey, 2004).

Empirical applications of the state space grid methodology to young children's socio-emotional development have revealed *both* neo-Piagetian inspired stage shifts in the *formal* organization of socio-emotional activity *and* individual variation in its *content* across these bifurcations, or phase transitions (Lewis et al., 1999; Lewis et al., 2004; Lewis & Cook, 2007). By actively employing the topological, qualitative methods of nonlinear dynamics within the organizationally focused conceptual framework of stage theory, Lewis has demonstrated the thoroughgoing compatibility of traditional structuralist models of development with developmental science's current focus on real-time variation and temporal dynamics. The utility of couching the "dynamics of wholeness" mathematics of NDS within the broader holistic structuralism of systems thinking—the "wholeness of dynamics" perspective—finds its fullest elaboration in the work of the "Dutch Masters" (Lewis, 2011b), such as van der Maas and Molenaar's applications of catastrophe theory to the study of Piagetian stage transitions (e.g., Jansen & van der Maas, 2001; Molenaar & Raijmakers, 2000; van der Maas & Molenaar, 1992; van der Maas & Raijmakers, 2009). No Dutch Master, however, has had a greater influence on the establishment of an inclusive metatheoretical framework for the DS approach to development than van Geert.

Van Geert and the "Groningen Approach"

Van Geert has long championed a principally *methodological* and *analytic* rendering of the DS approach to development, viewing the approach as a mathematical tool for supplementing conceptual frameworks already evident in the holistic structuralism accounts of classic developmental science, such as the work of Piaget (e.g., van Geert, 1997a, 1998b; van Geert & Steenbeek, 2005). In van Geert's (2004) words:

> The dynamic viewpoint is perfectly compatible with a great variety of developmental theories, simply because they entail many principles of change that are intrinsically dynamic. In that case, the dynamic viewpoint is almost like a methodological addition to those theories, providing them with tools that help them turn their conceptual statements into mathematically formulated, deductive models. (p. 374)

For van Geert and his Groningen approach, the defining feature of a DS approach to development rests in its *iterative* or *recursive focus*, wherein the state of a variable at time $t + 1$ is viewed as a function of the state of that variable at time t (van Geert, 1997a; van Geert & Fischer, 2009; van Geert & Steenbeek, 2005). In other words, the DS approach concerns itself with how one state transforms into another state over time—in broader terms, with developmental sequence and the process of movement from a preceding developmental level of organization to a subsequent one—and "any model that complies with this basic definition is a dynamic systems model" (van Geert & Steenbeek, 2005, p. 412).

With respect to what kinds of variables constitute appropriate material for dynamic systems modeling, van Geert (1997a) has adopted an "extremely liberal stance" (p. 280), arguing that the variable "need not be a physical thing and neither does it need to be directly reducible to known physical states of a system" (van Geert & Fischer, 2009,

p. 317). The level of organizational abstraction involved in a construct or variable is, in fact, immaterial to its viability as a frame of understanding within the DS approach to development. To quote van Geert (2006), "mathematics is a tool for understanding reality and is thus applicable to virtually anything that can be conceptualized, observed, or presumed, at any stage of psychological inquiry" (p. 504). Like Lewis, van Geert has argued for the ontological "reality" of all levels of organizational abstraction, from lower-order concrete acts to higher-order structural wholes (van Geert, 1998b, 2011; van Geert & Fischer, 2009). Thus, transformations from one context-general, organismic state of a system to another across macrodevelopmental time—for example, the transformation from one level of development in object permanence to another or from sensorimotor to preoperational intelligence—represent just as legitimate an ontological focus for DS modeling as the transformations from one real-time behavioral state to another in both micro- and macrodevelopmental time, for example, the shift from a walking to a running gait or the developmental transition from one kind of search behavior to another.

In their DS modeling efforts, van Geert and his Groningen colleagues have run the gamut from microdevelopmental studies of dyadic play—involving psychological parameters such as appraisals and goals—to macrodevelopmental studies of identity (e.g., Lichtwarck-Aschoff, Kunnen, & van Geert, 2010; Lichtwarck-Aschoff, van Geert, Bosma, & Kunnen, 2008; Steenbeek & van Geert, 2007, 2008; Vleioras, van Geert, & Bosma, 2008). Much of their modeling work makes use of logistic growth equations based on the Verhulst equation designed to model species population growth. As previously discussed, these iterative difference equations employ both positive and negative feedback loops to model the pattern transformative and pattern conservative forces at work in developmental process. Van Geert (1997a, 2000) has explicitly pointed out that the same kind of iterative processes undergird the local dynamics foundational to Piaget's model of development, as well as those of other classic systems theorists, such as Vygotsky. In fact, earlier modeling work by van Geert (1998a, 2000) notably produced successful developmental simulations of Piaget's broad stages of intelligence by computationally implementing the local process interplay of assimilation and accommodation.

Eschewing any form of foundationalism, proponents of the Groningen approach have explicitly articulated the relativity of "macro" and "micro" designations, recognizing that any level of an organizational whole, no matter how "abstract," can always be viewed as part of the bottom-up dynamics of some higher-order level of organization, just as the most "concrete" of system components can itself be viewed as a top-down, constraining whole relative to its lower-order dynamics (e.g., Kunnen & van Geert, 2012b; van Geert, 2011). Consequently, under the auspices of the Groningen approach, *explanation in developmental science involves the articulation of both structure and dynamics—organization and process—as complementary explanatory frames*, with the structures and stages characteristic of Piaget's and other classic systems approaches to development regarded not simply as epiphenomenal or illusory outgrowths of real-time, local dynamics but as explanatorily significant ways to structure our understanding of the local dynamics themselves, "enabl(ing) one to make developmentally relevant distinctions" (van Geert, 2006, p. 502; see also van Geert, 1998b). In other words, the characterization of organisms and their development in integrated whole terms is just as indispensible an explanatory context for the understanding of local dynamic fluctuation and variability as the characterization of local dynamics is for explaining the structure of the organism and its development as a whole.

Like Lewis, van Geert has appealed to the structure or topography of the state space to capture the context-general organization of organisms, both synchronically and diachronically. As van Geert (1997b) has suggested:

> a person's skill (or competence, ability, or whatever word one wishes to use) should be viewed as a *particular range in a phase space* . . . a competence, qua psychological property of a subject, is context-determined, as well as a well-defined property of the subject. (p. 196)

Just as the real-time dynamics of motion that take place within a state space are necessarily constrained by the stable structural properties of that state space, so an articulation of a system's real-time activity in context is necessarily framed within a broader understanding of the system qua system of that which characterizes the organism as a whole across time: "the person in his characteristic multitude of contexts" (van Geert & Fischer, 2009, p. 327; see also van Geert, 2006). As Piaget (1952) argued, every action of the organism speaks both to task-specific adaptation and to organism-specific organization. Or to quote van Geert and Steenbeek (2008) specifically with respect to the cognitive characterization of organisms, "knowledge and concepts are at the same time substance and process . . . are at the same time transient and 'soft-assembled' on the one hand and causal and conditional entities of the mind on the other" (p. 76).

As should now be evident, proponents of the Groningen approach, such as Lewis and his colleagues, embrace the explanatory pluralism of circular causality (Kunnen, Lichtwarck-Aschoff, & van Geert, 2012; Kunnen & van Geert, 2012a, 2012b; Lichtwarck-Aschoff et al., 2008). Their full endorsement of circular causality—across levels of organizational and time-scale abstraction—establishes *both* the here-and-now activity of an organism within a temporally specific context *and* the context-general, organizational quality that characterizes the organism in the longer term as distinct but complementary frames of explanation (van Geert, 1997b, 2003; van Geert & Fischer, 2009). Lichtwarck-Aschoff et al. (2008) have noted that "because of this reciprocal relationship between micro level processes and macroscopic structures, direct cross-generalizations across different time scales are in fact problematic" (p. 378). Invoking macroscopic structures as short-term antecedent mechanisms for understanding microdevelopmental process violates the distinct but reciprocal explanatory frames offered by these different contexts of analysis. Yet just as problematic is a reduction of macrolevel structure to microdevelopmental processes. It thus proves critical to establish both micro- and macrolevels of explanation for any phenomenon and its development and to recognize the complementary but unique processes involved as a function of the time scale and level of organization examined.

For an example of their commitment to circular causality, consider forays by proponents of the Groningen approach into the study of identity formation across both micro- and macrolevels of development. As Kunnen et al. (2012) have highlighted:

> Identity on a developmental time scale emerges out of real-time and day-to-day experiences, interactions and processes—that is, how one defines oneself is the product of many cumulative real-time interactions with the environment. At the same time, behaviors, thoughts, and emotions are constrained by the way a person defines herself. One's identity, self-definition, commitments, and values will determine why, when and how one reacts to a potential threat to one's identity—the identity sets the conditions and defines the parameters of the immediate goals and concerns. (p. 154)

With respect to the development of identity from early adolescence to adulthood, Kunnen and her colleagues have distinguished between specific micro and macrolevel qualities of identity formation. Microlevel dynamic aspects of identity revolve around real-time, nonreflective activity in context, that is, the context-specific couplings of real-time goals, emotions, thoughts, and actions in daily experiences involving conflicts over autonomy issues and the thwarting of specific goals. Macro-level dynamic aspects of identity, in contrast, revolve around individuals' explicit reflections on and abstractions of their stable and characteristic features, that is, commitment structures and levels of meaning making in knowing who one is and what one wants to be that are maintained and transformed in the midst of external information either consistent or actively conflicting with these extant structures (Kunnen, 2012; Kunnen & Bosma, 2000, 2012; Lichtwarck-Aschoff et al., 2008). Attempts to integrate the micro-level dynamics of real-time, specific goal-related conflicts and the macro-level dynamics of commitment formation have emerged from the Groningen group in the form of DS mathematical models that chart the coupled relations between the growth of autonomy and the growth of connectedness over developmental-time, employing parameters that instantiate both local, real-time dynamics and macroscopically stable characteristics of the system to attempt to capture bottom-up processes of dynamic construction *and* top-down processes of constraint (e.g., Kunnen et al., 2012; Lichtwarck-Aschoff et al., 2008).

Van Geert and his Groningen approach colleagues remain at the forefront of efforts to bring the quantitative mathematics of NDS to developmental science. Their work has few rivals both in terms of its mathematical rigor and its thoroughgoing process orientation, with strong emphasis placed on promoting the study of intraindividual variability in small *n*, longitudinal samples of individual systems (e.g., van Dijk & van Geert, 2007; van Geert & van Dijk, 2002). Yet despite the grounding of their work in the short-term fluctuation and variability of real-time dynamics, van Geert and his colleagues have endeavored to maintain equal grounding in the broader, macrodevelopmental structures and general processes for which the classic grand narratives of developmental science are known. Akin to the inclusive DS orientation of Lewis and his colleagues, proponents of the Groningen approach regard the dynamics of wholeness perspective of NDS not as a substitute for the holistic structuralism of classic systems perspectives but as a *supplement* to the explanatory legitimacy of organization. In the Groningen approach, all local dynamics of process operate within certain conditions of constraint—conditions which themselves transform over developmental time—and the grand narratives of Piaget, Werner, Vygotsky, and others have already established fully viable renderings of these constraints, specifically in terms of the synchronic and diachronic structures of developmental sequence. Thus, the inclusive DS approach to development—instantiated in the work of Lewis, van Geert, and their research colleagues—brings to developmental science a much needed focus on the real-time dynamics of process *without losing sight* either of the organizational whole that is the organism/system at any given point in time or of the developmental sequence of wholes within which the organism's/system's current level of organization is embedded. Full appreciation of the meaning of an organism's actions within its world requires *both* an embedding of that activity in the real-time dynamics of process *and* in the dynamically maintained structure or organization of the organism taken as a whole, across time and contexts, which itself is meaningful only when fully embedded within a developmental sequence of wholes.

THE EXCLUSIVE DYNAMIC SYSTEMS APPROACH TO DEVELOPMENT: ALL IS PROCESS, AND ORGANIZATION IS DERIVED

Undercutting the explanatory pluralism of the inclusive DS approach, the exclusive DS approach to development—instantiated most notably in the writings of Thelen and Smith, as well as Spencer—*privileges* the dynamics of wholeness vantage point over a wholeness of dynamics perspective. For proponents of the exclusive DS approach, all explanatory efforts ultimately resolve to the here-and-now dynamics of process, with the adaptive context of real-time activity becoming the only meaningful focus of scientific understanding. Proponents deny the explanatory legitimacy of atemporal, organizational abstraction, arguing instead that characterizations of the organism as a system totality—abstracted across time and context and embedded within a directional sequence of transformations in system organization—offer little insight into an understanding of systems and their activity until such characterizations are embedded and embodied in time-dependent, process-oriented, *dynamics of wholeness* terms. As such, the exclusive DS approach to development differs from its inclusive counterpart by its *antistructuralist stance*: Explanation arrives by embedding an organism's activity *exclusively* in the real-time, content-specific dynamics of adaptation (Witherington, 2007, 2011; Witherington & Heying, 2013; Witherington & Margett, 2011).

It is important to note that this antistructuralist stance amounts to a repudiation of *structural explanation*, not to a repudiation of "mental structures" per se. Though Thelen and Smith's early articulations of the approach (e.g., Smith & Thelen, 1993; Thelen & Smith, 1994, 1998) largely targeted behavioral and motor development—and, in the process, marginalized the "psychological" world of the organism by emphasizing, in particular, how organisms directly act on and in the world rather than via mediating representations of the world—Thelen, especially in her later writings (e.g., Thelen, 2005; Thelen & Bates, 2003; Thelen & Smith, 2006), markedly softened the anti-mental-structure rhetoric attached to her motor development articulations of the DS approach. As Thelen and Bates (2003) explained:

> Gibson's ideas had a strong influence on the initial works within dynamic systems theory as it was first applied to behavioral development (especially motor development). This emphasis on structure *outside the organism* led to a de-emphasis on the structures that are building up *inside the organism*. As a result Thelen and Smith's two books in 1994 focused more on behavior than the contents of the mind . . . in fact, there is no incompatibility between dynamic systems theory and the exploration of mental structures. . . . The difference has been really a matter of emphasis. (p. 388)

In fact, mental structures—in the sense of system components that characterize the inner, psychological workings of the organism—play an integral role in the dynamic field theory of embodied cognition first articulated in Thelen and Smith's dynamic systems reconceptualization of infants' A-not-B errors. Over the past decade, dynamic field theory has received theoretical and empirical elaboration in the neurologically oriented cognitive development work of Spencer and his colleagues and currently stands as the most prominent theoretical/modeling outgrowth of the exclusive DS approach to development (e.g., Buss & Spencer, 2014; Johnson, Spencer, & Schöner, 2008; Schutte & Spencer, 2010; Simmering, Schutte, & Spencer, 2008; Simmering & Spencer, 2008; Smith, Thelen, Titzer, & McLin, 1999; Spencer & Schöner, 2003; Thelen et al., 2001).

Nonetheless, an acceptance of structures, mental or physical, as components or parts of the organismic system does not entail an acceptance of holistic structuralism: the explanatory significance of structure *as a whole*. Proponents of the exclusive DS approach to development embed all talk of structure within the real-time initiating forces that give rise—in antecedent-consequent fashion—to physical activity in context. In other words, structures become legitimate facets of explanation only to the extent that they operate as real-time parts of a system in conjunction with other structures or parts—both intra- and extraorganismic—all of which, by means of their reciprocal relations with one another, contribute in bottom-up fashion to the establishment of system patterning, equally and without prescription. Structure as *abstraction* from real-time activity, signifying the form or organizational quality of that activity as a whole, still holds no explanatory value within the exclusive DS approach (Witherington, 2007, 2011; Witherington & Heying, 2013). Such a *monistic* approach to explanation promotes a kind of foundationalism in which the higher-order, organizational properties of systems ultimately reduce to the real-time dynamics of system process (Witherington, 2011). To illustrate this explanatory monism and its implications for an understanding of development, the chapter now turns to a general overview of the dynamic field theory of embodied cognition from Thelen and Smith, Spencer, and their colleagues.

Explanatory Monism: Conflating Structural Reification and Holistic Structuralism

The dynamic field theory of embodied cognition takes as its central focus the question of how higher-order psychological constructs, such as cognition, are coupled to the real-time dynamics of physical activity in a physical world (Smith, 2005; Spencer, Perone, et al., 2009; Thelen et al., 2001). It answers this question by integrating perceptual, motor, and cognitive activity all within the same field of real-time movement dynamics, neurologically grounding cognition in the process (Spencer, Perone, et al., 2009; Spencer & Schöner, 2003). Cognition, in this light, concerns the real-time adaptive acts of organisms in relation to task contexts; more specifically, cognition manifests as memory and representational states, which take the form of time-dependent neural activation patterns associated with an event in the world being "re-presented to the nervous system in the absence of the input that specified that event" and creating self-sustaining organismic activity (Spencer & Schöner, 2003, p. 393). Cognition as a context-general characterization of a living system's organization, *abstracted* from the time-dependence of real-time activity in task-specific context, is wholly absent from consideration. From the standpoint of dynamic field theory, in fact, the only explanatory value of cognition (or of psychological constructs in general) lies in its being "bound to the real time bodily processes through which we act in a physical world" (Smith, 2005, p. 288), for such constructs are "only useful if . . . linkable in context to my real-time sensorimotor activity" (Spencer, Perone, et al., 2009, p. 88). Rendering psychological constructs meaningful, in other words, involves casting these processes in the same continuous, spatiotemporal terms as physical body movements and neurological functioning, because "the remembered and abstract inputs to the action must remain compatible with and continuously coupled to the motor decision field so that the inputs can be meshed together to specify the action" (Thelen et al., 2001, p. 74).

Dynamic field theory has yielded a general model for the processes that underlie "goal-directed actions to remembered locations" (Spencer & Schöner, 2003, p. 402). It has successfully captured the real-time variability of behavior both across a series of spatial search tasks—such as different forms of the Piagetian A-not-B task, spatial recall and position discrimination tasks—and across time scales of developmental organization—ranging from infancy to adulthood (e.g., Clearfield, Dineva, Smith, Diedrich, & Thelen, 2009; Schutte & Spencer, 2010; Simmering et al., 2008; Simmering & Spencer, 2008; Spencer, Austin, & Schutte, 2012; Thelen et al., 2001). Elaborations of the model also apply to other domains of functioning, such as habituation, perceptual learning, and visual cognition (e.g., Buss & Spencer, 2014; Johnson et al., 2008; Schöner & Thelen, 2006; Spencer et al., 2011; Spencer et al., 2012). These models exemplify a local-to-global focus, wherein the dynamic modeling of time-dependent relations among brain, body, and environment jointly produce patterning in organismic functioning, and have made critical contributions to the dynamics of wholeness focus as applied to developmental phenomena. However, proponents of dynamic field theory also cast their model as a *substitute* for what they consider the illegitimate explanatory frame that global-to-local approaches employ when viewing performance in tasks such as A-not-B from the standpoint of the *epistemic subject*—from the vantage point of the organism as a "subjectively *lived body*" (Colombetti & Thompson, 2008, p. 56) meaningfully engaged with its world through different levels of developmental organization (Witherington & Heying, 2013). In so doing, proponents show the privilege of one form of explanation over another and paint both levels of explanation as competing alternatives rather than as complementary parts of a unified whole.

Consider dynamic field theory's ontological approach to the Piagetian A-not-B error (e.g., Clearfield et al., 2009;

Smith et al., 1999; Spencer et al., 2011). In the A-not-B error, infants in Stage 4 of Piaget's 6-stage object concept sequence successfully retrieve an object completely hidden in Location A, but when the object is subsequently hidden in a new location (B), infants will persist in searching for the object in its original hiding location (A). Framed in traditional Piagetian terms, the A-not-B error indexes a certain level of organization in the development of infants' objectification of self and world—that is, the object concept—via progressive differentiation of their activity from the objects on which they act. Piaget articulated the formal properties of this activity—its formal explanation—in terms of partial but incomplete phenomenological objectification of self and world: objects, though now clearly differentiated for the infant from her or his activity, nonetheless remain wed to a particular spatial location and are therefore not fully objectified (Piaget, 1954).

Proponents of dynamic field theory summarily reject Piaget's formal explanation for the A-not-B error and substitute what they consider an "embodied" conceptualization of performance, consisting of an organism's general reaching and remembering skills, their particular history of reaching to and looking at A, issues related to the task space itself, and the timing of reaching relative to the object's hiding. Proponents further argue that shifting relations among these sensorimotor and representational parameters—unfolding in real-time within particular task circumstances—account for both errors and successes in reaching for occluded objects *irrespective of the level of developmental organization*, meaning that the same dynamics explain both the perseverative reaching errors of young infants and the absent-minded errors of adults (e.g., automatically reaching for your keys where you normally keep them) (Spencer et al., 2011; Spencer & Schutte, 2004; Thelen et al., 2001). In Spencer and Schöner's (2003) words:

> The same developmental insights that capture changes in infants' performance in the A-not-B task can account for both qualitative and quantitative changes in the stability of spatial working memory processes later in development. (p. 402)

Indeed, from the task-focused vantage point of the local processes involved, A-not-B performance can be captured in infants, children, and adults by the same activation field dynamics (Spencer, Dineva, et al., 2009; Spencer et al., 2011). Yet although the local dynamics of perseverative reaching errors in young infants and the absent-minded errors of adults look comparable when framed in terms of behavioral content in a task-specific context, contextualizing this activity more broadly in terms of its formal, organizational properties—embedding the activity in the organism as an integrated whole—reveals dramatic differences, reflected in different levels of developmental meaning and significance, both for the person and her or his observers, and different characteristic engagements between the person and her or his world. As a developmental scientist, one would be hard pressed to argue that an A-not-B error holds the same epistemic meaning for an 8-month-old as compared to a 2-year-old or an adult. From the wholeness of dynamics vantage point, the very meaning of the task itself, the organizational significance of the organism's action in the task context, and the likely ramifications of such action in context for future activity all differ as a function of an organism's particular level of developmental organization. But by grounding explanation of the A-not-B error at any point in development solely in terms of "the coupled dynamics of looking, planning, reaching, and remembering within the particular context of the task" (Thelen et al., 2001, p. 5), dynamic field theory denies the explanatory importance attached to embedding any given A-not-B performance within a developmental sequence of organizational forms reflecting the organism as an integrated whole across time.

Why do dynamic field theory proponents soundly reject Piaget's—or any holistic structuralist's—formal explanatory stance as a legitimate frame of reference for understanding A-not-B performance in infancy, rather than viewing their dynamic account as a complement to the organizational framework of Piaget? Their rejection stems from the exclusive DS approach's ontological adherence to an explanatory framework based solely in terms of bottom-up, here and now, temporally unfolding antecedents to behavior (Witherington, 2007, 2011; Witherington & Heying, 2013). Constructs like object concept—which capture the formal, organizational aspects of real-time activity from the standpoint of the organism as an integrated whole—simply hold no explanatory power precisely because they are "timeless" and abstracted; lacking temporal and concrete grounding, how could such constructs explain anything? Proponents of dynamic field theory couch their conceptualization of explanation firmly in the realm of *antecedents* to behavioral *content*, not in the realm of abstracted form, viewing all invocations of structural explanation in exclusive functional, "push-from-behind" terms rather than in organizational, constraint terms (Witherington, 2007). Failing to acknowledge that structural explanation operates by means of formal and final explanatory processes, they read any explanatory appeal to structural wholes as a case of structural reification, calling forth the specter of an instruction-filled homunculus that temporally precedes and controls the behavior it explains. This amounts to a conflation of *structural explanation*—which appeals to formal and final processes of constraint, not temporal antecedents—with *structural reification*—by which higher-order forms are divested of their status as abstractions and rendered instead as concrete, underlying determinants of behavior via the temporal precedence of efficient causal control.

The local-to-global, distributed efficient causal lens through which dynamic field theory operates is most thoroughly articulated in Thelen et al.'s (2001; see also Thelen & Smith, 1994) conceptualization of Piagetian formal explanation. Thelen et al. make the all-too-common mistake of construing Piaget's object concept account in functional, antecedent-consequent terms, as a concrete "entity" or cause that temporally precedes, exists independent of, and serves as the efficient causal force for the real-time performance of an organism in context (Müller & Carpendale, 2001; Staddon, Machado, & Lourenço, 2001; Witherington, 2007). Given that such an abstracted entity cannot readily account for the enormous context-dependent variability in infant responding to the task and that no reasonable account exists for how this abstracted entity could actually motivate real, physical activity in the real, physical world, Thelen et al. (2001) argue that the object concept is explanatorily vacuous; psychological concepts such as object concept "do not offer us any help in understanding the mechanisms and processes involved in succeeding or failing at the A-not-B . . . there is a gap between invoking such constructs and specifying how they actually operate to motivate real-life behavior" (pp. 71–72).

In response to commentaries by Müller and Carpendale (2001) and Staddon et al. (2001) that underscore Piagetian explanation as formal, not functional in nature, Thelen et al. (2001) exposed the explanatory monism of the exclusive DS approach by asking "[W]hat is the real use of a mental structure with only formal properties?" (p. 71) and "if Piaget meant for mental structures to be only formal descriptions, our foundational issue remains: [W]here are the mechanisms that produce behavior?" (p. 72). These questions reflect the exclusive DS approach's assumption that structural accounts offer explanation only insofar as they involve temporally based, distributed efficient causal mechanisms, concretely grounded in real-time movement dynamics. Because structures, as abstractions, cannot cause in that fashion, structural explanation cannot serve as true explanation. This argument fails to acknowledge that structure and organization can explain in their own right and on their own terms as frameworks via formal and final processes of constraint, within which the particular, real-time dynamics of activity are meaningfully contextualized (see Overton, Chapter 2, this *Handbook*, this volume). Thus, from the ontological perspective of an exclusive DS approach to development, the organizational explanation offered in Piaget's account cannot possibly complement a dynamics of wholeness analysis at the level of real-time activity in adaptive context, for appealing to an object concept does not make sense within an antecedent-consequent framework of temporal relations: "The A-not-B error is not about what infants *have* and *don't have* as enduring concepts, traits, or deficits but what they *are doing* and *have done*" (Thelen et al., 2001, p. 4). But by reducing the organism as a whole to its activity in context, dynamic field theory loses sight of the organizational whole that characterizes organismic functioning in its synchronic and diachronic totality.

Soft Assembly: Privileging Activity in the Here-and-Now

For dynamic field theory specifically—and the exclusive DS approach to development generally—explaining an organism's activity arrives *not* by abstracting higher-order synchronic and diachronic forms/organizational qualities from that activity and embedding that activity within those forms *but* by framing activity exclusively in terms of here-and-now adaptation to local contexts (Witherington, 2007, 2011). The "global order" that characterizes systems within any given level of developmental organization—across contexts and real-time activity—and the orderly sequence of organizational transformations that characterizes such systems across developmental-time are epiphenomenal abstractions that lose sight of the real-time processes unfolding in the particularities of local context (Thelen & Smith, 1994). These global orders are mere *appearance* masking a *reality* of real-time activity in adaptive context. Understanding development thus requires a grounding of all analysis in the variability that time-dependent activity demonstrates during adaptive encounters with everyday contexts, for "what happens on the local level in real-time experience determines the developmental trajectory" (Smith & Thelen, 1993, p. 165) as "developmental time is continuous with and indeed fabricated from real-time experience" (Thelen & Smith, 1994, p. 304; see also Spencer & Perone, 2008).

The adaptive context stands front and center in the explanatory monism of the exclusive DS approach to development, with *activity as adaptation to local contexts* becoming the defining feature of organism-environment transaction in real- and developmental-time. This adaptationist focus is reflected in the principle of *soft assembly*, "the core assumption of a dynamic view of development" (Thelen & Smith, 2006, p. 274) within the exclusive DS approach. Soft assembly means that the components of a system "can assemble in many ways" (Thelen & Smith, 2006, p. 274) to yield differential real-time patterns of behavior in conjunction with the exigencies of specific contextual demands. Within this framework, "the emphasis is on how people assemble behavior in the moment in context" (Spencer et al., 2011, p. 261), and the organism as system becomes identified with its real-time adaptive efforts in the world. This renders questions of organization and patterning in the organism qua system meaningful only when couched in terms of the instrumental, problem-solving qualities of the organism's activity, "the pragmatic dimension of action" (Overton, 2006, p. 23). Rather than being viewed as an integrated whole that actively maintains its own macroscopic organization in the face of microscopic flux, the organism, as a self-organizing system, reduces to "patterns of behavior 'softly assembled' from multiple, heterogeneous components exhibiting various degrees of stability and change" with its development "envisioned as a series of patterns evolving and dissolving over time" (Thelen & Smith, 2006, p. 276). Patterning only counts at the level of time-dependent behavioral content, not at the level of abstracted system form.

When coupled with its antistructuralist stance, the adaptationist focus of the exclusive DS approach treats organization as an outgrowth of adaptation *but not also* as a precondition for adaptation. Viewed through the exclusivist lens of an adaptation focus, organization always operates in the service of adaptation and, in fact, reduces to adaptation in local context. Real-time activity gains no meaning from being embedded within the higher-order wholes that characterize the organizational invariance of the organism qua organism, that *singular*, *instantaneous* totality of the system as a whole. Such patterning, capturing as it does the context-general characteristics of systems, abstracted from their real-time adaptive activity, is discounted as explanatorily vacuous because, as an abstracted rendering, it fails to account for variability in behavioral content: "details are messy and fluid because problem solving is dynamic by its very nature" (Thelen & Smith, 1994, p. 311). The organism consequently becomes a collection of local acts of problem solving, a collection of attractor states reflecting real-time behavioral states in a problem-solving state space.

In the exclusive DS approach, "attractor states are not sitting around; they are not competencies waiting to be tapped. Rather, attractors come and go in real time—the attractor landscape is dynamic and changing on the timescale of behavior" (Spencer & Perone, 2008, p. 1644). This in itself certainly holds from the vantage point of an inclusive approach, as well—at least under conditions that attractor states are used to model real-time behavior—but for inclusive DS proponents, the structural properties, or topological constraints, that characterize the attractor landscape as a whole are just as critical to explanatory efforts in a DS approach as the ever-changing behavioral attractor states. The structure of the system qua system frames the dynamic variability that operates within its boundaries, determining and lending meaning to the range of potential activity available within any given period of system stability at the level of its overall organization. Such structural constraint is reflected in the "competency" of a system—the stable topography of its landscape for any given period of developmental time—and provides a meaningful framework within which to embed our understanding of real-time adaptations to local context, making it indispensable to a full understanding of system patterning (Lewis, 2000b, 2002; van Geert, 1997b, 2006; van Geert & Steenbeek, 2008).

For inclusive DS proponents, the "action-in-context" level of analysis—though certainly critical for understanding in its own right—cannot substitute for the explanatory perspective yielded through an organism qua organism level of analysis, abstracted across attractor states to characterize the phase space as a topographical whole. Instead, both perspectives on system activity—the instrumental-communicative and the expressive-constitutive (Overton, 2006, 2010)—complement one another and offer different levels of explanation. For *exclusive* DS proponents, in contrast, competencies, as abstractions, are necessarily removed from the variability of specific activity in context and therefore superfluous to understanding (Spencer et al., 2011; Thelen & Smith, 1994, 2006). Knowing does not constitute an abstract, context-independent property of organismic functioning but instead becomes another real-time activity, always "in the service of a task" (Thelen & Smith, 2006, p. 303) and never a means by which the very "task" nature of a context is defined. Content to explain action solely in terms of its instrumental functions—as task-specific adaptation—proponents of the exclusive DS approach to development define the organization of a system in terms of adaptation to local context without entertaining the complementary vantage point, that of defining a system's adaptation to local context in terms of its organization (Witherington, 2007, 2011).

Such a repudiation of organization's explanatory role derails the wholeness of dynamics perspective and the unique lens of inquiry it brings to the study of development, resulting in the reduction of developmental time to real time. As an integral facet of developmental explanation for *inclusive* DS proponents, the wholeness of dynamics perspective embeds an organism's current level of organization within a transformational sequence of prior and subsequent levels of organization across developmental time (Mascolo, Pollack, & Fischer, 1997; Murray, 1991; Overton, 1991, 2010). This establishes the developmental context as one of *temporal sequence*, or *structured* time, in which an interpretive framework is established for organizing what organisms do in their real-time encounters with specific contexts. Developmental analysis begins, as a result, with formal and final processes of constraint. For *exclusive* DS proponents, however, "dynamic principles erase the gap between real-time assembly of behavior and its assembly over ontogenetic time" (Thelen & Smith, 1994, p. 129), meaning that "developmental stability and change is always connected to the local details of behavior" (Spencer & Perone, 2008, p. 1645). In the absence of complementary sentiment to the effect that the local details of behavior are always connected to the organism as a whole, both synchronically and diachronically, such a privileging of local-to-global processes grounds developmental time exclusively in real time and denudes the abstracted flow of developmental time of its explanatory significance. Development no longer involves abstraction across time as it does under the auspices of holistic structuralism; form across time, generalized from real-time content, is rejected for its abstraction, its structural reification and its divorce from the particulars of the here-and-now.

Bound to and defined by the task-specific context in the same way as real-time activity is, development in the exclusive DS approach resolves to little more than "a history of past here and nows" (Thelen & Smith, 1994, p. 216), an "accrual of real-time events" (p. 244), with the word *accrual* suggesting that development is forged through accumulation or addition. In other words, developmental-time amounts to little more than a quantitative accumulation of real-time actions in context, reducing to a series of adaptations to local contexts rather than also being a higher-order whole within which such real-time activity can be contextualized (Witherington, 2007). Developmental history is critical for the exclusive DS approach, but as a variable of influence, it is simply another part weighted equally with all other parts, not a higher-order whole, an interpretive, organizational framework within which current real-time activity must be embedded to fully understand such activity; though causally involved in real-time emergence, developmental history still reduces to a collection of real-time particulars (Witherington, 2007, 2011).

From the vantage point of adaptive action-in-context, every change from one act of an organism to another points to a new, emergent organization of the relation between the organism and its environment. Each act is unique and specific to a whole host of contextual parameters, both intra- and extraorganismic. Yet from the wholeness of dynamics vantage point of the organism qua organism, some changes in acts point to new, emerging levels of developmental organization in the organism itself—to a *developmental* transition between levels of organization—whereas other changes in acts point to an established, stable level of developmental organization—*real-time* transitions from one act to another within an organizationally invariant repertoire of acts. For example, a visually guided reach from a 3-month-old—for whom reaches that terminate in grasps are novel—signals a transformation and new level of emergent organization in the organism in a way that a visually guided reach from a 5-month-old—for whom reaches that terminate in grasps form a stable part of her/his action repertoire—does not. Such a distinction graces the inclusive DS approach but not its exclusive counterpart.

Any given act, when viewed from the level of action-in-context, will always constitute a new, emergent form—an adaptation to local, here-and-now context—but may or may not constitute a new, emergent form when viewed from the level of the organism qua organism, though its content relative to a context is newly emergent. Every act can thus exist both as a whole with respect to the adaptive relation of organism to environment and as a part within the whole that is the organism qua organism—both defined in terms of the organism and defining of the relation between an organism and its environment. For proponents of an inclusive DS approach, emergent form at one level of analysis is perfectly compatible with organizational stability at another level, and both represent distinct, equally legitimate ways of explaining the action of a system. Developmental transitions involve the framing of an individual's existing level of organization—abstracted from the specifics of action-in-context—within a sequence of that individual's previous level(s) of developmental organization and subsequent level(s) of organization. Abstracting such organizational sequences is foundational to the wholeness of dynamics perspective and establishes a critical frame of meaning within which to embed the particulars of any given action in any given context. When the wholeness of dynamics and dynamics of wholeness perspectives are treated as alternate views of the same whole, self-organization is as much about the organism maintaining its overall organization in the face of behavioral and contextual variability as it is about the adaptive qualities of the organism's emergent real-time activity in task-specific context. Such is the explanatory pluralism of circular causality as embodied in the inclusive DS approach to development.

By regarding as superfluous the characterization of organisms and their development in integrated whole terms, however, proponents of an *exclusive* DS approach delimit what it means for systems to manifest circular causality. Despite its centrality in the writings of those who espouse an inclusive DS approach to development, circular causality is conspicuously marginalized in exclusive DS writings, rarely warranting much mention if not altogether absent. When exclusive DS proponents do write of circular causality, they apply it to the here-and-now level of behavioral content, suggesting that emergent activities such as walking, reaching, and remembering feed back to the very components that give rise to them. But when "higher-order" constructs are not couched in the immediacy of the here-and-now—when, in other words, constructs are framed in formal and final explanatory terms as atemporal abstractions from behavioral content—these same proponents routinely dispense with the explanatory framework of circular causality, treating such constructs as mere products or as illusory by dint of their "timeless" divorce from real-time activity (Witherington, 2007, 2011). It is important to note that Thelen and Smith's (2006) mention of circular causality and Lewis's three scales of emotional development in the 2006 sixth edition *Handbook* chapter on dynamic systems showed evidence of a possible broadening in their conceptualization of the principle. However, their brief discussion remains ambiguous as to the whole-to-part nature of interlevel relations and stands out more as an aberration than a new rapprochement toward formal and final cause, especially in light of the steadily maintained antistructuralist stance evident both in their chapter and in the exclusive DS approach generally.

The exclusive DS approach to development's narrowed conceptualization of circular causality, and of development in general, engenders a dichotomous stance through its privileging of process over organization, local-to-global dynamic construction over global-to-local organizational constraint and real-time dynamics over developmental-time abstractions (Witherington, 2007). It treats fundamental explanatory principles of development, like directionality, teleology, sequence, and irreversibility, as *appearances* to-be-explained by the *reality* of real-time dynamics rather than as formal and final organizational frames within which to contextualize those very dynamics. Just as its antistructure stance marginalizes organization in process, so this stance severely undercuts the concept of development and ultimately undermines the explanatory potential in principles of nonlinear dynamics for uniting developmental science. Since "real time, context-specific behavior, generalized knowledge, and competence are all one" (Thelen & Smith, 1994, p. 179) and because the here-and-now is privileged relative to other levels of analysis, the unification of global order and local variability that exclusive DS proponents purport to achieve stems not from synthesis but from reduction, as the "appearance" of global order is reduced to the "reality" of local variability (van der Maas, 1995). Maintaining such a reductionist stance in the metatheoretical repertoire of the DS approach to development threatens to unravel the whole enterprise of understanding development in dynamic systems terms (Witherington, 2011).

CONCLUSION: IN SEARCH OF UNIFIED METATHEORETICAL GROUND

Despite their shared roots in the mathematical constructs and tools of NDS, proponents of the DS approach to development are metatheoretically divided with respect to what constitutes viable explanation in the understanding of development. Those who espouse an exclusive DS approach to development ground themselves in an *explanatory monism* by establishing the dynamics of wholeness perspective as foundational and primary to the understanding of organismic activity and its development. Those who espouse an inclusive DS approach to development ground themselves in an *explanatory pluralism* by embracing both a dynamics of wholeness and a wholeness of dynamics perspective as equal, complementary vantage points of understanding. Proponents of the inclusive DS approach fully commit to the perspectivist philosophy of von Bertalanffy's GST, embarking on a synthetic integration of NDS's temporal dynamics focus and GST's holistic structuralism. In contrast, proponents of the exclusive DS approach dispense with the timeless abstractions of GST's holistic structuralism in favor of championing the *real*, *legitimate* explanation of NDS's temporal dynamics focus. From the vantage point of a *dynamics of wholeness* perspective, these differences between inclusive and exclusive approaches vanish, yielding an ontologically unified framework for understanding development based around the principle of self-organization. However, from a *wholeness of dynamics* perspective, approach differences readily surface. Whereas inclusive approaches frame bottom-up processes of self-organization within a broader circular causal framework that accords equal explanatory status to the topological constraint of system organization *at all levels of organizational abstraction*, exclusive approaches summarily dismiss the explanatory importance of organizational abstraction, instead requiring that all explanatory efforts reduce to the real-time dynamics of action-in-context.

Such ontological differences reveal a fundamental divide in how DS proponents bridge the false dichotomies—for example, structure versus function, organizational stability versus dynamic process, global directional order versus local intraindividual variability—that have historically plagued developmental psychology (Witherington & Margett, 2011). For the inclusive DS approach, integrating the false dichotomies of development arrives through a perspectivist framework, wherein the organization/structure/form and the process/real-time functioning of organismic activity represent distinct but interdependent perspectives on the indissociable unity that is organized process. For the exclusive DS approach, integration arrives through the privileging of one vantage point over another, yielding a form of foundationalism at the level of the approach's explanatory efforts. The perspectivist framework of an inclusive DS approach—marked by an emphasis on the relativity of perspective and vantage point—embodies the metatheoretical tenets of the Relational-Developmental-Systems paradigm in which "synthesis and analysis, together with reason and observation, operate in an interpenetrating reciprocal fashion . . . in which each individual approach is valued not as a potentially privileged vantage point, but as a necessary line of sight on the whole" (Overton, 2010, p. 18). As relational metatheory, the inclusive DS approach bridges and ultimately transcends false dichotomies by framing them in *both-and terms*, transforming them into complementary pairs (Kelso & Engstrom, 2006). In contrast, the foundationalist framework of an exclusive DS approach—marked by an antistructuralist stance and privileging of the here-and-now adaptation of activity to local contexts—is ontologically incompatible with the perspectivist inclusivity of the Relational-Developmental-Systems paradigm. By narrowing its frame of legitimate explanation and by privileging certain vantage points over others, the exclusive DS approach more readily aligns with a Cartesian-Split-Mechanistic paradigm, reinforcing a dualistic, either-or approach to reality rather than transcending it (Witherington, 2011).

It is important to emphasize that from the vantage point of a *dynamics of wholeness* perspective, the exclusive DS approach to development is far removed from a Cartesian-Split-Mechanistic paradigm. In its emphases on system irreducibility, emergence without prescription, and the reciprocal, nonlinear relations among components of a system that fuel the emergence of novel system patterning, the exclusive DS approach—just like its inclusive counterpart and systems approaches generally—rejects the mechanistic "principle of *unidirectional, linear, and additive associative or causal sequences*" in which "elements must be related either according to their contiguous co-occurrence in space and time or according to simple efficient and material mechanical cause-effect sequences that proceed in a single direction" (Overton, 2013, p. 39). Recall that DS approaches, when looking at system organization within the bottom-up context of temporal precedence, view efficient causal processes as distributed across all of the fully interdependent parts of a system, none of which is privileged in the emergence of form. All DS approaches, whether inclusive or exclusive, reject the absolutist notions of cause and effect—antecedent and consequent—that underlie the Cartesian-Split-Mechanistic paradigm. Thus, within the confines of the dynamics of wholeness perspective, the exclusive DS approach fully entrenches itself in a *relational* focus, not in the analytically decomposable view of a mechanistic world view which treats parts and forces as independent elements "that preserve their identity regardless of context" and that combine in additive fashion to yield "simple complexity" (Overton, 2013, p. 38).

For the exclusive DS approach to development, however, "there is ultimately a rock bottom unchanging nature to Reality" (Overton, 2013, p. 38), as the Cartesian-Split-Mechanistic paradigm espouses, and that *Reality* is *temporally unfolding process*; the temporal dynamics of real-time process preserve their identity irrespective of developmental level of organization. The exclusive DS approach both privileges—and takes as foundational—*process over organization* (Witherington, 2011; Witherington & Heying, 2013). It privileges and takes as foundational the dynamics of wholeness perspective over the wholeness of dynamics perspective; real-time action-in-context over the organism as an integrated whole across time and context; nonrecursive change between levels of organization over circular causality. Process is prior to and constitutive of organization for proponents of an exclusive DS approach, but organization is *not* prior to and constitutive of process in their worldview. Thus, the exclusive DS approach embraces the splitting and foundationalism of the Cartesian-Split-Mechanistic paradigm *in its ontological approach to the nature of explanation itself.*

The specific *split metatheoretical* character of the exclusive DS approach to development has its roots in the contextualist focus that both inclusive and exclusive DS approaches share when articulating the dynamics of wholeness perspective. Under a contextualist worldview, the particularities of here-and-now time and context assume paramount importance for understanding action and its development (Witherington, 2007). "The event alive in its present" succinctly captures the fundamental mindset for this framework, with continuous change and novelty marking its core foci (Pepper, 1942, p. 232). In Pepper's (1942) words, "nothing is more empirically obvious to a contextualist than the emergence of a new quality in every event" (p. 256). Though contextualism is synthetic rather than analytic in its focus, its synthesis remains wed to the particularities of the here-and-now, to the level of specific action-in-context; as Overton (2007) has argued, "the holism of contextualism is about parts-whole relations of the adaptive act" (p. 158), not of the self-organizing system as an integrated totality. Understanding development within contextualism resolves to the study of variability in activity during real-time, adaptive encounters with everyday contexts.

Contextualism, however, is a dispersive rather than an integrative worldview. As its focus repeatedly narrows to specific action in specific contexts, contexualism avoids establishing an integrative framework abstracted from such particulars and establishes a view of reality as "multitudes of facts rather loosely scattered about and not necessarily determining one another to any considerable degree" (Pepper, 1942, pp. 142–143). Given its dispersive focus, contextualism "in its 'pure' state . . . cannot serve as an adequate metamodel for the study of human development" (Ford & Lerner, 1992, p. 10; see Lerner & Kauffman, 1985) and "consistently shows a tendency to lose its identity and to become a part of mechanism or organicism" (Overton, 1984, p. 219). When contextualism merges with mechanism, the contextualist focus on local-to-global dynamic construction becomes ontologically foundational, with the local, temporally bound dynamics of particular actions in real-time context—captured via distributed efficient causality—constituting the only basis for explanation. Under such a merger, the organization that emerges from the ceaseless flux of these real-time dynamics exists as little more than a momentary, epiphenomenal by-product of bottom-up causal forces. Although higher-order organization in the system is irreducible to lower-order organization, all organization is, in the final analysis, causally reducible to the local processes that give rise to it. The "appearance" of organization ultimately reduces to the "reality" of ceaseless flux, with pattern (the whole) serving as consequent to the antecedent of process (part-part relations). It is precisely this mechanism-contextualism blend that underlies the split metatheoretical character of the exclusive DS approach to development, invoking qualities of the Cartesian-Split-Mechanistic paradigm in the process (Overton, 2007; Witherington, 2007, 2011; Witherington & Heying, 2013).

The Relational-Developmental-Systems paradigm is forged not through a merger of contextualism and mechanism but through what Overton (2010) has termed a "principled synthesis" (p. 11) of contextualism and an *organismic* worldview (see also Overton, 1984, 2007; Overton & Ennis, 2006). The organismic worldview or organicism (Pepper, 1942) lies at the heart of GST's *wholeness of dynamics* vantage point, its holistic structuralism. Organicism takes as its basic metaphor the organism as active constructor of reality through interaction with the world (Reese & Overton, 1970). By this perspective, any living, organized system constitutes an irreducible, integrated whole, and its development is marked by irreversible, progressive, and qualitative changes in the formal properties of that whole (Overton, 1984; Pepper, 1942). Organicism, in other words, grounds its explanatory framework in formal and final explanations, in the abstraction of formal properties from real-time system activity in the ever-changing present (Lerner & Kauffman, 1985).

The Relational-Developmental-Systems paradigm preserves the distinct explanatory foci of both organicism and contextualism through its principled synthesis of the two, establishing each worldview as a unique but complementary frame of understanding with respect to the other rather than as an *absolute* mode of truth in its own right. Within this explanatory pluralism, the issue of local-to-global dynamic construction is addressed through contextualism's focus on the "grass-roots" particularities of real-time acts adapting to their contextual settings—a dynamic interplay of organismic system components constrained instrumentally by local context—yielding, in turn, the continuous emergence of new action qualities, or wholes. Similarly, the issue of global-to-local organizational constraint is addressed through organicism's formal and final explanatory outlook, with higher-order forms—reflecting the abstracted organization of a system that characterizes functioning across a variety of contexts—necessarily framing the lower-order local dynamics on which they depend. Both organicism and contextualism—as different but simultaneous levels of explanation—constitute necessary lines of sight for our understanding of system activity and development, with neither assuming ontological privilege or precedence (Overton, 2007). It is precisely such a principled synthesis of organicism and contextualism that underlies the explanatory pluralism of the inclusive DS approach to development, fully establishing it as a representative of the Relational-Developmental-Systems paradigm.

Through its grounding in the mathematical and conceptual principles of nonlinear dynamics, the DS approach to development has revolutionized the study of temporal dynamics and championed the importance of *intraindividual variability* and real-time activity in developmental science. The principal strength of the approach lies in the rigorous methodological and analytic framework it establishes for addressing the question of process in development. However, the approach's greatest strength can also turn into its greatest weakness. When focus on the temporal dynamics of process—the dynamics of wholeness perspective—becomes all-consuming and rendered as ontologically foundational to the organization and wholeness it seeks to explain, the approach's promise "to bring theoretical coherence" (Thelen & Smith, 2006, p. 307) to developmental science ushers in an explanatory monism that simply privileges one side of a polarity, *process*, over the other, *organization*. Such a monistic take on explanation, revealed in the exclusive DS approach, undermines the very synthesis that the approach attempts to provide and promotes a split metatheoretical frame for understanding development. Realization of the approach's potential as a Relational-Developmental-Systems paradigm at all levels of the research process requires the explanatory pluralism of an inclusive DS approach to development.

CHAPTER 4

Dynamic Development of Thinking, Feeling, and Acting

MICHAEL F. MASCOLO and KURT W. FISCHER

THE DYNAMICS OF HUMAN ACTION: THE PERSON ←→ ENVIRONMENT SYSTEM 115
THE HOW OF DEVELOPMENT: THE EPIGENESIS OF PSYCHOLOGICAL STRUCTURES 115
THE STRUCTURE OF ACTION 116
THE EMOTIONAL GROUNDING OF INDIVIDUAL ACTION 117
INTERSUBJECTIVITY AND THE COREGULATION OF THINKING, FEELING, AND ACTING 118
SOCIOCULTURAL CONTEXT AND SEMIOTIC MEDIATION 120
DYNAMIC SKILL THEORY: TOOLS FOR TRACKING THE DEVELOPMENT OF INTEGRATIVE PSYCHOLOGICAL STRUCTURES 120
A COMMON SCALE OF SKILL MEASUREMENT 121
DEVELOPMENTAL CHANGES IN PSYCHOLOGICAL SKILLS 121
DEVELOPMENTAL CHANGES DURING INFANCY: FROM REFLEX PATTERNS THROUGH SENSORIMOTOR ACTION SYSTEMS 122
Tier 1: Reflexes 122
Tier 2: Sensorimotor Actions 123
DEVELOPMENTAL CHANGES, TODDLER TO ADULTHOOD: FROM REPRESENTATIONS THROUGH ABSTRACTIONS 124
Tier 3: Representations 124
Tier 4: Abstractions and Principles 125
DYNAMIC SKILL THEORY AND THE COMMON SCALE: A SUMMARY 126
THE SHAPES OF DEVELOPMENT: RANGES, WEBS, AND PATHWAYS 126
DEVELOPMENTAL RANGE 127
HOW COACTIVE SCAFFOLDING PRODUCES HIGHER-LEVEL SKILLS 128
DEVELOPMENTAL ANALYSIS OF JOINT ACTION 128
NONLINEARITY AND THE SHAPES OF DEVELOPMENT 130
WEBS AND DEVELOPMENTAL PATHWAYS 131
ILLUSTRATING THE CONSTRUCTIVE WEB: PATHS IN THE DEVELOPMENT OF READING 131
FORGING A PATH BY WALKING 132
DEVELOPMENT IN INFANCY: CHANGES IN SKILLS FOR RELATING TO PERSONS AND THINGS 133
THE DEVELOPMENT OF REACHING IN INFANCY 133
FROM NEONATAL PREREACHING TO SELF-DIRECTED REACHING 133
THE DEVELOPMENT OF REACHING TO EAT 135
DYNAMIC VARIATION IN THE DEVELOPMENT OF REACHING 135

People are different. The differences are pervasive. Humans act differently in different contexts. There is no average person, and only under some very special conditions (see Molenaar & Nesselroade, Chapter 17, this *Handbook*, this volume; Nesselroade & Molenaar, 2010) can means or averages adequately represent any individual's performance. These ideas constitute the fundamental starting point that is omitted in most frameworks for explaining human action. Analysis should *begin* with analysis of the role of context, and with an appreciation that variability is fundamental to human action—that we human beings naturally vary our actions based on context and support for skilled performance. People do not follow narrow models of ability that force them into little boxes such as *intelligence* or *learning style* (Fischer & Bidell, 2006; Fischer, Knight, & Van Parys, 1993).

Human action is integrative. Despite the differences between people and differences in how people act in various contexts, action in the world necessarily involves some sort of integration of cognitive, motivational, affective, evaluative, and motoric processes. We do not act as a series of separable or isolated modules; rather, we act as whole organisms, even if the particular patterns of cognition, conation, and affect differ from context to context and from person to person. Further, the development of structures of thinking, feeling, and acting is the result of an open-ended *probabilistic epigenetic* process (Gottlieb, 2007) that brings together in a relational matrix multiply embedded biological, psychological, and sociocultural systems. A person's behavior cannot be parsed into separable genetic and environmental components. To understand human action and its development, it is necessary to understand how the persons as integrative relational systems operate in particular physical and sociocultural contexts.

In other words, human activity is both organized and variable, dynamically changing according to systematic principles. The primary goal of cognitive, affective, and developmental science is to characterize these principles: How are cognition, emotion, and action organized? What principles are required to describe the ways that people naturally vary their performances? How do organized patterns of thinking, feeling, and acting take shape over time? Taken together, these principles—person-in-context and variability-as-information—represent the backbone of dynamic systems theory.

Children and adults are flexible and inventive in their action and thought, adapting old ideas to new situations, inventing concepts, formulating plans, and constructing hypotheses in the course of participating in a wide variety of cultural practices. These statements make sense to psychologists and educators, who see evidence everywhere of the relational, constructive, self-organizing, self-regulating, and culturally contextualized nature of human psychological processes. Yet the most widely used conceptions of psychological structure and its development have not reflected this relational, dynamic, constructive, and contextualized picture of psychological processes. In fact, the opposite is true. In the past, the major models of development have described psychological structure in static, formal terms, with concepts such as linear growth, universal stages, innate (i.e., strictly biologically determined) linguistic modules, and static cognitive competencies; portraying psychological organization as fixed and unchanging.

The task of developmental science is to capture organized patterns in this variability and to propose models to account for both the variability and the stability (Nesselroade & Molenaar, 2010) of behavior and development. In this chapter we demonstrate how the concepts and methods of *dynamic systems theory* (see also Witherington, 2011, Chapter 3, this *Handbook*, this volume) provide a framework and tools for analyzing this variability and detecting the order within it. This framework is consistent with what others (e.g., Lerner, 2006; Lerner & Benson, 2013; Overton, 2006, 2010, 2013, Chapter 2, this *Handbook,* this volume; Overton & Lerner, 2012) refer to as the *Relational-Developmental-Systems* model. One set of key findings associated with dynamic systems theory is that qualitatively new cognitive abilities emerge naturally in learning and development, transitioning from one form of action or representation to another. Humans are self-creating, self-organizing, and self-regulating systems grounded in meaning through the action of our bodies and our cultures.

Tools from dynamic systems analysis provide ways of embracing the variability in order to find the order within it (see Witherington, Chapter 3, this *Handbook*, this volume). In this chapter, we present a framework for conceptualizing psychological structure as dynamic self-organizing systems constructed by human agents. We begin with an introductory overview of dynamic systems theory as a way to describe learning and development through dynamic organization of self-constructed, socially embedded skills and activities (actions, thoughts, and emotions). This position contrasts with traditional static views of psychological structure based on reductionist scientific theory inherited from the Cartesian-Split-Mechanistic tradition in philosophy (see Overton, 2013, 2014, Chapter 2, this *Handbook*, this volume, for a discussion) and producing systematic but inadequate understandings of psychological structure, including failures to explain the scope of developmental variability. The dynamic framework and research tools crafted for analyzing development and learning provide a methodology for the study of psychological structures, including both their variability and the order in the variation (Molenaar, Lerner, & Newell, 2014). These concepts and tools explain both long-term macrodevelopment and short-term microdevelopmental variability in dynamic structures. These models and methods illuminate analysis of relations among cognitive, social, emotional, and neurological development. All these parts work together to explain how we humans act in all our rich complexity.

THE DYNAMICS OF HUMAN ACTION: THE PERSON ←→ ENVIRONMENT SYSTEM

The first step toward studying learning and development using dynamic systems principles is to articulate a dynamic account of human psychological functioning. There has been what might be called a *relational turn* in many areas of the social sciences (Overton, 1998, 2013, Chapter 2, this *Handbook*, this volume). To analyze human psychological functioning, it is often necessary to decompose complex activity into its component parts and systems. Over the past decades, however, theory and research has shown that understanding the complexities of human functioning requires that we understand how behavior emerges from *relations between coacting* (←→) *systems* rather than as products of independent aggregates functioning in isolation from one another (Gottlieb & Halpern, 2002). The relational turn is evident in theory and research across the human spectrum, including analyses of the epigenetics of human development and evolution (Lickliter & Honeycutt, 2010, Chapter 5, this *Handbook*, this volume); emotion-cognition interaction (Dolcos, Iordan, & Dolcos, 2011; Turiel, Chapter 13, this *Handbook,* this volume); the possible role of a mirror resonance system in underwriting social relationships (Spunt & Lieberman, 2013); and the cultural mediation of thinking, feeling and acting (Cole, 1996; Mistry & Dutta, Chapter 10, this *Handbook*, this volume; Wertsch, 2007; see Overton, Chapter 2, this *Handbook*, this volume, for other examples). The relational turn does not simply call for more powerful ways to assess how diverse variables influence behavior. Instead, it calls for models that explain how psychological acts are constituted in real time by coactions among biological, psychological, and sociocultural processes operating within and between persons.

A parallel aspect of emerging developmental models is an appreciation for the *embodied* nature of psychological processes and their development (Gallagher, 2005; Overton, Chapter 2, this *Handbook*, this volume). The concept of embodiment proceeds from a rejection of the traditional Cartesian-Split-Mechanistic paradigm that postulates the functioning of a separate and distinct mental sphere that lies behind behavior and controls it autonomously from within. From the perspective of embodiment, thinking, feeling, and acting are products of the dynamic intercoupling of the brain, body, and world. Thinking and feeling are ongoing *processes* that arise from the ways in which bodies operate within concrete physical, social, and cultural *environments*. Thinking is not a disembodied process of manipulating abstract symbols in an incorporeal mind; instead, thoughts have their developmental origins in sensorimotor-affective activity in the concrete physical, social, and cultural world.

THE HOW OF DEVELOPMENT: THE EPIGENESIS OF PSYCHOLOGICAL STRUCTURES

Over the past decades, epigenesis has become an increasingly prominent core concept in developmental science's understanding of developmental processes (see, e.g., Lerner & Benson, 2013; Overton, 2006). As Overton (2013) points out:

> Epigenesis is conceptualized as "probabilistic epigenesis" (Gottlieb, 1992), which designates a *holistic* approach to understanding developmental complexity. Probabilistic epigenesis is the principle that the role played by any part of a relational developmental system—DNA, cell, tissue, organ, organism, physical environment, and culture—is a function of all of the interpenetrating and coacting parts of the system. It is through complex *reciprocal* bidirectional and *circular reciprocal interpenetrating* actions among the coacting parts that the system moves to levels of increasingly organized complexity. Thus, epigenesis identifies the system as being completely *contextualized* and *situated*. (p. 53)

Broadly, probabilistic epigenesis refers to the idea that anatomical and psychological structures emerge over time through embodied actions in the world, and are neither preformed nor predetermined (Gottlieb, 2007). It is this epigenetic process that nullifies any attempt at explaining any action, prenatal or postnatal, as "strictly biologically determined" (i.e., "innate").

At the molecular biological level, the related term *epigenetics* is used to designate the "study of . . . [processes] that determine which genome sequences will be expressed in the cell, . . . [processes] that control cell differentiation and give the cell an identity that is often passed on through mitosis" (Griffiths & Tabry, 2013, p. 75). Thus, processes beyond the level of the genes (e.g., RNA, cytoplasm, DNA methylation) play a role activating gene expression at points of development (Danchin et al., 2011; Meaney & Ferguson-Smith, 2010; Nugent & McCarty, 2011). Epigenetics and the processes of epigenesis it entails challenge what has been termed the "*central dogma* of the *modern synthesis*" (Huxley, 1942/2009) in evolutionary theory. This central dogma states that the direction of causality between genetic and nongenetic processes in the creation of proteins is unidirectional (from DNA → RNA → mRNA . . . → Protein). Within this scheme, genes orchestrate the building of proteins, but are themselves unaffected by the processes involved in protein synthesis. However, research has shown that nongenetic biological processes, particularly DNA methylation and histone modification, function to activate and inhibit gene expression during protein synthesis (Meaney, 2010; Šerman, Vlahović, Šerman, & Bulić-Jakuš, 2006; Sun, Sun, Ming, & Song, 2011). As such, the epigenetic model embraces the idea of bidirectional rather than unidirectional causality between genetic and extra-genetic processes (DNA ↔ RNA ↔ mRNA . . . ↔ Protein).

Processes that regulate gene expression are sensitive to changes that occur at multiple levels of organismic functioning. In a multiply nested epigenetic system, no single part of the relational developmental system (e.g., genes, extra-genetic biological processes, behavior, sociocultural experience) is autonomous or primary in human psychological development. Psychological structures are emergent products of coactions among both horizontal (gene-gene, cell-cell, organism-organism) and vertical (gene-cytoplasm, cell-organ, organism-ecosystem) aspects of the relational developmental system. For example, the offspring of rat mothers who show high levels of maternal care during a pup's first week of life (i.e., grooming, pup licking, nursing) show lower levels of stress as adults than offspring of less nurturing mothers. These maternal behaviors produce a suite of biological changes in rat pups, some of which are involved in the silencing and expressing of genes (Weaver et al., 2005). Research has identified epigenetic processes involved in the construction of psychological structures in humans as well. These include the development of attachment (Lickliter, 2008; Schore & Schore, 2008); emotionality and stress regulation (Champagne, 2010); suicidality among adult survivors of maltreatment (Weaver et al., 2005), and other domains (Jablonka & Lamb, 2005).

THE STRUCTURE OF ACTION

Given that development proceeds according to the principle of probabilistic epigenesis, the next issue concerns the embeddedness of this process in the coactive person ←→ environment system as development proceeds across life span. Figure 4.1 provides a schematic representation of the coactive person ←→ environment system. As indicated in the figure, the person ←→ environment system is composed of five categories of coacting processes. These include: (1) individual *acts*; (2) the physical and psychological *objects* toward which acts are directed; (3) *other people*; (4) some form of *mediational means*—that which we act *with*; and (5) physical and sociocultural *contexts*. The foundational assertion of *dynamic coactive systems* approach is that what we *do* and how we *develop* are *emergent* products of *coactions* that occur between and among component parts of the *person ←→ environment system*. The parts of the person ←→ environment system are inseparable (i.e., the system is holistic) as causal processes in the production of action and experience.

The first part or component of the system consists of the structure and functioning of individual acts and their objects, indicated at Figure 4.1 at Points A and B. A *psychological act is a goal-directed integration* of meaning, movement, and phenomenal experience. To act is to experience. As indicated by Overton (2006):

> Experience manifests its relational dialectical as well as its embodied character in being what James terms a "double-barrelled" (1912, p. 10) concept. "It recognizes in its primary integrity no division between act and material, subject and object, but contains them both in an unanalyzed totality" (Dewey, 1925, pp. 10–11). *Experience* refers to *both* the action of the subject (i.e., the subject's embodied active exploration, active manipulation, and active observation of the object world) *and* the object world's active impingement on the subject. "It includes *what* men [sic]do and suffer, *what* they strive for . . . and endure, and also *how* men [sic] act and are acted upon (p. 10)." (p. 68)

Actions have several properties:

- Acts are *intentional* processes in the sense that they are either performed *on* something, directed *toward*

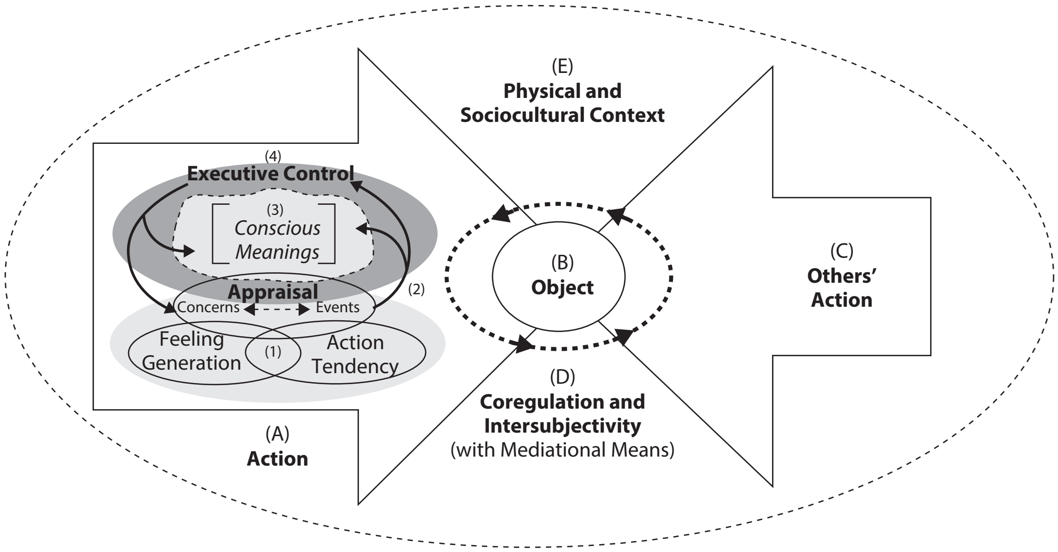

Figure 4.1 The coactive person-environment system.

something, or are *about* something, real or imagined (Fischer, 1980; Searle, 1983). For example, when hitting a baseball, the act of *hitting* is performed *on the ball*; the ball is the *object* of the act of *hitting*.

- Psychological acts are *meaning-mediated* processes. Persons act on the basis of the meaning events have for them. *Meaning* is a central psychological category: to the extent that a process is mediated by meaning, that process is a psychological one (Bruner, 1990). The patellar reflex (knee jerk) is mediated by activity at the level of the spinal cord and operates without participation of higher-level meaning. In contrast, inhibiting a knee jerk is mediated by the goal of keeping the knee still, knowledge of when the hammer will strike, and so forth. Inhibiting a reflex is thus a psychological act. There are as many forms of meaning as there are forms of acting. Meanings have their origins in patterns of *embodied* (sensorimotor-affective) activity in the physical and social world (Noë, 2004; Piaget, 1952) and develop through successive differentiation and integration (Overton, Müller, & Newman, 2008; Piaget, 1952; Werner & Kaplan, 1963). The role of meaning in action is indicated at Point (4) in Figure 4.1.
- Psychological actions are *goal-directed* operations on the world. This implies that persons have some degree of *agency* or control over their representational, experiential, and motoric processes (Fischer, 1980). Research clearly indicates that infants exhibit a capacity for primitive forms of agency and goal-directedness from birth (DeCasper & Carstens, 1981; Trevarthen & Reddy, 2007). In development, intentional acts become organized into hierarchically nested symbol systems (Mascolo, Fischer, & Neimeyer, 1999). Higher-order meanings—especially valued images of self—operate as goals that drive action. Goal-directed agency is represented at Point (4) in Figure 4.1.

Psychological acts are integrative processes. There is no such thing as a simply cognitive or emotional or conative or behavioral process; any action that affects the world necessarily involves some integration of meaning, feeling, needing, and motor action. For example, when playing baseball, action, object, means, and meaning operate as a dynamically coupled and unified system. A change in any single part can result in a change in the action itself. The form of a batter's swing varies depending upon whether he is attempting to hit a fast-moving hardball or a large and looming softball.

THE EMOTIONAL GROUNDING OF INDIVIDUAL ACTION

At its core, psychological functioning is an *embodied* system that has its basis in sensorimotor-affective activity. Emotions are fast-acting experiences that arise from (initially nonconscious) motive-relevant transformations in a person's relation to the world. The core emotional parts of psychological functioning are indicated in Figure 4.1 at Point (1). Drawing on current emotion theory (Mascolo, Fischer, & Li, 2003), any given emotional state is composed of at least three coacting categories of processes. These include *motive-relevant appraisals*; *affect (feeling) generating processes*; and *motive-action tendencies*.

- *Appraisals* consist of the nonconscious assessment of relations between perceived events and an individual's goals, motives, desires, or concerns (Frijda, 2012). Although many models of emotion view appraisal as a form of cognitive process (Ellsworth & Scherer, 2003), this is misleading. Although appraisals may involve cognition, they are primarily *motivational* processes; they reflect relational registrations of the fate of a person's motives (Roseman, 1991).
- *Affect-generating processes* consist of syndromes of central nervous system (Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012), peripheral nervous system (Kreibig, 2010), and bodily changes (Dunn et al., 2010) that bring about the phenomenal experience of a particular class of emotional feeling. Theorists, researchers and laypersons alike have suggested that different emotional states are associated with different sensory qualities (*qualia*) (Bermond, 2008). However, because people tend to find phenomenal experience difficult to describe, they often resort to the use of metaphor to describe feelings (Ortony & Fainsilber, 1989).
- *Action tendencies* refer to classes of voluntary and involuntary *action* that function in the service of a person's goals, motives, and concerns within any given context (Frijda, 2012). Different emotional states are defined in terms of different appraisal-affect-action configurations. For example, fear arises in the context of appraised danger (Nezlek, Vansteelandt, Van Mechelen, & Kuppens, 2008), and involves a phenomenal tone that people experience as a state of hyperactivation (Davitz, 1969). In fear, persons are motivated to *remove the danger*, which can be achieved in diverse ways (e.g., fight/flight; tend/befriend; freezing) (Bracha, Ralston, Matsukawa, Williams, & Bracha, 2004).

In any given context, emotions emerge over time as a product of coactions that occur among component appraisal, affect, and action systems. Appraisal processes continuously and nonconsciously monitor relations between perceived events and the entire range of a person's goals, motives, desires, and concerns. Appraised changes in the relations between events and motives continuously (and nonconsciously) modulate emotion. Changes in affect and emotional experience *select, amplify, and organize these same appraised events for conscious awareness* (Lewis, 1996; Mascolo et al., 2003). Appraisal and affect coact in the construction and organization of conscious awareness. For example, experienced drivers often find that they are able to operate motor vehicles without conscious awareness for long periods (Charlton & Starkey, 2011). However, if a child were to run into the road, the driver, immediately aware of the danger, takes evasive action. The transition from *nonconscious* driving to *conscious awareness* implies that the processing of road conditions must occur continuously, albeit outside of awareness. This example demonstrates how *conscious awareness arises as the product of nonconscious processes*. The nonconscious, fast-acting effects of emotional activation orient attention and organize both intentional and unintentional action (Freeman, 2000). The emotional construction of conscious awareness is indicated in Figure 4.1 at Point (E).

INTERSUBJECTIVITY AND THE COREGULATION OF THINKING, FEELING, AND ACTING

The third aspect of the coactive person ←→ environment system consists of the actions of *other people* (Point C in Figure 4.1). Psychological inquiry has traditionally operated within a Cartesian-Mechanistic framework that embraces strong dichotomies such as *individual/social*, *self/other*, *subject/object*, *inner/outer*, *mind/behavior*, and related dualities (Overton, 2006, Chapter 2, this *Handbook*, this volume). From the Cartesian view, psychological life is understood as a subjective and internal process that is set off against an objectively external world of objects and people. Viewed in this way, the problem of other people—how we come to know and be known by "other minds"—becomes a difficult one. From the Cartesian view, individuals have no direct access to the minds of others. Infants begin life as separate (and egocentric) entities who must somehow break into the world of social relationships. To address this problem, theorists have suggested that individuals must either project their own subjectivities onto others (Goldman, 2006; Gordon, 1986), or they must construct theories of mind to infer the types of mental states that lie behind the external behavior of others (Gopnik & Meltzoff, 1997; Stich & Nichols, 1992).

Theory and evidence calls into question the traditional Cartesian conception. A large and growing number of phenomenological (Gallagher, 2008), linguistic (Racine & Carpendale, 2008; Wittgenstein, 1980), and embodied systems perspectives (Overton, 2006; Thompson, 2007) hold that infants and adults are embodied beings who are able to experience their physical and social worlds directly. Several implications arise from these approaches. First, from an embodied view, there is no such thing as a separate, internal sphere of mind that *lies behind* action. That which is often called *mind* is a form of *action* in the world (Overton, 2006, Chapter 2, this Handbook, this volume; Wertsch, 1998). Second, as a form of embodied activity, psychological action is not something that necessarily operates within a hidden interior. Overt acts are not separate external somethings regulated by a hidden internal something. Instead, observable action is the external *manifestation* of psychological activity; the *internal* and *external* are private and public manifestations of common processes (Ter Harke, 1990). In face-to-face interaction, there is ordinarily no need to *infer* the experiential states of others; instead, we read such states directly from the other's expressive actions. Wittgenstein (1980) states:

> "We *see* emotion."—As opposed to what?—We do not see facial contortions and make the inference that he is feeling joy, grief, boredom. We describe a face immediately as sad, radiant, bored, even when we are unable to give any other description of the features .... In general I do not surmise fear in him—I see it. I do not feel that I am deducing the probable existence of something inside from something outside; rather, it is as if the human face were in a way translucent and that I were seeing it not in reflected light but rather in its own. (§570, p. 170)

This does not imply that experience is *never* hidden; it is only to say that experience is not hidden *a priori*. Humans can hide their psychological states. When they do, they hide the *external* manifestations of experience—not a private interior (ter Hark, 1990).

Research corroborates an embodied-relational conception of development in infancy and beyond. First, research suggests that infant-caregiver dyads are capable of establishing rudimentary forms of intersubjectivity soon after infants are born. Intersubjectivity can be defined in terms of the capacity for shared or coordinated action or experience within episodes of joint action (Foolen, Lüdtke, Racine, & Zlatev, 2012; Matusov, 1996). Support for this view comes from many sources. Meltzoff and Moore (1977, 1983) have shown that neonates are capable of matching facial actions modeled by others. By 2 months of age, infants and their caregivers engage in emotionally charged turn-taking involving sequences of smiling, cooing, and related coordinated acts (Trevarthen, 1979; Trevarthen & Hubley, 1978). In these exchanges, infant and caregiver not only coordinate their facial and vocal action, but they coordinate the emotional *experiences* that arise within the affective dance that occurs between them (Gallagher & Hutto, 2008).

The idea that young infants are capable of primitive forms of intersubjectivity is bolstered by the discovery of *mirror neurons* (Cattaneo & Rizzolatti, 2009; Gallese, Eagle, & Migone, 2007; see also Marshall, Chapter 7, this *Handbook*, this volume). Mirror neurons consist of neurons, initially discovered in the prefrontal lobes of monkeys, which become activated both when observing behavior in others and when executing the same action by the self. There is some controversy about whether mirror neurons exist in humans. Some studies suggest that functions that attributed to mirror neurons in monkeys exist in humans (Kilner, Neal, Weiskopf, Friston, & Frith, 2009); others suggest otherwise (Lingnau, Gesierich, & Caramazza, 2009). The possibility that mirror neurons (or similar such systems) operate in humans suggests that a common neurological system may underlie both the observation and production of certain classes of motor behavior. Such common pathways provide a foundation for understanding how infants are capable of entering into emotionally mediated social interactions from the start of life: Although individual persons are separate and distinct organisms, the mirror resonance system may provide the means for experiencing correspondences—however primitive at first—between experience of others and similar experiences within the self (Meltzoff, 2011).

These arguments suggest a dramatic revision of traditional conceptions that depict individuals as prior to social relationships or that identify cognitive development as a precondition for social development (Kohlberg, 1994; Piaget, 1932). Whereas some approaches suggest that intersubjectivity is a *derivative product* of cognitive development, the relational perspective suggests that psychological development *builds on* a primordial capacity for intersubjectivity. The capacity for intersubjectivity is what makes face-to-face communicative exchanges between infants and caregivers possible.

Intersubjective communication is not a matter of passing discrete messages back and forth between interlocutors. Face-to-face communication operates as a *continuous process system* (Fogel, 1993) in which both partners are simultaneously active as "senders" and "receivers." As one individual speaks, her partner is continuously active as both "receiver" (interpreting verbal and nonverbal meaning) and "sender" (providing nonverbal and sometimes verbal feedback). Thus, unlike in discrete state communication systems (e.g., email, snail mail), the "message" communicated in intersubjective interaction is neither fixed nor discrete. As interlocutors continuously adjust the structure and content of their communications to each other in real time, the "message" itself changes in the process of its "transmission." When thinking about communication as a dynamic, continuous, and intersubjective process, discrete concepts like "sender," "receiver," "message," and "transmission" lose their meaning.

If social interaction operates as a continuous process, it follows that within face-to-face interaction, social partners *coregulate* each other's action and experience. Coregulation refers to the process by which social partners continuously adjust their actions, thoughts, and feelings to the ongoing and anticipated actions of their social partners (Fischer, 1980; Fischer & Bidell, 2006; Fogel, 1993; Lerner, 2006; Mascolo, 2013; Semin & Cacioppo, 2008). In coregulated interaction, each partner's ongoing actions operate as *part of the process* of the actions of the other. If this is so, it is not possible to understand the production of action by focusing only on what occurs within the heads of solitary individuals.

SOCIOCULTURAL CONTEXT AND SEMIOTIC MEDIATION

The final components of the person ←→ environment system include the *sociocultural context* (Figure 4.1/Point E) and the use of *cultural tools* (Point D) to mediate higher-order action (Cole, 1996; Wertsch, 1998). Like individual actors, culture operates as a network of dynamic processes rather than as a fixed or monolithic entity (see Mistry & Dutta, Chapter 10, this *Handbook*, this volume). Cultures function as systems of dynamic meanings, practices, values, and artifacts distributed throughout a linguistic community. Symbol systems play a central role in the constitution and dissemination of culture. As forms of representation, symbols are used to make one thing (i.e., a signifier, e.g., the word "friend"; a picture of a person) stand for or represent something else (i.e., the signified; e.g., an actual person; the meaning of *friend*). The *semiotic function* allows individuals to create meanings that go beyond the information given (Bruner, 1990; Burke, 1966).

Among the symbolic processes that constitute cultural activity, language is perhaps the most important. Language operates as a generative and rule-governed system of signs (words). Signs are *generative* vehicles that mediate the construction of *arbitrary* meanings *shared* within a given community. These properties make language a quintessential tool in the construction and dissemination of culture. Signs are *arbitrary* in the sense that their meanings are derived from social practice rather than from the physical or perceptual qualities of their referents. For example, the term *friend* identifies a socially structured way of defining how people relate to each other; its meaning is not determined by the perceptual qualities of any particular individual.

Second, signs allow meanings to be easily shared among members of a linguistic community. Anyone who understands the English language can be taught the meaning of the word *friend* almost instantly. It is difficult to communicate novel meanings using nonlinguistic symbolic forms (e.g., pictures, pantomime). Finally, sign systems are *generative* in the sense that they allow persons to construct an infinite number of meanings from a finite number of linguistic rules and elements. For example, one can generate novel conceptions of "friend" simply by adding modifiers (e.g., *best friend*, *girlfriend*, *friend with benefits*). Thus, when a child learns how to use a term like *friend*, he gains access to a world of meanings, practices, and values that have their origins in culture (Damianova & Sullivan, 2011; Vygotsky, 1978).

Psychological functioning is a coactive product of processes that operate within and between individuals. No single aspect of the person ←→ environment system is primary in the constitution and regulation of action. As a result, it is not possible to understand the origins and development of psychological activity simply by examining individual actors (or isolated parts of individual actors). Instead, to understand psychological development, it is necessary to examine how integrative structures of thinking, feeling, needing, and acting undergo differentiation and integration as products of multiply nested coactions that operate throughout the person ←→ environment system.

DYNAMIC SKILL THEORY: TOOLS FOR TRACKING THE DEVELOPMENT OF INTEGRATIVE PSYCHOLOGICAL STRUCTURES

Psychological structures functioning according to epigenetic processes are integrated systems of thinking, feeling, and acting that operate within particular sociocultural contexts. Skills are types of psychological structures. Skills are control structures; they reflect a person's capacity to exert control over elements of thinking, feeling, and acting within particular sociocultural contexts. Skills are not inherently generalized structures. Instead, they are tied to particular psychological domains, tasks, and physical and social contexts. Skills are dynamically coupled properties of persons-in-contexts. The structure of running, for example, differs depending on whether a person is running on a rubberized track, a beach, or an inclined plane. Similarly, a skill developed in one psychological domain (e.g., arithmetic) will not necessarily generalize for use in other psychological domains (e.g., music, storytelling) or even in highly related domains or tasks (e.g., subtraction). Skills develop slowly over time as individuals coordinate lower level elements of acting, thinking, and feeling into higher-order wholes within and between domains and contexts.

A COMMON SCALE OF SKILL MEASUREMENT

Our research has established a scale of hierarchical complexity that children and young adults move through as they learn and develop. This scale provides a key advance for developmental science—a *common ruler* (scale) for measuring change and variation in activity. This discovery is similar to creation of the centigrade or Fahrenheit scales for temperature, and to the meter or foot for length. Unfortunately, psychological measurement has produced mostly arbitrary scales based on a single psychological characteristic, such as intelligence, achievement, or personality. These scales have been grounded in statistical models assuming stable (static) ability and so-called normal distributions (for critique, see van Geert & van Dijk, 2002; Wahlsten, 1990), and they assess behavior in one situation. A more useful scale allows measurement of different skills in various situations and is not tied to one situation or assessment instrument.We have discovered a consistent pattern of cognitive/emotional/cortical transformations in development, with periods of reorganization occurring at regular intervals during development (Fischer, 1980; Fischer & Bidell, 2006; Stein, Dawson, & Fischer, 2010). This pattern is illustrated in Figure 4.2. At regular intervals (e.g., at approximately ages 2, 4, 6, and 10 years) children reorganize their embodied actions to form more complex capabilities. Along with the reorganizations, these changes are marked by spurts in performance. We have found these reorganizations to follow a sequence of 13 levels of skill that develop through four broad tiers with a series of three levels within each tier. The four tiers include *reflexes* (i.e., action patterns, present at birth, that require environmental affordances as a necessary condition for their activation and use), *sensorimotor actions* (i.e., controlled actions performed on physical and social objects), *representations* (i.e., signs and symbols), and *abstractions* (i.e., representations of generalized, intangible meanings). Each successive change from one tier to another constitutes a qualitative transformation—that is, a fundamental shift in the structure of thinking, feeling, and activity that is exhibited within particular domains and contexts. The capacity to exert control over action patterns that are present at birth (i.e., reflexes) is different from the capacity to intentionally execute novel actions and to construct action-based meanings in the context of objects and other people (sensorimotor actions). Similarly, the capacity to make on set of things, actions, or experiences *stand for* another object, thing, or experience in its absence (i.e., representations) differs from the capacity to construct action-based meanings in the context of objects, persons, and events (i.e., sensorimotor acts). Finally, the capacity to construct representations of intangible, hypothetical, and generalized meanings (i.e., abstractions) differs substantially from the lower-level capacity to represent the concrete aspects of observable events (i.e., representations).

Within tiers, skills develop through an iterative cycle of levels. Similar structures recur in each tier, reflecting a dynamic cyclical growth process. Within each tier, a person first differentiates a series of individual *single sets* (i.e., single reflexes, acts, representations, or abstractions). Over time, after an individual differentiates multiple single sets, the person gains the capacity to coordinate at least two sets to form *mappings*. Thereafter, with further development, individuals become able to differentiate multiple mappings and organize them together to form *systems*. At the fourth level of each tier, the person differentiates multiple systems to form a higher-order *system of systems*, which is the equivalent of a new kind of unit that begins the next tier—a *single set* of a new type. The broad growth cycles (tiers) of reflexes, actions, representations, and abstractions are identified in the left column of Figure 4.2. Levels of skill—the specific clusters of discontinuities that arise within tiers—are indicated to the right of each tier.

DEVELOPMENTAL CHANGES IN PSYCHOLOGICAL SKILLS

In this section, we illustrate the use of the common scale through an analysis of developmental changes in integrative structures of thinking, feeling, and acting from birth to adulthood. Although we focus primarily on the structure

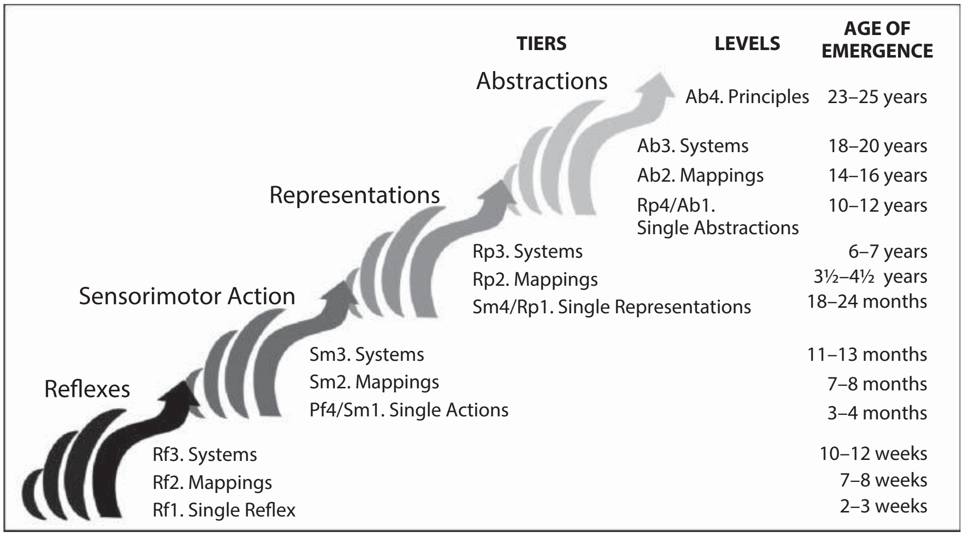

Figure 4.2 Levels and tiers in the development of psychological skills.

of the child's participation in physical and social activity, whenever possible, we also identify how individual functioning operates within coregulated sign-mediated social interaction.

DEVELOPMENTAL CHANGES DURING INFANCY: FROM REFLEX PATTERNS THROUGH SENSORIMOTOR ACTION SYSTEMS

Psychological development builds on primordial forms of intersubjectivity that already exist in the interactions between newborns and their caregiver. The first evidence of such activity can be found in the form of neonatal matching of a number of adult facial actions (e.g., tongue protrusion, lip protrusion). Because infants cannot directly observe their own facial expressions, they cannot use vision to coordinate their own facial activity with the seen facial actions of their caregivers. One explanation of this finding is that similar biological systems (e.g., a mirror resonance system) mediate the processes of both performing an action (e.g., tongue protrusion) and seeing someone else perform an action (e.g., seeing an adult stick out the tongue). From this view, when an infant observes an adult's facial action, the biological processes that mediate the act of seeing the adult's facial action simultaneously activate parallel (matching) states of affect and action readiness in the infant. These primordial experiences of intersubjective attunement between caregiver and infant provide the foundation upon which further social development builds.

Tier 1: Reflexes

Beginning around 2 to 3 weeks, infants begin to operate within the reflexive tier of development. At this point, infants are capable of constructing *single reflexes* (Rf1). They start to exert control over simple elements of action that are both present at birth and that arise in the context of direct physical and social contact. Single reflexes are not like knee jerks or eye blinks. They involve the active control of action patterns that are available at birth and function within the context of direct environmental affordances (e.g., grasping a blanket placed in the infant's hand). In the social sphere, infants exhibit simple reflexes by looking at the mother's face when it is directly in front of the child or by cooing back to a smiling mother looking and cooing toward the baby (see Figure 4.3a).

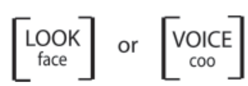

Figure 4.3a

By 7 to 8 weeks, infants begin to coordinate at least two reflex acts into a *reflex mapping* (Rf2) (see Figure 4.2). For example, in contexts in which a caregiver engages infants in direct facial and vocal interplay, infants can begin to exert coordinative control over simple acts of looking at mother and cooing (see Figure 4.3b).

Figure 4.3b

By 10 to 11 weeks, with the onset of *reflex systems* (Rf3) (see Figure 4.2) infants begin to coordinate multiple such mappings together in the context of direct social stimulation. For example, holding a precocious 2-month-old baby in his arms, with a smile and animated voice, a father repeatedly and slowly says “I love you” to his infant. In this context, the infant coordinated acts of looking at the father, hearing the father’s utterance, and with smiling and positive affect, reflecting the prosody and sound of her father’s voice into a vocalization sounding strikingly similar to “I love you” (see Figure 4.3c). This form of affective attunement and reciprocity between infant and caregiver corresponds to what Trevarthen (1979) termed *primary intersubjectivity*.

Figure 4.3c

Tier 2: Sensorimotor Actions

Beginning around 3.5 to 4 months of age, skills undergo transformation as infants gain the capacity to construct skills in the sensorimotor tier of development (see Figure 4.2). At this point, infants begin to gain the capacity to coordinate multiple reflex systems into a single *system of reflex systems*, which is the equivalent of the first level of the *sensorimotor tier*—single *sensorimotor actions* (Rf4/Sm1). Using sensorimotor actions, infants begin to exert spontaneous control over single goal-directed acts. For example, a 4-month-old can *reach for a seen ball* while accommodating the act of reaching to slight changes in the trajectory of the ball; alternatively, an infant can begin to control acts of looking in order to *track the movement of a seen ball* as it moves through a trajectory in space. In social interaction, drawing on expectations acquired over a history of responsive caregiver-child interaction, an infant can coordinate multiple sensorimotor acts (e.g., smiling, vocalizing, looking, hand movements) to initiate social exchanges with others (see Figure 4.3d).

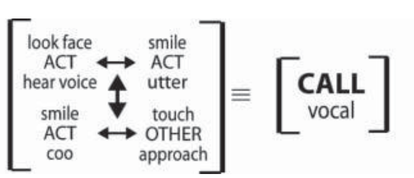

Figure 4.3d

By 7 to 8 months of age, infants begin to coordinate sensorimotor actions into a sensorimotor mapping. Using such mappings, an infant can coordinate looking and reaching into a single seamless controlled skill. She can *reach* for an object *in order to look at it*; or actively *look at an object* in order to *reach for it* as it moves through space. By 9 months, infants are capable of establishing what Trevarthen and Hubley (1978) termed *secondary intersubjectivity*—the capacity to engage in shared reference with an adult. This involves a capacity to coordinate an understanding of what others see or want with what the self sees or wants (see Figure 4.3e).

Figure 4.3e

Using sensorimotor mappings, an infant is able to coordinate acts of *looking at a toy* with a separate act of *seeing his caregiver* look at the same toy. *Social referencing* arises as infants coordinate *looking* at a caregiver’s emotional facial actions (happy, mad, or sad) with the child’s own act of *approaching* an object in the world. For example, an infant can use the mother’s positive or negative facial expression as an indicator to touch or not to touch a particular seen toy.

By 12 to 13 months of age, infants can coordinate two or more sensorimotor mappings into a *sensorimotor system* (SM3). In the realm of acting on objects, a sensorimotor system corresponds to Piaget’s *tertiary circular reactions*. At this level, children can coordinate multiple acts of reaching, moving, and manipulating a new toy to see its various sides and observe how it works in action. In the social sphere, children begin to develop the capacity to use gestures to make rudimentary requests (i.e., pointing; Gros-Louis & Wu, 2012; Tomasello, Carpenter, & Liszkowski, 2007). At the very least, pointing requires an infant to coordinate his own sight of a wanted object (e.g., looking at a toy) with his caregiver’s gaze at the same object (i.e., seeing mother look at the toy), while simultaneously making movements directed toward both the object (e.g., extending the arm) and the caregiver (e.g., alternating looking at mother and object). Over time, the child is able to make refinements in his expectations of the mother (i.e., that she will bring the object) and the gestures used to enlist her support (using the index finger, etc.) (see Figure 4.3f).

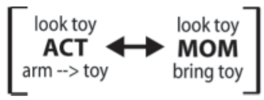

Figure 4.3f

DEVELOPMENTAL CHANGES, TODDLER TO ADULTHOOD: FROM REPRESENTATIONS THROUGH ABSTRACTIONS

The next major transformation a child's capacity to construct novel skills occurs between 18 and 24 months of age. Here we find the emergence of the semiotic function entailing the use of symbols and signs. Using the semiotic function, children are able to make one thing stand for another. Following Saussure (1983; see also Cassirer, 1944; Piaget & Inhelder, 1969), genuine semiotic capacities require the capacity to separate *signifier* (i.e., representational vehicle) from *signified* (i.e., the meaning, referent or object of the signifier). Thus, symbols and signs are genuine semiotic vehicles in the sense that they both *stand for* something else and are *detached* from their referents (e.g., using the word "mother" in the absence of the mother). *Signs* (e.g., the word "mother") differ from *symbols* (e.g., using the vocalization "mumee" to refer to mother) in the sense that they represent conventional rather than personal meanings. Although the shift from sensorimotor action to representations is a dramatic one, the transition occurs gradually and takes a variety of forms. Prior to the emergence of signs and symbols, children are capable of forms of representational activity that are dependent upon the local sensorimotor context. For example, an 8-month-old can take the opening of a door as a *signal* or *index* that the mother will soon be present (Namy, 2009; Piaget, 1951).

Tier 3: Representations

With the onset of construction of skills in the *representational* tier of development, children gain the capacity to coordinate multiple complex action patterns at the level of sensorimotor systems into a higher-order system of sensorimotor systems, which is the equivalent of a *single representation* (see Figure 4.2). Using single representations, children are able to make one thing (e.g., a sound sequence; a picture) stand for another (e.g., an object; the meaning of a word). Single representations allow children to form images and ideas of objects and meanings that have no immediate basis in sensorimotor experience. Children are able to spontaneously control the constructive formation of a mental image; they can use words to stand for absent objects, or to represent the concrete meanings of such objects.

At this level, children can represent concrete ideas in the form of a simple declarative sentence, such as "Eating candy is good" or "Mommy is nice." They begin to use objects to represent absent qualities in pretend play. For example, a child can pretend that a stuffed animal is a teddy bear and pretend to make it walk. In the social sphere, children begin to construct single representations of self (e.g., "I am a girl"; "I have a mommy") and to assign value to those representations (e.g., "I am a good girl") (see Figure 4.3g). Rochat and Passos-Ferreira (2009) refer to shared symbolically mediated evaluations as a form of *tertiary intersubjectivity* between child and caregiver.

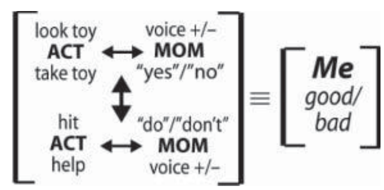

Figure 4.3g

Beginning around 3½ to 4 years of age, children gain the capacity to coordinate at least two single representations into a representational mapping. Using representational mappings, a child is able to represent the relationship between two concrete ideas. At this level, children are capable of representing relations involving *reciprocity* (e.g., "Daddy gave me a present because I drew him a picture"), *quantity* (e.g., "Mommy is tall and I am small"), *cause-and-effect*, (e.g., "Jack fell down because Jill pushed him"), and so forth. Here are three mapping relations depicted in Figure 4.3h.

Figure 4.3h

Beginning around 6 to 7 years of age, in supportive contexts, children coordinate two or more representational mappings into a single *representational system* (Rp3). Using representational systems, children can construct a concrete but systematic logical line of reasoning. In the classical Piagetian conservation task, for example, children are able to understand that changes in the height of the

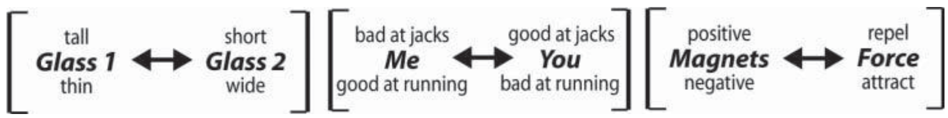

Figure 4.3i

water when it is poured from a tall glass into a short one are compensated by changes in the width of the glasses. In so doing, children are able to represent the relation between two relations, namely, that changes in height *from tall to short* are *compensated for* by changes in width from *thin to wide*. In social relationships, a child can begin to defend against negative feelings that arise from social comparisons. "Jake is better than me at playing jacks, but I'm better at running than Jake." Three illustrations of representational systems are shown in Figure 4.3i.

Tier 4: Abstractions and Principles

Beginning around 10 to 11 years of age, in high support contexts, preteens can begin to construct skills at the next broad tier of development—*abstractions* (see Figure 4.2). Using abstractions, an older child can begin to represent generalized, intangible, and hypothetical aspects of events, people, things, and processes. Abstractions arise as older children gain the capacity to coordinate at least two lower-order representational systems into a *system of representational systems* (see Figure 4.2, Rp4), which is the equivalent of a higher-order *single abstraction* (Figure 4.2, Ab1). For example, at this level, in contexts that support their construction, a preadolescent can begin to coordinate at least two lower-level conceptions at the level of representational systems into a higher-order single abstraction. For example, a 10- to 11-year-old could construct an abstract concept of conservation by generalizing over what is common to two or more concrete examples of conservation—say, conservation of liquid and conservation of mass. In so doing, a child might use the following line of reasoning:

> In general, conservation means that the amount of something stays the same even though there is a change in what it looks like. In the water task, there is the same amount of water in the tall and thin glass as there is in the short and wide one. When the water is poured from the tall glass into the short one, changes in the height are made up for by changes in the width of the glass. So, even though it looks different, there's the same amount of water in both glasses. This is kind of the same as what happens in the sausage task. The two balls of clay are the same at the beginning. When you roll one out to make it into a sausage, the clay becomes long but thin. The changes in the length of the clay are made up for by changes in the thickness. So, the ball of clay has the same amount as the sausage. In both situations, the amount of the thing is the same even though what it looked like changed.

The coordination of two or more concrete representational systems into a single abstraction can be represented as follows:

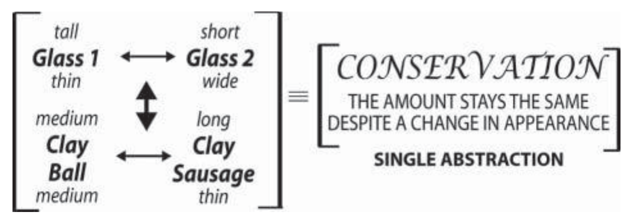

Figure 4.3j

Beginning around 14 to 16 years of age, adolescents gain the capacity to coordinate two or more single abstractions into an *abstract mapping* (see Figure 4.2, Ab2). Using abstract mappings adolescents can represent the relation between two abstract ideas (see Figure 4.3k). For example, a 15-year-old can represent what is meaningful in her life in terms of the relation between two core goals: "The two most important things in my life are my family and my school. I need a good education for my future, and my family is always there to support me in school and other areas."

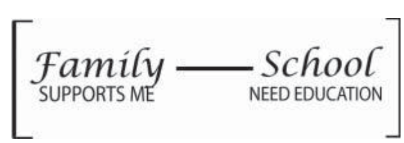

Figure 4.3k

As teenagers approach young adulthood, they gain the capacity to coordinate at least two abstract mappings into a single coordinated *abstract system* (Figure 4.2, Ab3). In so doing, 18- to 20-year-olds are able to construct highly differentiated relations between multiple abstractions, each of which is grounded in the coordination of multiple systems of lower-level concrete representations of events. For example, a young adult can begin to represent the relation between two aspects of his career and two aspects of his personal life (see Figure 4.3l).

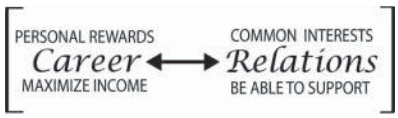

Figure 4.3l

Beginning around 22 to 23 years of age, among individuals with deep experience or advanced training in particular careers or domains, a person is capable of coordinating two abstract systems into a single integrated *abstract principle*. Abstract principles reflect an extremely high level of differentiation and integration of abstract ideas, each of which organize a wealth of lower level abstract and concrete knowledge. For example, as represented in Figure 4.3m, highly reflective individuals can organize a series of abstract systems from various aspects of life into a higher-order principle that defines one's personal theory of a good life (Mascolo & Fischer, 2010). Evidence strongly supports the existence of the first 12 levels of skill proposed by dynamic skill theory, and there is now initial evidence showing growth spurts among highly accomplished individuals during early adulthood (Dawson-Tunik, Commons, Wilson, & Fischer, 2005).

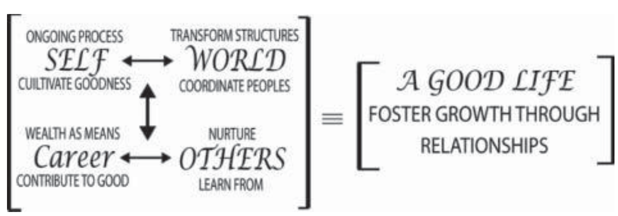

Figure 4.3m

DYNAMIC SKILL THEORY AND THE COMMON SCALE: A SUMMARY

The common scale for behavioral complexity captures both long-term development and short-term learning (Dawson & Wilson, 2003; Fischer, Bernstein, & Immordino-Yang, 2007). It is marked by clusters of discontinuities, such as abrupt changes in growth patterns and clusters of items in scaling (Fischer & Rose, 1994; Fischer & Silvern, 1985; van Geert, 1998). Rasch (1980) scaling of interview and test data have provided consistent evidence of common patterns of discontinuities (Dawson & Wilson, 2003; Dawson, Xie, & Wilson, 2003), forming a scale of 13 levels of hierarchical complexity. The scale also relates to the outline of developmental stages that Piaget (1983) described, but performance is not fixed at one age but instead varies across the scale, marked by clusters of behaviors demarking discontinuities. The scale has important similarities to those suggested by Case (1991), Biggs and Collis (1982), Halford (1982), and McLaughlin (1963). Interestingly, discontinuities in growth of brain activity seem to follow the same scale (Fischer & Rose, 1994).

THE SHAPES OF DEVELOPMENT: RANGES, WEBS, AND PATHWAYS

As we stated at the beginning of this chapter, the pervasive variability of human behavior is essential to the dynamics of human behavior. People act differently in different situations, with different people, in different emotional states. *Variability* is everywhere in human activity and development. Although there is great order in human action and development, people are not stable, and exhibit no fixed patterns of intelligence or learning styles. A child who can solve an arithmetic problem one day or in one situation frequently cannot solve the same problem the next day or in a different but apparently similar situation. Contexts and emotions change who we are. Different children of precisely the same age frequently cannot perform the same cognitive tasks. Variability in the level of psychological performance is the *norm,* not the exception (see Molenaar & Nesselroade, Chapter 17, this *Handbook*, this volume; Nesselroade & Molenaar, 2010).

Variation in the complexity of an individual's skills is manifested in different ways. First, at any given point in time, individuals do not function at a single level of development. Instead, the complexity of a person's actions fluctuate within a *range* of levels depending on a broad set of variables, including context, psychological domain, time of day, the behavior of social partners, task, emotional state, and so forth. Second, psychological development does not occur in monolithic stages of general abilities. Instead, development assumes different forms in different psychological domains, tasks, and sociocultural contexts. Psychological structures do not develop through a single pathway. Instead, both within and between individuals, skills in different contexts (e.g., arithmetic, social relationships, storytelling, science, self-understanding) develop along diverse pathways that both converge and diverge over time. In this way, developmental change looks more like a multidirectional web than a unidirectional ladder. In what follows, we examine sources of both order and variability in the development of psychological structures within and between individuals.

DEVELOPMENTAL RANGE

An important feature of skill development is that individuals do not function at any single level at any point in development. Skills are context-sensitive control structures; they reflect a person's capacity to exert control over thinking, feeling, and acting within particular sociocultural contexts, psychological domains, and tasks. At any given point in development, the form and level of a person's skills vary as a function of local conditions, including the nature of the task or task domain, the emotional state of the person, and the degree of support and assistance provided by the social context. In this way, in development, a person does not operate at any single point along the common scale; instead, individuals function with a *range* of different possible levels. This is called the *developmental range*.

The developmental level, content, and emotional valence of a person's psychological structures vary dramatically as a function of priming and immediate social support, emotional state, and cultural experience (Fischer & Heikkinen, 2010). A child's *optimal* level of performance refers to the level of skill within a particular domain that she is capable of producing under conditions of *high contextual support*. A child's *functional* level of performance occurs under everyday conditions that provide *low contextual support*. High-support (e.g., providing examples of higher-order performance, or providing rubrics or other forms of structured assistance) contexts direct children's attention toward relevant aspects of a task. An individual's optimal level of functioning under conditions of high support is typically higher than his or her functional level in the absence of such support.

To understand the concept of developmental range, consider the wide variation documented in the structure of children's stories or narratives about positive and negative social interactions (Ayoub & Fischer, 2006; Fischer & Ayoub, 1994; Raya, 1997). To illustrate, in one study 5-year-old Susan watched her counselor use dolls to act out a pretend story about social reciprocity. In the story, a child doll named Susan makes a drawing of her family, and gives it to her father. Then the daddy doll hugs the girl doll, thanks her, and gives her a toy in return. At this point, Susan was immediately able to act out a story involving positive social reciprocity at the same level of complexity as the counselor's story. However, 10 minutes later, when the girl was asked to act out the best story she could about people being nice to each other, she acted out a much simpler story, simply making the Daddy doll give lots of presents to the child doll, with no reciprocal interaction between them.

Further changes in complexity occurred after a shift in the child's emotional state. Soon after the above interactions, Susan spontaneously began to engage in aggressive doll play. At this point, the counselor showed her another story involving reciprocal nice interactions between father and child. This time, when Susan acted out the story, she switched the content from positive to negative and organized it around an aggressive exchange between the father and daughter. However, despite the shift to negative emotion and aggression, Susan nonetheless sustained the level of complexity of her story.

In this example, the level of complexity of the child's storytelling shifted dynamically with changes in the immediate situation, the child's emotional state, and the form of social support provided by her counselor. It is thus incorrect to characterize an individual's skills as simply being at one developmental level at any given point in development. Instead, the level of complexity of individual action fluctuates within a *developmental range*. Different contexts for assessment routinely entail such substantial variations. Children (and adults) show distinct levels of competence under different conditions, even for a single domain such as stories about nice and mean social interactions between peers (Ayoub & Fischer, 2006; Brown & Reeve, 1987; Fischer, Rotenberg, Bullock, & Raya, 1993). Figure 4.4 documents changes in the age of emergence of successive levels of psychological skill levels under a series of different conditions, including conditions of high and low support. As indicated in Figure 4.4, a person's optimal level typically functions one or more levels higher than his or her functional level. Further, the distance between an individual's optimal and functional levels of performance (developmental range) typically expands with development. Skills at higher levels of functioning (e.g., abstract mappings and above) may never emerge in some people.

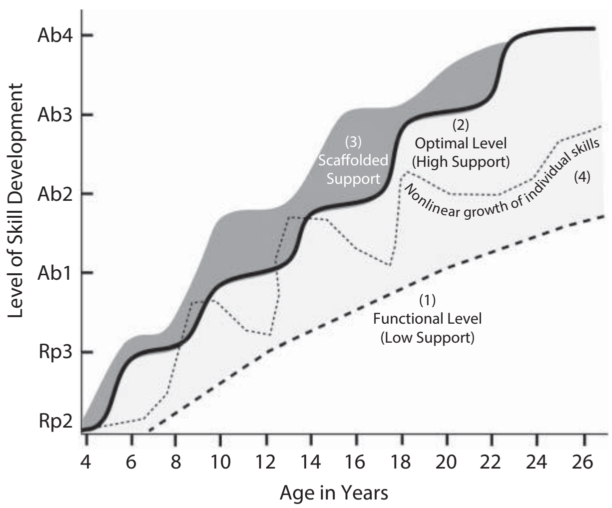

Figure 4.4 Four growth curves showing low, high, scaffolded, and variable support.

HOW COACTIVE SCAFFOLDING PRODUCES HIGHER-LEVEL SKILLS

It is helpful to differentiate an individual's *scaffolded* level of performance from his *optimal* level of performance under conditions of *high support*. Scaffolding occurs when more expert others assist an individual in the performance of any given activity (Gauvain, 2005; Wood, Bruner, & Ross, 1976). Scaffolding differs from high support in that when scaffolding, a more expert person tends to perform part of the task for the child, or otherwise provide instruction that directs the child's actions in ways that the child could not accomplish alone. In contrast, under conditions of *high support*, an individual is able to complete an activity by him or herself, without the intervention of someone else during the process of executing the task. A child who is able to imitate a story modeled by someone else, but does so without further assistance beyond the modeling itself, is operating at her optimal level under conditions of high support. Scaffolding occurs when this child requires instruction or cueing during the process of telling or retelling a story. Under scaffolded conditions, a child's higher level of performance is dependent on the continued intervention of another person. Under conditions of high support, beyond the support itself a child is able to complete the task alone.

In any given task, an individual's scaffolded level of performance tends to be higher than his *optimal* level. This is because control over elements of the task is distributed between teacher and learner. Scaffolding functions to raise an individual's level of functioning to levels beyond that which he can achieve alone. In this way, as Vygotsky (1978) suggested, the level of skill produced when a child is learning a new skill with the assistance of others operates in advance of the level of skill a child exhibits when working alone.

Social scaffolding, however, is not the only type of scaffolding that organizes development and learning. We use the term *coactive scaffolding* to refer to the ways in which aspects of the person ←→ environment system outside of an individual's direct control function to raise the individual's performance beyond that which he or she can sustain alone (Mascolo, 2005). Social scaffolding is one form of coactive scaffolding. Other forms of scaffolding include *task scaffolding*, *ecological scaffolding*, and *self-scaffolding*. *Task scaffolding* occurs when aspects of the task itself (or the objects of action) operate in ways that support higher levels of performance. For example, when playing Scrabble, the simple act of moving tiles around suggests different letter combinations that a player can use (intentionally or otherwise) to identify novel words. *Ecological scaffolding* occurs when the relationship between the actor and context functions to support high-level performance. For example, when a mother holds an infant in her arms, the baby is optimally positioned to gaze toward the mother's face. The distance between the infant's face and the mother's face is approximately equal to the limits of a neonate's visual acuity. In this way, the ecology of the holding environment supports the act of looking into the mother's face. *Self-scaffolding* (Bickhard, 1992) occurs when the actor herself creates her own conditions for supporting higher-level functioning. Self-scaffolding occurs in the context of problem solving, for example, when a person uses an already known way of solving a problem to solve a similar but novel problem.

DEVELOPMENTAL ANALYSIS OF JOINT ACTION

Scaffolding directly contributes to the moment-by-moment formation of psychological structures. We have developed a series of tools for conducting developmental analyses of joint action as it occurs in moment-by-moment interactions between individuals. This system allows empirical analysis of the micro- and macrodevelopment of psychological structures as they emerge between people in joint action. The process of assessing changes in the structure of joint action involves several steps. These include (a) *performing task analyses* of the actual or optimal endpoints of development within particular domains; (b) *analyzing the* *structure of joint action* (how individuals organize patterns of acting, thinking, and feeling in relation to each other in particular contexts); and (c) *tracking changes in the structures and processes of joint action* over time. A developmental analysis of the role of coactive scaffolding in organizing a developing skill is depicted in Figure 4.5. The top panel of Figure 4.5 contains a task analysis for *manipulating a handheld jack-in-the-box*. As indicated in the figure, to manipulate a jack-in-the-box successfully, it is necessary to understand the goal of the task as *making the jack pop: hold the box*, *turn the crank up and down*, and *sustain turning* until the *jack pops*.

The operation of a handheld jack-in-the-box is beyond the capacity of a 15-month-old child. However, with assistance, most 15-month-olds can perform at least part of the task. The middle panel of Figure 4.5 depicts a *dyadic action structure* that identifies the ways in which control over components of the jack-in-the-box tasks is distributed between a 15-month-old boy and his mother at a particular moment in time. The left portion of the diagram identifies the configuration of acts over which the *child* was able to exert control (i.e., looking at the box while turning the crank up and down for several jerky turns); the right portion identifies those parts over which the *mother* exerted control (i.e.,

TABLE 4.1 Levels and Forms of Social Scaffolding

Level and Form	Example
9. Physical Guidance. E uses physical contact, directly or indirectly, to direct N's task activity.	Uses hand-over-hand contact to guide N in crossing laces.
8. Model. E demonstrates or shows N how to perform a task or action.	Cross your laces like this.
7. Direct. E directs, instructs, or otherwise indicates how to perform a task or action.	First cross your laces, then put your left lace through the opening.
6. Interpret/Explain. E draws on authoritative understanding to interprets or explains event.	When you cross your laces, it looks like the letter "X"
5. Hold. E offers or agrees to perform part of a task or carry part of the emotional burden of a task.	Don't worry; if you don't finish it all, I'm here to help.
4. Distance. E asks questions or makes statements intended to prompt constructive activity on part of N in order to meet the challenge.	N: "What makes it nighttime?" E: "What is the difference between night and day?"
3. Restate/Expand. E repeats, reframes or adds additional information that extends the meaning of N's statement.	N. It gets dark at night. E. It gets dark at night when the sun goes down.
2. Encourage. E reassures or modulates N's self-evaluation in order to support ongoing activity.	You can do it; it's just like you tied your laces yesterday.
1. Prompt. E cues N to deploy existing skill.	Okay, tie your shoes!

Note. Higher levels of scaffolding indicate increasing degrees of support.

holding the box while modeling the turning of the crank). The symbol in the middle of the diagram identifies the form of *coregulated action* that occurs between parent and child. Table 4.1 identifies a series of nine levels of social scaffolding. Each level is defined in terms of the degree of structuring assistance provided to a learner by a teacher. In this situation, the child is able to turn the crank for several turns after his mother *models* (Scaffolding Level 8) the action and *encourages* (Level 2) the child to perform it.

The bottom panel of Figure 4.5 identifies the structure of action between the parent and the child only minutes later. In this situation, the child sits on his mother's lap, his back leaning against his mother, while his mother uses hand-over-hand guidance (Scaffolding Level 9) to assist the child in both turning the crank and holding the box. The scaffolded structure of the child's behavior in this situation is different than it was just moments before. In this situation, without her physical support and hand-over-hand guidance, the child would have been unable to exert any degree of control over the process of turning the crank and holding the box. The dyadic action analysis shows precisely how particular relations among components of the person ←→ environment system (e.g., hand-over-hand guidance ←→ child holding the box ←→ mother's bodily support ←→ child's posture in relation to the box) support higher order action. By tracing changes in the structure of dyadic action over time, one can illuminate how children gradually seize control and master configurations of thinking, feeling, and acting that have their origins in coactions that occur within the person ←→ environment system.

NONLINEARITY AND THE SHAPES OF DEVELOPMENT

Along with optimal level and functional level, Figure 4.4 shows four growth curves that are indicative of the dynamic variability in the shapes that development takes over time. An individual's functional level (Curve 1) performance in any given skill tends to increase slowly over time. Changes in functional level tend to occur only after individuals have had time to consolidate lower-level skills into more stable higher-level skills that can have broad application beyond their contexts of acquisition. In contrast, changes in optimal level performance (Curve 2) tend to follow spurts in brain development (Fischer & Rose, 1994) and are revealed primarily under conditions of high support. As a result, growth curves tend to follow a scalloped pattern reflecting a spurt in growth, followed by a period of consolidation. Repeated high-support assessments over time reveal the earliest age of emergence of new levels of skill. Under scaffolded support, an individual-with-assistance is capable of performing at levels that extend beyond his or her optimal level. This is indicated in the shaded area beneath Curve 3. In most cases, it is best to view a child's scaffolded level as reflecting activity at the dyadic rather than individual level of performance.

Everyday development occurs across a wide variety of contexts, conceptual domains, tasks, and conditions. Psychological structures tend to show wide variations in level of complexity from one point in time to another. As a result, psychological development tends to be profoundly *nonlinear* rather than linear. Curve 4 in Figure 4.4 depicts a typical nonlinear growth curve. Particular skills tend to develop in fits and starts, and exhibit both forward progression and backward transition (Granott, 2002). Backward transitions (i.e., temporary regressions) occur for many reasons, many of which have to do with variations in local conditions (degree of support, type of task, etc.). However, backward transitions also serve important developmental functions (Bassano & Van Geert, 2007). Backward transitions often occur as individuals build a novel skill.

This occurs for several reasons. It is often necessary for individuals to return to lower levels of functioning in order to consolidate (form increasingly integrative connections among) component parts of newly formed skills (Feldman & Benjamin, 2004). Backward transitions also occur when, after completing the construction of one part of skill (e.g., when learning to tie shoes, building the skill to cross the laces), children return to a lower level of functioning to begin construction of a second part of the developing skill (e.g., learning to loop one lace around another). Nonlinear growth of skills is the rule rather than the exception in the development.

WEBS AND DEVELOPMENTAL PATHWAYS

In the standard metaphor for development, children are tracked along a single, unidirectional *developmental ladder,* and educators assume that all children move along the same ladder. The *constructive web* framework provides tools for rethinking variability to capture patterns of variation in skill development. Different groups of children commonly move along alternative developmental pathways. When children (and adults) are seen as moving along different pathways, the teacher's work is changed from forcing students to learn in one way to finding the best pathways for children to follow. There is not only one learning sequence but many alternatives. Different children learn along different pathways.

Figure 4.6 depicts a constructive web exhibiting a variety of different converging and diverging paths. The pathways that make up the web can represent different strands of development within a single individual, different individual strands, or different groups of individuals. The pathways of construction vary in their degree of stability as one moves to higher levels of development. In Figure 4.6, bold lines that form the base of a developmental pathway indicate the automatization of skills that occurs with over-learning and routinization. *Automatized* skills (e.g., reading words with reading proficiency) require little or no attentional resources for their execution (Usoof-Thowfeek, Janoff-Bulman, & Tavernini, 2011). Functional level skills are those that require conscious control and attentional resources, but are effectively stable for everyday activities (e.g., reading a picture book for a 7-year-old). Optimal level skills are those that individuals can sustain under high support conditions (e.g., modeling a simple story for a 7-year-old), whereas scaffolded levels occur as adults assist children in constructing skills currently under

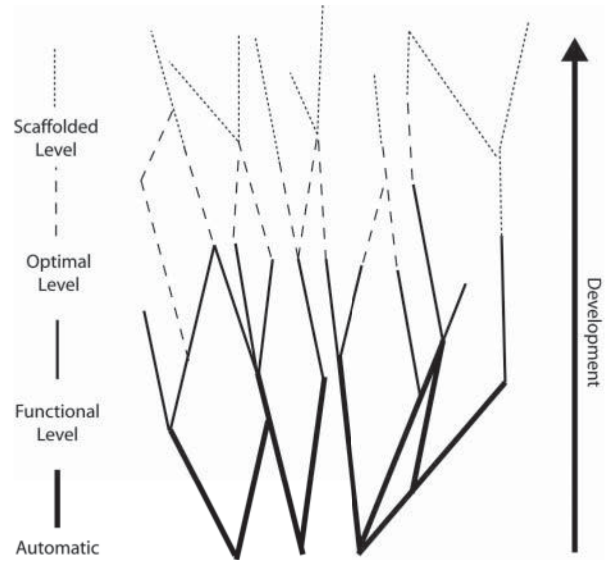

Figure 4.6 Constructive developmental web.

development. Within a developmental web, an individual's developmental range corresponds to the area through which an individual's skills fluctuate with changes in context, emotional state, instruction, domain, and so on.

ILLUSTRATING THE CONSTRUCTIVE WEB: PATHS IN THE DEVELOPMENT OF READING

Young children can begin to read words at an early age. Most curricula treat all children as if they learn in the same way. However, that is not true: Different children learn differently, taking distinctive pathways to learn how to read words. This is true even for children learning one language, such as English, and it is even more pervasively true when all the many human languages are considered. Children learning Mandarin have to master four tunes or melodies that mark each word, and they have to learn Chinese characters that do not represent the sounds of the words. Their tasks are vastly different from reading Spanish or Rumanian or even English. For example, Knight and Fischer (1992) found three different pathways to reading that were hidden in the variability of early readers. As shown in Figure 4.7, different readers actually followed *distinct* pathways for reading. Many readers showed one pathway (A), but others showed the two alternative pathways (B and C). The first pathway occurred among readers who were readily able to integrate sight, sound, and meaning when learning to read. The other pathways occurred in children who had difficulty integrating sight, sound, and meaning. The second pathway was marked by

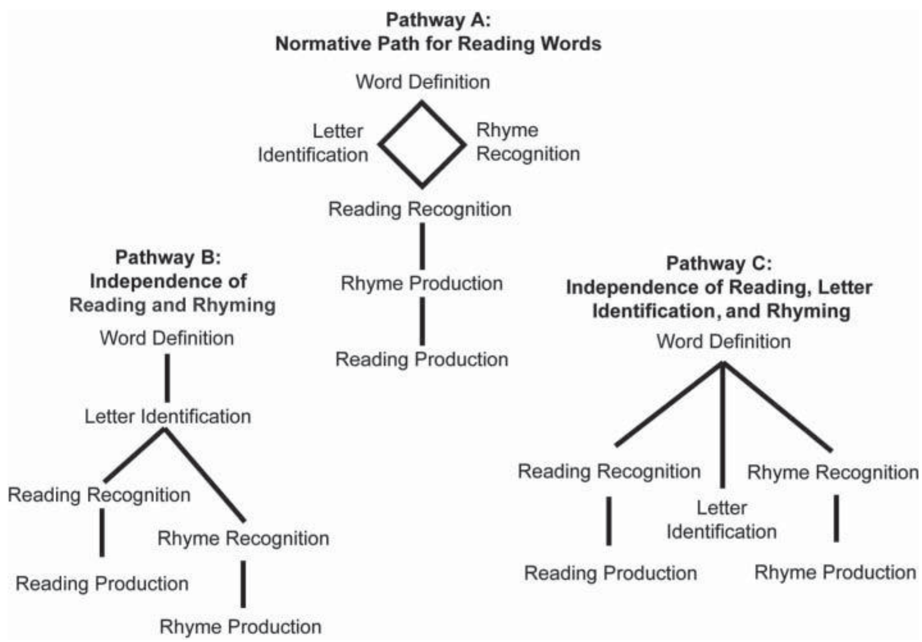

Figure 4.7 Pathways in the development of word reading.

Source: From "Dynamic Development of Action and Thought" (pp. 313–399), by K. W. Fischer and T. R. Bidell, in *Theoretical Models of Human Development*, R. M. Lerner (Ed.), Volume 1 of the *Handbook of Child Psychology*, 6th ed., W. Damon and R. M. Lerner (Editors-in-Chief), 2006, Hoboken, NJ: Wiley.

an independence of visual (e.g., word identification and reading production) and auditory (rhyme recognition and rhyme production) aspects of reading. The third pathway involved even further independence in the development of the subskills of reading. For this group, letter identification developed independent from word recognition and reading production, which developed independent from rhyme recognition and production. Most children in the second and third groups learned to read; however, they followed a different path from the "normal" one (Fink, 2007; Fink & Samuels, 2007).

In another series of studies we found strong evidence that different kinds of readers show distinct organization of their visual field. It turns out that astronomers can benefit from having a different organization of their visual field, which is distinct from the normative pattern that eye specialists describe: Instead of having a rapid drop-off in the sensitivity of the visual field moving away from the fovea (central visual area) and toward the periphery, some astronomers demonstrate instead a heightened sensitivity in their periphery. They benefit from this sensitivity, as evidenced by greater success at identifying patterns across wide areas of the visual field, such as the complex patterns that are shown by black holes. Astronomers with dyslexia were more successful at identifying black holes from patterns of waves (Schneps, Rose, & Fischer, 2007).

An implication of these findings is that people develop along alternative pathways, and teachers can help different kinds of readers learn in ways that embody the most effective remedial educational strategy for them. That is, instead of attempting to speed up "normal" development in ineffective readers, teachers can seek ways of helping to channel children along pathways that work well for them to converge on the goal of skilled reading (Fink, 2006; Wolf & Katzir-Cohen, 2001). By trying different methods of teaching reading, teachers can channel development, providing environmental support to build bridges to effective reading. Children with difficulty reading can experiment to find ways of learning to read and write skillfully for them. Fink (2007) found that many dyslexic adults had found their way to becoming skill readers and writers despite their dyslexia. This approach is being realized in educational efforts for many dyslexic children (Fischer et al., 2007; Rose & Meyer, 2002) and also in work with maltreated and aggressive children (Ayoub & Fischer, 2006; Kupersmidt & Dodge, 2004; Watson, Fischer, Andreas, & Smith, 2004).

FORGING A PATH BY WALKING

It is important to note that the pathways embedded within a developmental web are neither preformed nor predetermined. Instead, developmental pathways, like the development of psychological structures themselves, are emergent products of coactions that occur among component parts of the person ←→ environment system over time. The developmental web is itself a product of constructive process. Thus, instead of thinking of developmental trajectories as already existing pathways that preexist the developmental process, it is better to think of the process of development as akin to the process of *making a path through walking* (Thompson, 2007).

The developmental web provides a framework for understanding the development of differing socioeconomic groups, cultures, ethnicities, or races, and children with learning or psychological problems. Against the backdrop of a developmental ladder based on European American, middle-class norms, children from different social groups are frequently seen as exhibiting deficits in development. Within the web metaphor, many developmental differences become alternative pathways instead of deficits; and curricula, interventions, or therapies can be created based on these alternative pathways. Research methods should allow detection of alternative sequences instead of forcing all children to either fit or not fit one sequence. Remarkably, much research on development has treated sequences not as variable phenomena to be explained but as fixed milestones in a ladder. In the early 1970s, Flavell (1971) and Wohlwill (1973) called for more research on variation in sequences, but only recently has this call been taken seriously. Most neo-Piagetian analyses ignore evidence for variation and branching and overgeneralize the uniformity of cognitive and emotional development. Given the pervasive evidence of cognitive variability, why do the most prominent models of psychological structure continue to be static conceptions such as stage, competence, and biologically determined core knowledge? It is time to rebuild the study of learning and development based on dynamic systems.

DEVELOPMENT IN INFANCY: CHANGES IN SKILLS FOR RELATING TO PERSONS AND THINGS

Infant development from the reflex tier through the sensorimotor action tier demonstrates all the hallmarks of dynamic development discussed earlier including dramatic developmental transformations over time; the dynamic coconstruction of sensorimotor skills within intersubjectively mediated social interaction; development along diverse pathways; and dynamic variations in the form of sensorimotor action as a function of context. In this section, we examine structural changes in the development of sensorimotor skills through an analysis of the pathways over the course of infancy. Thereafter, we extend our discussion of development in infancy to an analysis of claims made about the capacities of young infants to understand objects and people.

THE DEVELOPMENT OF REACHING IN INFANCY

Analysis of the development of how infants reach-to-eat provides a rich illustration of structural change in skills through the reflex and sensorimotor action tiers of development (see Figure 4.2). In this section, we track developmental changes in reaching in infancy using the common skill scale, with particular attention to the development of the everyday skill of *reaching to eat*.

FROM NEONATAL PREREACHING TO SELF-DIRECTED REACHING

The development of reaching has its early origins in the *prereaching* acts of neonates (Rader & Stern, 1982; von Hofsten & Ronnqvist, 1993). From birth, when a seen object is placed within reach, infants attempt with effort to extend their arms toward the object. Prereaching is highly dependent on the relation between the infant's posture and social context. The infant's body must be supported and oriented toward a seen object that is placed within the infant's reach. Movements of the two arms are generally undifferentiated, leading to bimanual rather than unimanual arm extension. As the arms extend, the hands—which normally assume a fisted position—fan out reflexively. Acts of prereaching are typically jerky, uncoordinated, and inaccurate. When an arm does reach its target, neonates do not spontaneously grasp the touched object. For a neonate to grasp an object, it must be placed directly in the hand. Over the first 2 months of life, the rate of neonatal prereaching declines (Rader & Stern, 1982). During this time, when infants extend their arms, their hands remain fisted rather than flexed. The breakdown of the extension-flexion reflex begins to give way to more differentiated forms of reaching.

Table 4.2 depicts alternative trajectories in the development of prereaching and reaching over the course of infancy. In their analysis of infant reaching, Foroud and

TABLE 4.2 Developmental Changes From Prereaching to Reaching

Form of Reaching	Description	Structure of Reach
5. Self-Directed Reaching. Single sensorimotor acts (Rf4/Sm1, 3.5–4 months)	Reflex systems are coordinated into a single, self-directed sensorimotor act of reaching. Object must be within reach and placed in front of child. Accuracy improves substantially.	4. Differentiated Head/Mouth and Whole Body Directed Prereaching. Reflex systems (Rf3, 10–11 weeks)	Child directs either (a) multiple bodily movements or (b) more differentiated whole body movements toward object. Accuracy increases, but remains poor.	3. Head/Mouth and Whole Body Directed Prereaching. Reflex systems (Rf2, 7–8 weeks)	Child directs either (a) head and mouth or (b) whole body toward seen object. Accuracy is poor.	2. Diffuse Prereaching. Single reflexes (Rf1, 2–3 weeks)	Extension-flexion reflex dissipates. Single elements of action directed toward object. Hands fisted rather than flexed. Movements remain jerky. Accuracy is poor.	1. Neonatal Prereaching.	With object placed in front of neonate, both arms extend jerkily toward object as fingers fan out. Accuracy is poor.	

Note. Arrows in right column indicate patterns of differentiation and integration in development over time.

Whishaw (2012) identified three early levels of prereaching. The first, *diffuse prereaching*, was observed between the first and third month of life. This form of prereaching operates at the level of *single reflexes*. Diffuse prereaching involves the activation of fragmented and incomplete movements of the hands, limbs, head, and mouth in the direction of a seen target (a toy or piece of food). These motor movements are typically uncoordinated, stopping and starting at different times, and fail to reach their targets. For example, presented with an object while sitting in an inclined position, one infant alternatively shifted her eyes toward the target; opened and closed her hands; extended her torso; and made circular movements with her hands.

The second form of prereaching involves *head and mouth directed prereaching*. Step Rf2 in Table 4.2 depicts the structure of this skill at the level of reflex mappings (i.e., coordinations of two single reflexes). For example, one infant moved her head and mouth in the direction of a wanted object placed in front of her. A more developed form of head/mouth prereaching occurs at the level of reflex systems (Table 4.2/Step Rf3). (Reflex systems are integrations of two reflex mappings.) For example, another infant, looking at the wanted object, puckered her mouth, and moved her hands in a circular fashion toward the object. Failing to reach it, she clasped her hands together and brought them to her mouth—as if she were actually bringing the object to her mouth! A third form of prereaching involves *whole body prereaching*. In this version of prereaching, an infant directs her entire body toward the object as a single unit (Table 4.2/Rf3). These observations indicate that prereaching shows a variety of dynamically shifting forms as it develops in very young infants.

Table 4.3 shows changes in the structure of action within the sensorimotor tier of development. With the development of single sensorimotor actions (Table 4.3/Sm1), an infant is capable of executing single fully coordinated actions such as *reaching for a seen object*, *grasping a touched object*, or *bringing an object to the mouth*. Although 4-month-olds are capable of performing single actions, it is not until 7 or 8 months of age that infants are able to coordinate two sensorimotor actions into a *sensorimotor mapping* (Table 4.3/Step Sm2). At this level, reaching becomes more coordinated. By integrating two sensorimotor actions, an infant can adjust her reach around an obstacle in order to reach for and grasp an object. Alternatively, from the outset of a situation, an infant

TABLE 4.3 Developmental Transformations in Adaptive Reaching

Form of Reaching	Description	Structure of Reach
5. Fully Integrated Reach-to-Eat. Sensorimotor systems (12–13 months)	Infant is able coordinate both gross (e.g., extend/withdraw arm) and fine motor movements (e.g., pincer movement) within a three-dimensional space. Child fully able to pronate (i.e., rotate wrists in anticipation of grasping) and supinate (e.g, rotate hands) with movement relative to targets.	LIFT FOOD / REACH / SUPINATE ⟷ PRONATE / GRASP / WITHDRAW
4. Transition to Seamless Reach-to-Eat. Compounded sensorimotor mappings (Sm3, 9–10 months)	Reach-to-eat becomes more differentiated (infant initiates reach by flexing elbow rather than shoulder) and integrated (arm initiation immediately coordinated with wrist rotation in anticipation of object).	REACH FOOD — GRASP FOOD; WITHDRAW TO MOUTH
3. Intercoordinated Reaching and Grasping. Sensorimotor mappings (Sm2, 7–8 months)	Infant is able to coordinate fully differentiated reaching and grasping actions. Reaching and grasping are fully intercoordinated and adjust to each other.	REACH OBJECT — GRASP OBJECT
2. Undifferentiated Reach-to-Eat. Complex sensorimotor actions (4 months +)	Infant is able to reach, grasp food from mother's hand, and transport it to the mouth. Movements are undifferentiated both within (e.g., child uses whole hand rather than pincer) and between (grasping food is part of sliding action) actions.	REACH FOOD ~ PRE-ADJUST GRASP ~ GRASP (diffuse); SLIDE FOOD TO FACE ~ "MOUTH" FOOD
1. Self-Directed Reaching. (Single sensorimotor acts, 3.5–4 months)	Infant is able to control single actions (reaching, grasping, transporting) at a single time; objects must be within child's sight and reach.	REACH TOY or GRASP TOY (diffuse) or MOVE TOY TO MOUTH

can coordinate previously separate acts of reaching and looking in order to *reach for an object in order to look at it,* or *look at an object in order to reach for it*. By 12 to 13 months, using *sensorimotor system,* infants are capable of seamlessly coordinating multiple actions in elaborated acts of exploring and manipulating objects (Table 4.3/Sm3).

THE DEVELOPMENT OF REACHING TO EAT

In addition to these broad transformations, there are also a series of subtle changes in reaching and grasping during this time. Sacrey, Karl, and Whishaw (2012) analyzed the structure of *reach-to-eat* (reach-grasp-eat) movements both in adults and in developing infants between the ages of 6 to 12 months. Table 4.3 identifies developmental changes in the structure of the infant's reaching and reach-to-eat skills between the ages of 6 and 12 months of age. At 6 months, infants exhibit a set of uncoordinated reach-to-eat actions. Unlike adults, 6-month-olds initiate reaching by flexing the shoulder rather than the elbow. Although they open their digits as they extend their arms, they fail to position the fingers over the food (pronation) or to rotate their wrist to orient to the food (supination). To grasp, infants open the entire hand and close it around the food. Instead of lifting their wrists, infants tend to slide the food from the hand of the caregiver. Bringing the food to the mouth, the infant mouths it in order to eat it (Table 4.3/Sm1+).

The 9-month-old's reach-to-eat skill shows marked advance. Similar to the adult, the infant begins the reach by flexing the elbow. The primary advance involves coordinating the movement of the arm with initial skill in rotating the wrist toward the seen target. Accuracy increases, as infants are able to correct diverging paths of movement in relation to the object (Table 4.3/Sm2+). By 12 months, the child's reach-to-eat skill approximates that of the adult. Operating at the level of sensorimotor systems, an infant can coordinate both gross (e.g., extending/withdrawing arms) and fine motor movements (e.g., the pincer) within a three-dimensional space (e.g., rotating wrists toward/away from the food/mouth in approach/withdrawal phases).

DYNAMIC VARIATION IN THE DEVELOPMENT OF REACHING

Like most actions, the structure of reaching varies as a function of object, posture, context, the individual child, and other important variables (Clearfield, Feng, & Thelen, 2007; Lobo & Galloway, 2008; Schöner & Dineva, 2007). For example, research has demonstrated that the structure of anticipatory grasping of objects changes over infancy. Before 4 months of age, infants accommodate their hands around an object placed in the hands, but show minimal preadjustment to objects prior to physical contact. At 5 months, infants differentially adjust their grasping movements prior to physical contact in response to visually salient features of objects (Barrett, Traupman, & Needham, 2008). Between 5 and 12 months, infants become more adept at adjusting their grasp to the physical orientation of objects. Infants preadjust their grasp to horizontally presented objects beginning around 5 months; to vertically presented objects at 7 months (Witherington, 2005); and to diagonally presented objects by 11 to 12 months (Wentworth, Benson, & Haith, 2000). Further, infant reaching is highly sensitive to postural constraints. Among infants under 5 months of age, the quality of reaching is diminished when infants assume a supine (0°) rather than seated (70°) or reclined (45°) position (Carvalho, Tudella, & Savelsbergh, 2007)

Research has demonstrated that the developmental course of reaching varies in different children. Thelen and her colleagues have identified diverse, richly textured trajectories in reaching behavior in individual children (Corbetta & Thelen, 1996; Corbetta, Thelen, & Johnson, 2000; Spencer, Vereijken, Diedrich, & Thelen, 2000). As a group, infants tend to shift from bimanual reaching to unimanual reaching beginning around 4 months, and briefly return to bimanual reaching around the time that they begin to walk (Corbetta & Bojczyk, 2002). Corbetta, Thelen, and Johnson (2000) examined how infants between 5 and 9 months of age adjust their reaches (unimanual versus bimanual) as a function of variation in object size. They identified three groups of infants: One group consistently matched the form of their reach to the size of the ball, shifting from bimanual reaches with larger balls to unimanual reaches with smaller ones. A second group was inconsistent in their matching, and a third never altered their reaching.

THE POWER AND LIMITS OF SENSORIMOTOR ACTION: WHAT DO INFANTS “KNOW” ABOUT OBJECTS AND PERSONS?

In the past decades, research has documented the capacity of infants to construct knowledge in a variety of social and nonsocial areas. The literature assessing infant cognition is enormous. Researchers have studied infant understanding of number (de Hevia & Spelke, 2010), objects (Baillargeon et al., 2012), space (Keil, 2008), concepts and categories (Oakes, Horst, Kovack-Lesh, & Perone, 2009), causality (Newman, Choi, Wynn, & Scholl, 2008), language (Gervain & Mehler, 2010), imagery (Moore & Johnson, 2011) and other minds (Meltzoff, 2011; Wellman, 2011). Some infancy researchers have proposed that infants are equipped with domain-specific innate (i.e., strictly biologically determined) knowledge, which allows them to reason about objects and people from early in infancy. For example, Carey and Spelke (2008) suggest that “human reasoning is guided by a collection of innate domain-specific systems of knowledge. Each system is characterized by a set of core principles that define the entities covered by the domain and support reasoning about those entities” (p. 169). In the case of number, Carey and Spelke suggest that such strictly biologically determined knowledge includes “core principles of one-to-one correspondence and succession (every number has a unique successor)” (p. 176). Similarly, in the domain of knowing about persons, Wynn (2008) states,

> I propose three innately given components of understanding as our entree to understanding the social world: First: . . . Infants reason about inanimate objects in terms of naive physics, while they reason about social beings in terms of mental attributes such as goals, desires, and attitudes . . . . Second: The goals, desires, and attitudes that young infants ascribe to social beings, and via which they interpret their behavior, are inherently mentalistic attributions . . . . Third: Infants are not interpreting interactions among agents and assigning attitudes dispassionately, but are judging these social interactions. The actions of one intentional being toward another are viewed in valenced terms, as “good” or “bad,” from early infancy. (p. 303)

These are bold claims and, in employing the term *innate*, in its sense of being strictly biologically determined, rather than its correct meaning of “present at birth,” (see Bateson, Chapter 6, this *Handbook*, this volume; Overton, Chapter 2, this *Handbook*, this volume) they totally ignore the *probabilistic epigenetic* development that occurs prenatally (Gottlieb, Wahlsten, & Lickliter, 2006; Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume). Nevertheless the claims have found a receptive audience because they have led to robust findings from a large and growing number of cleverly designed and well-controlled experimental studies. We examine but two examples of these studies. Izard, Sann, Spelke, and Streri (2009) familiarized newborn infants with auditory sequences containing different numbers of syllables (e.g., “ra-ra-ra-ra” or “ra-ra-ra-ra-ra-ra-ra-ra-ra-ra-ra-ra”). After familiarization, as the auditory presentation of the syllables continued in the background, infants were presented visually with four different stimulus displays containing either a congruent (the same number of shapes as syllables) or incongruent (a different number of shapes from syllables) number of shapes. To determine whether infants could differentiate number across different kinds of stimulus characteristics, each of the four test arrays was composed of a different type of geometric shape with a different fixed color. Three ratios of congruent to incongruent shapes were used: 4:8, 4:12, 6:18, with large and small numbered arrays presented equally in congruent and incongruent conditions. Results indicated that newborn infants looked longer at stimulus displays in which the number of objects was congruent rather than incongruent with the number of auditorally presented syllables. The researchers interpreted these findings to indicate that newborns are capable of perceiving abstract number.

In a study on social knowledge, Luo and Baillargeon (2010) reported a series of studies suggesting that young infants are capable of reasoning about psychological states. Six-month-old infants were habituated to trials in which a female agent sat between two objects (A and B) and consistently reached for A. Both objects were always visible to the infants. In the hidden-object condition, only A was visible to the agent; a screen occluded B from the view of the agent. In a sighted object condition, B was only partially occluded from the agent's view. After eight familiarization trials of the agent reaching for A, the positions of the objects were reversed and the screen was removed. At this point, the agent reached for either A (old object event) or B (new object event). In the sighted object condition (in which the agent could see both A and B before the test phase), infants looked longer at the new object event, suggesting that they expected the agent to exhibit her earlier established preference to reach for A. However, in the hidden object condition (where the agent could not see B prior to the test), looking time was equal for both the new event and the old event, suggesting that, faced with an entirely new choice, the agent would have no preference for A or B. From these data, the researchers concluded that the infants "realized" that the agent's repeated actions on Object-A during the familiarization trials could not be interpreted as revealing a preference for Object-A over Object-B if she could not see Object-B.

These are remarkable findings. The interpretation of these findings, however, has proven highly controversial (Mix, Huttenlocher, & Levine, 2002; Oakes, 2010). Some developmental scientists caution against making claims about complex mental processes based on habituation procedures that require minimal responsiveness on the part of infants (Bremner, 2000; Kagan, 2008). Others note that the phenomenon of habituation remains poorly understood (Schöner & Thelen, 2006). Still others underscore the continued need to ensure a high level of control over nontarget variables when using habituation (Cohen, 2002). Against this backdrop, we nonetheless take these data to indicate something meaningful about infant development. However, we also raise issues regarding their interpretation. Some approaches to infancy research seem to proceed under the assumption that infants are fundamentally little adults. Operating under this assumption, research is designed with the goal of identifying the earliest moment in development at which infants can perform adult-like tasks. Evidence of successful performance at very young ages is then interpreted as indicating that infants possess core, adult-like abilities. However, advocates of such positions often do not consider (a) the rich, structuring role that perceptual input plays in mediating infant abilities; (b) how presumed infant abilities undergo developmental change; and (c) alternative interpretations that do not require invoking complex psychological processes.

Carey (2009) has suggested that infants are born with innate (i.e., strictly biologically determined) systems for representing number, including an "object file" system for discriminating among small numbers of objects (e.g., one, two, and three objects), and an analogical system for representing larger numbers of objects. The distinction between these two systems comes from research suggesting that although infants can make fine distinctions between one-, two-, and three-item displays, their capacity to make distinctions between stimulus displays containing larger numbers of objects is less refined. By 6 months of age, infants can discriminate stimulus displays that differ by a 2:1 ratio (e.g., infants can differentiate 8-dot displays from 16-dot displays). Over time, infants become capable of discriminating stimulus displays containing increasingly more refined ratios. By 9 months of age, infants can discriminate 3:2 comparisons. However, it is not clear why there is a need to invoke biologically determined knowledge to explain these results. One might suggest that working memory capacity provides a more parsimonious explanation for small set discrimination. Zosh, Halberda, and Feigenson (2011) have shown that infants (like adults) are able to represent two or three subsets of information in perceptual working memory at any given time. If this is so, perceptual changes in stimulus displays involving small numbers of items are likely to be highly salient to infants and adults. As the number of items in a stimulus display increases beyond an infant's working memory, the ability to make fine distinctions among stimulus displays would diminish. At this point, however, the infant would still be able to make comparisons among stimulus displays containing a small number of phenomenally distinguishable groupings of larger numbers of items.

Thus, the most parsimonious explanation of the infant's capacity to discriminate among these diversely numerated stimulus displays is that infants are comparing perceptually salient groupings of object ensembles. Performance is constrained by the *phenomenal aspects of perception* with a minimum of surplus activity. Although it is reasonable to refer to such discriminations as *analog* (Carey, 2009), it is highly unlikely that "innate" knowledge is necessary to explain the data. Similar interpretations apply to other examples of seeming complex cognitive manipulations in infancy. McCrink and Wynn (2004) reported a study in which 9-month-olds were shown five objects that move behind a screen, followed by another five objects. When the screen was removed, infants looked longer if they saw 5 objects than if they say 10, suggesting that the infants expected to see the larger rather than smaller group. Again, the most parsimonious explanation of these data is that infants are able to hold in mind the phenomenal aspects of larger and smaller arrays of objects in highly structured perceptually based tasks that require little indicative activity on the part of the infant. The data do not suggest that infants can add, subtract, or manipulate representations of objects independent of perceptually salient events.

Interpretation of the results of infant performance on the social tasks described above raises similar issues. In the Luo and Baillargeon (2010) study concerning reasoning about psychological states, in the sighted object condition (in which an agent consistently chose Object A over Object B before the test phase), during the test phase infants looked longer when the agent reached for B over A, suggesting that infants expected the agent to reach for Object A. However, in the hidden object condition (where the agent reached for A but could not see B prior to the test phase), looking time was equal in the test phase regardless of whether the agent reached for Object A or B, suggesting that infants had no expectations of where the adult would reach. However, Luo and Baillargeon (2010) argue that these data indicate that the infant is capable of *reasoning* about the internal *mental* states of the agent—in particular, that "infants recognize that an agent's representation of a scene may be incomplete relative to their own" (p. 304). Adopting Luo and Baillargeon's (2010) interpretation would unnecessarily support the idea that preverbal infants are able to form representations of the behavior of others as the product of intentions, beliefs, and desires; all understood as internal mentalistic states. And this interpretation would suggest that if young infants are able to form internal mentalistic representation, then the foundation for social knowledge and reasoning must be strictly biologically determined.

From the standpoint of an embodied, coactive model of psychological development, an infant's sense of the intentionality of another person's action does not proceed as an act of mind-reading (i.e., one mind attempting to penetrate the hidden contents of another). Rather than mind-reading, an infant's sense of the intentionality of other's actions arises in embodied coactions with others within richly textured social worlds. As Gallagher (2008) points out,

> We do not ordinarily need to go further than what is already the rich and complex comprehension that we gain through the perception of a situated agent—that is, of an agent who is situated in an environment which also tells us something about what that person is doing and thinking. (p. 168)

Thus, in social encounters, infants and adults alike do not need to make inferences about the contents of another person's mind. Instead, goals, intentions, emotions, and perception of events can be perceived directly from the other's actions and how those actions are deployed in the physical and social world. From this view, to understand how infants perform tasks that seem to call for complex social reasoning, one must identify the full range of the infant's embodied perceptual experience within a given social encounter. Thus, for example, in the study by Luo and Baillargeon (2010) just discussed, information about the adult's goals and perceptions is directly available in the infant's perceptual experience of the adult's actions. The infant does not have to infer something that is *hidden in the mind* of the adult; the infant perceives the adult's intention in the adult's repeated act of reaching itself. The infant does not have to construct an image of what the adult is seeing *within the adult's private experience*; the infant sees directly what the adult sees.

Luo and Baillargeon (2010) also argue that their results suggest that the infants were able to recognize that the adult had an "incomplete representation" (p. 303) of the stimulus situation. However, there is a difference between saying that infants know *what is in the mind of the other* (can reason about the mental states of others) and saying that infants are able to construct a sense of what an adult can or cannot *see* in the context of direct perceptual experience. From an embodied systems perspective, the infant does not have to have an understanding of the *mental states* of the adult; the infant only needs to discriminate how the adult's intentions-in-action in the test phase are predicated on whether or not she was able to *see* one object or both objects in the familiarization phase. In this way, the infant need not adopt the *internal perspective* of the adult; the infant only has to view the task from her *physical position*. Although such a capacity might seem like a complex accomplishment, research suggests that mirror resonance processes may operate as part of the neuronal processes that mediate social perception. In social coactions with others, subpersonal mirror neurons may be activated when one individual sees another person performing an intentional action (Molenberghs, Cunnington, & Mattingley, 2012). Research suggests that the mirror resonance system may distributed throughout many places in the brain, including the motor cortex, Broca's area, and the parietal cortex, the primary visual cortex, cerebellum, and areas within the limbic system (Catmur, Mars, Rushworth, & Heyes, 2011; Molenberghs et al., 2012). The activation of the mirror resonance system may function as the neurological substrata that mediates the immediate but nonarticulated perception of the other person's intentional actions (Gallagher, 2008). In this way, in perceptually and emotionally rich social encounters, the intentional states of the other may become immediately available to the infant, even in the absence of a *theory of mind* or skills for simulating the experiences of others.

Research on early infant abilities holds out the promise of transforming our understanding of the foundations of psychological development. However, to fulfill this promise, there is a need to examine how such capacities emerge and function within the larger coactive person ←→ environment system (Mascolo, 2013). The sensorimotor-affective world of the infant is richly structured and deeply informative (Ray & Heyes, 2011). Cognitive processes that operate in infancy are constrained and informed by intermodally organized *perceptual* processes that operate within sensorimotor action in the world (Bremner, 2000; Vaillant-Molina & Bahrick, 2012). Such perceptually based meanings stand in contrast to the genuinely *symbolic* representations that toddlers and older children construct in the absence of direct experience (Johnson, Younger, & Furrer, 2005; Namy, 2009). To appreciate how the phenomenal world of the infant differs from that of toddlers and young children, it is necessary to assess *developmental changes* in structure of meaning over time (Campos et al., 2008) and to identify the ways in which *specific physical and social contexts* contribute to the organization of those structures (Campbell & Namy, 2003). It also requires that theorists and researchers avoid the temptation to study infant cognitive processes in isolation. As Oakes (2009) points out,

> [T]o understand the nature of infant cognitive skills, it is necessary to understand how . . . the field has focused on dissecting cognitive abilities in infancy; our task now is to put those abilities back together again so that we can understand how they work together in development. (p. 352)

Thus, without considering how early cognitive skills operate as parts of a larger person ←→ environment system, we risk misrepresenting the nature of infant abilities.

PATHWAYS IN THE DEVELOPMENT OF PSYCHOLOGICAL STRUCTURES FROM CHILDHOOD THROUGH ADULTHOOD: THE CASE OF EVERYDAY MORAL ACTION

In the following, we examine development that occurs beyond infancy in the representational and abstract tiers of development (see Figure 4.2). In examining these later emerging tiers, we explore the development of integrative structures of sociomoral action from early infancy through the life span. The study of moral development has undergone profound changes. The field has shifted from moral reasoning (Kohlberg, 1981; Lapsely, 2006) as a primary concern toward articulation of the role of emotion, social context, and culture in moral judgment, action, and identity (Turiel, Chapter 13, this *Handbook*, this volume). Researchers have suggested morality has its origins in prelinguistic evaluative judgments in infancy (Hamlin, Wynn, & Bloom, 2007) in empathy and sociomoral emotions emerging during the second year of life (Mascolo & Fischer, 2007; Roth-Hanania, Davidov, & Zahn-Waxler, 2011); and in the socialization of conscience and self-regulation in early childhood (Kochanska, Koenig, Barry, Kim, & Yoon, 2010; Thompson & Newton, 2010). Scholars and educators have called for a renewed emphasis on the development of moral character (Damon, 2011; Lapsley & Yeager, 2013). Thus, the study of moral development has ushered in a renewed emphasis on character and conscience that is reminiscent of the work of Hartshorne and May (1928–1930).

These are important advances. We note three central issues related to the study of moral development (see also Nucci & Gringo, 2011). First, in abandoning broad-based stage models of moral reasoning, many investigators have abandoned the goal of analyzing *structural transformations* in the development of moral activity (Gibbs, Moshman, Berkowitz, Basinger, & Grime, 2009). For example, although hundreds of important studies examine individual differences in temperament, socialization practices, and moral/prosocial behavior, only broad classes of aggregated behavior—often abstract across contexts—are assessed (Eisenberg, 2000; Grusec, 2006; Kochanska & Aksan, 2006). Changes in the *form* of moral and prosocial behavior have been neglected. Second, although investigators have acknowledged the multiplicity of moral orientations (e.g., justice, care, duty), the orientations are sometimes treated as if they were separate and distinct domains (Juujärvi, 2006). However, evidence suggests that although different moral concerns (e.g., rights, care, virtue) are partially distinct, they tend to overlap and codevelop over time (Walker, 2006; see also Rose, Rouhani, & Fischer, 2013). Finally, in rejecting the primacy of moral reasoning in the study of moral development, there has been a proliferation of studies on the role of automatic moral judgment, emotion, conscience, and socialization in the production of moral and prosocial behavior. With exceptions (e.g., Turiel, 2002, 2010, Chapter 13, this *Handbook*, this volume), theory and research in these areas proceeds largely in isolation from each other. There is a need to develop ways to understand how moral cognition, emotion, and action develop in relation to each other within individuals and particular sociocultural contexts.

Instead of privileging any single aspect of moral functioning, we suggest that there is a need to understand moral development as the study of changes in integrative patterns of moral cognition, emotion, and action as they arise within individuals in particular sociocultural contexts. In what follows, drawing on dynamic skill theory, we illustrate ways to track developmental changes in (a) the *integrative structure* (cognition-affect-action) of moral activity; (b) in *everyday* rather than interview contexts (c) with regard to *contextualized* rather than abstract moral issues. In so doing, we illustrate how moral functioning undergoes transformation as children construct increasingly differentiated and integrated structures of moral thinking, feeling, and acting. This approach offers the promise of bringing together theory and research from structural-developmental, socialization, and sociocultural approaches to moral development.

FROM AFFECT TO IDENTITY: PATHS IN THE DEVELOPMENT OF STRUCTURES OF MORAL ACTION

A moral action is one that is mediated by standards that specify conditions that *ought* to (or ought not) exist. In invoking this definition, we adopt a broad view in which the realm of everyday morality incorporates what Taylor (1989) calls *strong evaluation*. This encompasses not only judgments of *right or wrong* but also judgments of *care for others, worth, virtue,* and *goodness* (Blasi, 1990; Sabini & Silver, 1982; Taylor, 1989). Emotion plays a central role in the organization of moral behavior; however, moral emotions (guilt, shame, jealousy, etc.) are moral because they are mediated by some sort of evaluative standards, however implicit (Blasi, 1999). As suggested in Figure 4.1 (Point 1) and as articulated in our relational perspective, there is no reason to privilege affect over cognition, automatic over controlled processes, or nonconscious over conscious processes (Haidt, 2001; Hassin, Uleman, & Bargh, 2005; Mlodinow, 2012) in the construction of action, moral or otherwise. From the relational perspective, debates about the primacy of fast-acting affective judgments versus deliberative reasoning in moral development are fruitless. Instead, there is a need to understand how diverse psychological processes work together in the construction of moral action (Decety, Michalska, & Kinzler, 2012).

Figure 4.8 presents a developmental web identifying trajectories in the construction of integrative structures of moral action from preschool through adolescence. The web charts developmental changes within three domains of moral actions: *autonomy/rights*, *virtue/character*, and *harm/care*.

- *Autonomy/rights* domain. This reflects the predominant Western concern with the primacy of individual freedom. Development in this domain moves initial concerns about individual interests in principles of individual rights, respect, fairness, and reciprocity (Shweder, Much, Mahapatra, & Park, 1997).
- The *virtue/character* domain. This is organized around attempts to live up to particular values and virtuous ways of being in the world (Blasi, 2005). Development in this domain moves from the socialization of committed compliance (Kochanska & Aksan, 2006) to the development of virtue, moral character and identity, and a commitment to moral purpose (Carr, 2006; Damon, 2011; Frimer & Walker, 2009). Actions organized with

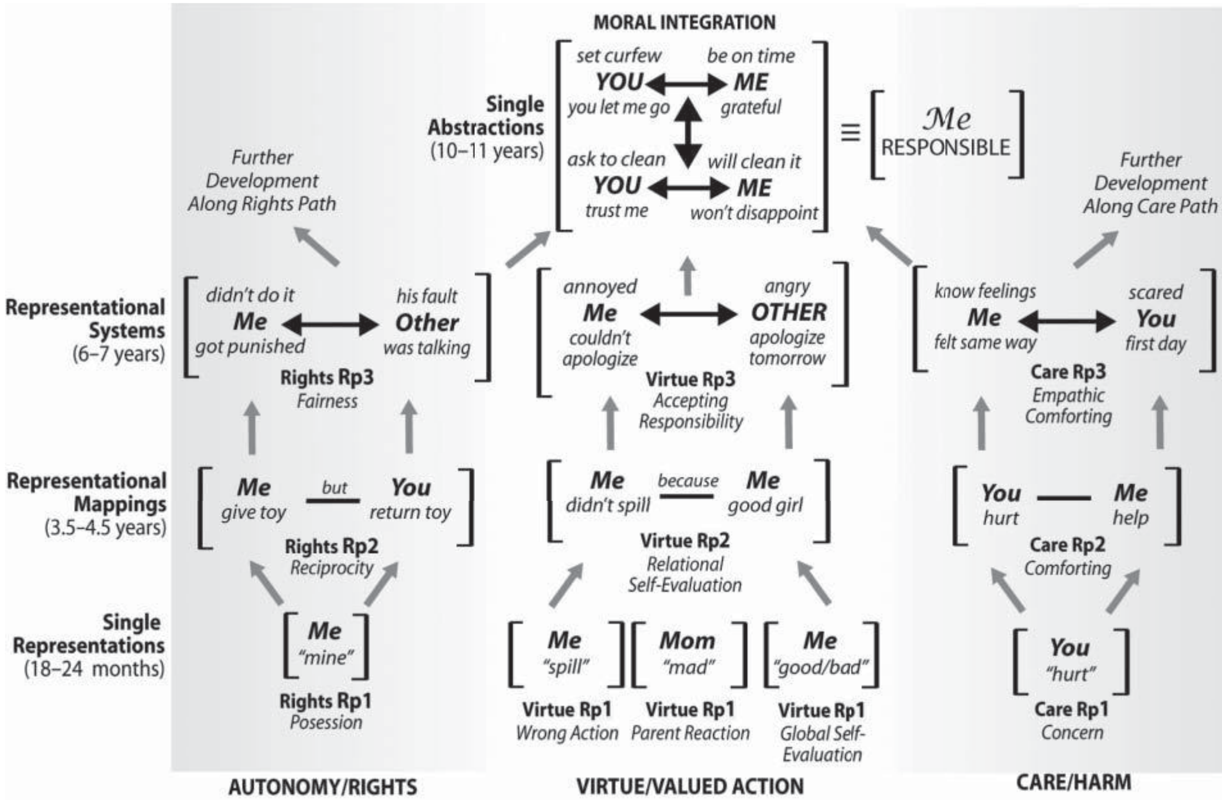

Figure 4.8 Trajectories of moral action: Autonomy, virtue, and care.

respect to concerns about *harm/care* domain. Development in this domain has its early origins in sympathy and empathy toward others (Svetlova, Nichols, & Brownell, 2010) and moves toward the higher-order principles of care and compassion (Ottoni Wilhelm & Bekkers, 2010).

The developmental web presented in Figure 4.8 indicates multiple starting points, pathways, and endpoints in the development of integrative structures of moral action. The actual paths through which moral skills develop differ both within and between individuals. Depending on differences in temperament, parenting, and other circumstances, the developmental course of children's moral skills may be biased along divergent autonomy-, virtue-, or care-based pathways. Within persons, individuals vary according to the mode and developmental complexity of their moral actions depending on the nature of the problem at hand (Walker, 2006), emotion (Fischer, Shaver, & Carnochan, 1990), the presence of others (Thornberg, 2007), and other variables. Thus, individuals who, at one moment, act on a principle of care for someone in distress can, at another, invoke an autonomy orientation to defend a threat to property.

AUTONOMY, RIGHTS, AND THE ETHOS OF FAIRNESS: FROM INDIVIDUAL INTEREST TO INDIVIDUAL RIGHTS

The left pathway of Figure 4.8 describes the emergence and development of moral action mediated by standards of moral autonomy, fairness, and rights. As indicated in Step Rp1 of the RIGHTS pathway, 18- to 24-month-olds use single representations to defend their property (e.g., "mine!"). Around this age, children begin to offer simple spontaneous and solicited apologies (i.e., "sorry") to their siblings, although they are more likely to do so when requested by a parent (Schleien, Ross, & Ross, 2010).

By 3 years of age, children are able to identify and intervene in transgressions against third parties (Vaish, Carpenter, & Tomasello, 2010). The toddler's emerging moral sense is a double-edged sword: Using single representations, they also begin to lie about wrongdoings.

In a study in which preschoolers were asked not to peek at a toy while the experimenter was not looking, 25% of 2- and 3-year-olds lied about peeking at the toy when asked (Evans & Lee, 2013).

Beginning around 3½ to 4½ years of age, children's moral sense undergoes transformation as they gain the capacity to form *representational mappings*. At this level, children begin to develop a rudimentary sense of fairness and reciprocity. For example, at this level, children begin to demonstrate an awareness of simple reciprocity norms. For example, as indicated in Step Rp2 (Figure 4.8), one 4-year-old girl, when asked to share her toy horse, responded, "Here he is. But I want him back soon" (Markström & Halldén, 2009, p. 119). At this level, children are able to invoke a range of concrete strategies for managing rules for both strategic and normative purposes. At this level, children are also able to construct simple representations of fairness and indirect reciprocity. For example, children witnessed a puppet who struggled to achieve the goal of climbing a ladder. The struggling puppet was helped by a second puppet and hindered by a third. When distributing scarce rewards to the puppets, 4½-year-olds almost always gave more rewards to puppets who helped over those who hindered (Kenward & Dahl, 2011). These findings suggest that at this level, children engage in *indirect reciprocity* when making judgments about the bad behavior of others. When rewards were plentiful rather than scarce, 4½-year-olds distributed the rewards equally to helpers and hinderers, indicating a preference for equality.

Beginning around 6 to 7 years of age, with the capacity to construct *representational systems*, children are able to construct more stable representations of fairness, reciprocity, and rules for regulating autonomous relations between people. Children often invoke standards of fairness for their own strategic gain. For example, as depicted in Step Rp3 (Figure 4.8), in a study assessing children's criticism of school rules, Thornberg (2007) described how one 7-year-old girl protested against her teacher's reprimand: "Gabriel was talking very much to me and tried to take my rubber [eraser], and then our teacher sent us both out. It wasn't my fault; it was his fault . . . I didn't do anything" (p. 423). Children often use self-serving arguments to justify their behavior in situations in which they extend care for others. For example, when asked why she helped another student in distress, one 7-year-old girl responded, "Well if I helped him [when he needed help], he'd help me when I need help." This is not to say that all invocations of fairness and reciprocity are self-serving. In situations involving distributive justice, unlike younger children, 7-year-olds begin to take personal need into account when distributing scarce resources (Kienbaum & Wilkening, 2009).

CULTIVATING CONSCIENCE: FROM COMMITTED COMPLIANCE TO MORAL CHARACTER (VIRTUE)

The middle pathway in Figure 4.8, broadly considered, describes developmental changes in the cultivation of conscience and moral virtue from early childhood through adolescence. Movement through this pathway develops from the early socialization of committed compliance (Kochanska et al., 2010) through to the internalization and appropriation of social standards (Hardy, Padilla-Walker, & Carlo, 2008), and culminates in the moral identification of the self in terms of appropriate moral standards (Patrick & Gibbs, 2012). Kochanska & Aksan (2006) define *conscience* as an "inner guidance system" for regulating behavior and emotion in terms of everyday sociomoral standards. In a series of remarkable research investigations, Kochanska and her colleagues (Kochanska, Barry, Jimenez, Hollatz, & Woodard, 2009; Kochanska, Philibert, & Barry, 2009), Eisenberg and her colleagues (Eisenberg, 2010; Spinrad et al., 2012), and others (Thompson, 2012) have examined how children's dispositions interact with socialization in the construction of moral self-regulation.

The development of conscience develops in the context of mutually responsive relationships between infants and their caregivers (Kochanska & Aksan, 2006). Kochanska has shown how individual differences in dispositions toward fearfulness and effortful control interact with socialization processes to produce individual differences in children's conscience over the first 6 years of life. For example, in children with a disposition toward fearfulness, gentle parenting strategies that deemphasize power assertion are associated with higher levels of moral self-regulation. Pathways to the development of conscience in fearless children are more complex. According to Kochanska, for fearless children, gentle parenting strategies are unlikely to produce the level of emotional arousal required to induce rule following and internalization. However, power assertion also undermines rule following by fomenting anger and resentment toward the parent. The development of moral self-regulation in fearless children is dependent on the formation of a mutually response relationship that mitigates the emotional effects of discipline

(Kochanska, 1995; Kochanska & Murray, 1997). Children's dispositions toward effortful control facilitate the development of moral self-regulation (Kim & Kochanska, 2012; Spinrad et al., 2012). However, even here, the capacity for effortful control interacts with other variables in the production of prosocial behavior (Eisenberg et al., 2010; Kim & Kochanska, 2012). Kochanska, Barry, et al. (2009) showed, for example, that individual differences in the capacity for effortful control were unrelated to variations in future disruptive behavior in guilt-prone toddlers. However, higher levels of effortful control were associated with less future disruptive behavior in less guilt-prone toddlers. Thus, there are multiple paths toward the development of conscience.

Along with describing the development of conscience and moral virtue, in a more detailed sense the middle pathway in Figure 4.8 describes changes in the child's capacity to represent and regulate actions in terms of everyday social rules and standards of value. During the second year of life, infants gain the capacity to bring their behavior in line with parental requests ("do's") and prohibitions ("don'ts") when they are prohibited from touching toys (Kochanska & Tjebkes, 1998), and even when tempted to do otherwise by a malicious puppet (Emde & Buchsbaum, 1990). Beginning around 18 to 24 months of age, as a result of the history of interaction between children and their caregivers, toddlers are able to *represent single concrete meanings* (e.g., simple rules) in the absence of direct sensorimotor experience. For example, as indicated in Step Virtue/Rp1 (Figure 4.8), 2-year-olds can form single concrete representations of their wrongdoings (e.g., "I spilled the milk") and of caregiver reactions to wrongdoing (e.g., "Mommy mad"). They can also evaluate both themselves and others positively or negatively (e.g., "I a good girl").

Over the third year of life, children are able to begin to make connections among multiple single representations, but these connections tend to be relatively global and undifferentiated. For example, in their analysis of moral language use in two children, Wright and Bartsch (2008) reported several such statements produced by young children: "I bad get bump [spanking]" (2;6); "Oops! I splashed and that's not very good" (3;2); "My cousin hit me and she's a bad girl" (3;2); "I wasn't good. I was going to fight" (3;8). It is not until 3½ to 4½ years of age, when children are able to form representational mappings, that they are able to represent explicit relations among two or more single concrete ideas. Wright and Bartsch (2008) reported the following moral utterances that function at the level of representational mappings: "I'm picking up mine because I want you to be happy" (3;4), "If I be real good at the community center, will you get me a prize?" (4;2), and, as indicated in Step Virtue/Rp2 (Figure 4.8): "I didn't spill it last night uh huh Mommy? Because I'm a good girl last night" (4;2).

With the onset of the capacity to coordinate two or more representational mappings into a higher-order representational system, 6- and 7-year-olds can position themselves using more stable and nuanced representations of moral rules. Children begin to position themselves in flexible ways in relation to moral infractions. Perregaard (2010) provides an example of how moral rules are socialized and how a 9-year-old girl and her parents resisted an exchange. Julie had revealed that her teacher asked her to leave class for talking during a lesson. Discussing the event with her parents, Julie flexibly assumed a series of moral positions in which she alternatively deflected, denied, acknowledged, and ultimately took responsibility for her transgression. Julie initially attempted to portray herself as a victim of her teacher's arbitrary use of power (i.e., "I *had* to leave class . . . I *happened* to talk only *once*"). Several moments later, Julie attempted to *deny* that her teacher asked her to stop talking: "She did not ask me to stop . . . and then the first time I talked I was kicked out." In response to her parent's questioning, Julie then acknowledged that her teacher did, in fact, tell the whole class to stop: "No. Well yes. She had said several times to the whole class that we should be quiet." Finally, when pressed further, hiding part of her face behind a napkin, Julie shifted to the complex strategy of *overcorrecting* for her misdeed, "I really have been thinking about it . . . but it annoys me, because I didn't get a chance to apologize to Ida, and I can't apologize tomorrow." Julie's shifting moral positions evolved at the level of compounded representational systems (multiple systems linked together over time). The structure of her overcorrection is indicated in Step Virtue Rp3 (Representational Systems in Figure 4.8).

DEVELOPING CONCERN FOR OTHERS: FROM EMPATHY TO THE RULE OF CARING

The right pathway in Figure 4.8 depicts developmental changes in expressions of concern for others over the course of childhood. Infants begin to develop a concern for others even before the first birthday. Roth-Hanania et al. (2011) demonstrated that 10- to 12-month-old infants begin to show signs of concerned affect as indicated by facial and vocal indicators of sadness or a sympathetic face (lowered eyebrows; raised brow; downturned lips) in the context of a person exhibiting overt signs of pain. Between 12 and 18 months, infants increasingly attempt to comfort another person who is in pain (Roth-Hanania et al., 2011; Vaish et al., 2010; Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman, 1992). By the end of the second year, acts of comforting become more sophisticated, and begin to reflect the needs and desires of the distressed individual.

As indicated in Step Care Rp1 (Figure 4.8), beginning around 18 to 24 months of age, toddlers construct single symbolic representations of circumstances related to another person's distress. Vaish et al. (2010) have shown that 18-month-olds show sympathetic concern to others who are the victims of harmful events, even if the victim does not show signs of emotion. In naturalistic contexts, children's empathic concern for others becomes increasingly representational over time. This is illustrated by the observations that appear below. The first three observations are from Zahn-Waxler (1990); the last are from Wright & Bartsch (2008).

- A child is pounding with a cup and accidentally hits father hard in the nose. (Father gives loud "ouch.") Child drops cup, looks very serious, leans forward to father for a kiss (14 months).
- A child bangs head against mother's face in an excess of affection. (Mother restrains, verbally prohibits and explains, "that hurts.") Child says "kiss, kiss" and kisses mother. Then bangs head on mother again and says, "hurting, hurting" (18 months).
- A child pulls cousin's hair. (Mother tells her not to.) Child crawls to cousin and says, "I hurt your hair; please don't cry," then gives her a kiss (24 months).
- "He got yellow feets and toes and I don't want to hurt him" (28 months).
- "Poor Donna crying" (30 months).

With the emergence of the capacity to form representational mappings between 3½ and 4½ years of age, children's caring actions can be mediated by an increasingly explicit awareness of the relation between their own experiences and those of others. In a study on the development of friendship, Avgitidou (2001) described a poignant example of a caring action at this level involving two 4-year-old boys. One boy, Chris, reluctant to be interviewed, stared at the floor in response to a researcher's invitation to play. Observing the encounter, the boy's friend Thanasis "came and stood next to him and leaning his face towards him in order to look him in the eyes he said 'Go Chris,' I did that (the interview). Chris became distressed and ready to cry and then Thanasis held his hand and said 'Would you like me to come with you?' . . . I obtained two chairs while Thanasis kept hold of Chris' hand and looked at his face" (p. 150). The structure of this caring act is depicted at Step Care Rp2 in Figure 4.8.

At this level, empathic children are capable of a variety of rather surprising comforting strategies. For example,Warming (2011) described an interaction between two 4-year-old boys attending a daycare center. One boy, having bloodied his knee, began to cry. Seeing the first boy's knee, in a happy voice, second boy said, "Congratulations! I've hurt my knee too!" In this situation, the second boy engaged in an act of "emotional solidarity." By forming an emotional alliance with the hurt boy, the comforter not only signaled that the hurt child was not alone in his suffering, but also that the boy's pain could even be seen as a sign of honor. Still further, the comforter was able to communicate that the boy's pain could be endured and would soon pass.

With the emergence of representational systems at 6 to 7 years of age, children's expressions of care become still more stable and consolidated. Children begin to use a variety of comforting strategies involving increasingly coordinated representations of the internal perspectives of self and other (Burleson, 1982). Clark, MacGeorge, and Robinson (2008) described a variety of comforting strategies used by older children and adolescents, including *accounting* (i.e., offering an explanation), *minimization* (playing down the magnitude of the event), expression of *sympathy*, providing *advice*, expressing *optimism*, and providing *companionship*. For example, at this level, as indicated in Step Care Rp3 (Figure 4.8) a child might comfort a friend who is anxious on the first day of school by saying, "I know how you feel. It's scary on the first day of school. I cried on my first day too" (Hoffman, 2000). This comforting strategy contains a combination of *sympathy* and *accounting*.

CONSOLIDATING MORAL IDENTITY THROUGH ADOLESCENCE: THE RECONCILIATION MODEL

One aspect of moral development involves the construction of a *moral identity* (Hardy & Carlo, 2011). An identity refers to the ways in which an individual answers the question, "Who am I?" A moral identity is one in which *moral commitment* plays a central role in the constitution of identity (Frimer & Walker, 2009; Krettenauer, 2011). Frimer and Walker (2009) proposed a model of moral identity defined in terms of the coordinative reconciliation of *agency* and *communion* motives. Their approach provides a relational alternative to conceptions of morality that represent agency and communion as opposing values. Building upon the work of Colby and Damon (1993) and Blasi (2004), Frimer and Walker (2009) maintain that "doing the right thing manifests in mature people not *in spite of* but *because* of who they are as persons—because of their identity" (p. 1669, emphasis added). Frimer and Walker (2009) suggest that in development, values of agency and communion will necessarily come into conflict with each other. Such conflict generates disequilibrium that can be resolved in two basic ways: one can either abandon one motive in favor of the other or *reconcile* the values into an increasingly integrated identity. The choice to reconcile agency and communion goals transforms the self into a moral identity that guides sociomoral action in the world. The formation of a moral identity is not inevitable; it represents but one of several pathways that moral development can take in adolescence.

Using an extended self-understanding interview, Frimer and Walker (2009) examined the relations between moral centrality (the importance of moral concerns in one's self-understanding) and a variety of measures of morally relevant behavior in young adults. They found that communal values positively predicted moral behavior, whereas values organized around self-interest negatively predicted moral behavior. Narratives that contained an interweaving of agency and communal values also predicted moral behavior. Frimer, Walker, Lee, Riches, and Dunlop (2012) found that in contrast to a comparison group, protocols of moral exemplars contained integrative structures in which agency was seen as a means to communion (see also Hart and Fegley, 1995). Matsuba and Walker (2005) demonstrated that young adult moral exemplars differed from comparison individuals in the centrality of agency and communal values in their self-narratives. The life stories of moral exemplars exhibited a concern for societal betterment, ideological depth, and feelings of empowerment. Themes related to redemption and contamination were more characteristic of nonexemplars. This suggests that an integrated moral identity organized around agency and communion can properly be seen as an optimal endpoint of moral development.

As children approach adolescence, they often begin to make requests for increased autonomy and responsibility (Daddis, 2011). During this time, progress toward the construction of a moral identity occurs as children begin to *identify* with their responsibilities. As shown in Figure 4.8 (Moral Integration) using single abstractions, preteens can identify themselves in terms of generalized responsibilities to others (e.g., living up to parental expectations). For example, one 10-year-old girl identified responsibility as a dilemma between autonomy and duty: "They [parents] ask you to do something; they don't tell you to do something, they say, 'oh, can you do this?' and if you don't it just feels like you're sort of letting them down a bit" (Such & Walker, 2004, p. 236). As indicated in Step V4, such an abstraction is formed by generalizing across multiple concrete acts of choosing to comply with parental requests (e.g., choosing to respect a parent's curfew; choosing to clean one's room).

As indicated in Figure 4.9, at the level of abstract mappings, 14- to 16-year-old teens can represent the relation between two abstract ideas. With respect to moral identity, teens can begin to represent the relation between moral selfhood and one's obligations to others. For example, one 16-year-old male identified as a moral exemplar describes his ideal identity as one in which he would: "be there for people, for my kids, not to leave them or anything like that. I'm responsible for what I do. Even I know now I will stick to what I say is to be responsible for what you do" (K. S. Reimer, unpublished data, 2013). This abstract mapping is represented in Figure 4.9a. This individual defines himself in terms of an abstract relationship between his sense of personal responsibility and his sense of care for others. In so doing, he defines his moral identity not in opposition to social obligations, but instead *through* them.

As 18- to 20-year-olds gain the capacity to coordinate at least two abstract mappings into an abstract system, they can represent higher-order relations between autonomy and

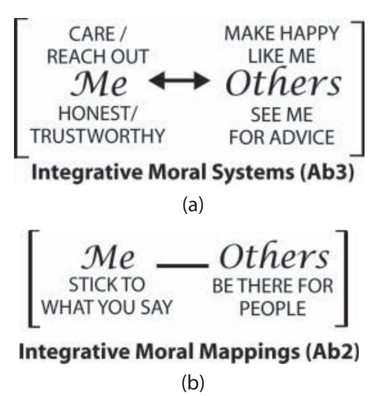

Figure 4.9 Abstract structures of integrative moral identity in late adolescence.

communion. For example, a 16-year-old moral exemplar said the following about the moral centrality of *care* in his sense of self: “I’m the kind of person that *really cares about people*, and I really *want to see people be happy*, because I’m very *positive and I want people to be as positive as I am*. And so I, like, reach out to people so they know that life isn’t as bad as people make it out to be. And I’m pretty *generous and pretty honest*. But I try to be pretty *trustworthy* and I’m the kind of person that *lots of people can look to for advice or whatever*” (K. S. Reimer, unpublished data, 2013). This precocious teen’s sense of moral identity is represented in Figure 4.9b.

Among the motives that direct human action, perhaps none are more powerful than a desire to live up to valued images of self (Kagan, 1996). An integrated moral identity serves as a kind of moral guide for social action (Tangney, 2002). Not all adolescents develop a sense of self structured around agency and communion. Moral identity can develop toward unmitigated self-interest, unmitigated care, or toward an integrative reconciliation between them. When moral concerns play an integrating role in identity, they gain the ability to transform who we are and how we act in the world (Blasi, 2005).

CONTINUING THE MORAL TRAIL: FROM ADOLESCENCE THROUGH ADULTHOOD

We play out our lives against the backdrop of inescapable moral frameworks (Taylor, 1989). Psychologists have identified a series of different moral frameworks that give meaning and structure to human lives. These include frameworks organized around *autonomy, justice* and *rights*, *care/community*, *divinity/spirituality*, *virtue/character*, *duty/authority*, and *contamination/sanctity* (Carr, 2006; Graham et al., 2011; Shweder et al., 1997). One way to approach the study of moral development over the course of life is to examine changes in the ways in which categories of moral concerns structure what adults take to be *important* in their lives. We refer to an individual’s representations of what is most important in life as his or her *core goal structure* (Mascolo & Fischer, 2010). Consistent with research on moral identity (Frimer & Walker, 2009), one might expect that core goal structures are rarely organized in terms of any single moral orientation. Instead, with development, individuals draw from multiple sociomoral orientations, both implicitly and explicitly, to frame their sense of what is important in life. In particular, one might expect that core goal structures would incorporate increasingly integrated representations of agency and communion themes over the course of development.

To test this proposition, we conducted a cross-sectional study assessing developmental changes in core goal structures (one’s sense of what is important in life) over the course of adulthood. On an online questionnaire, 338 adults between the ages of 18 and 75 were asked to enter written responses to the question “What do you experience as the most important thing in your life right now?” They were asked to explain why the issue was important to them, and to provide concrete examples. Responses were examined for the presence of a series of moral themes. These included *agency* (references to personal goals and projects), *care/community* (references to the desire to care for specific others or society), *divinity* (statements referring to the role of God or spirituality in life), *virtue* (references to moral qualities that can be held by individuals), and *duty* (references to obligations to others or deference to authority). References to duty and virtue were rare in this sample, and were not explored further.

Figure 4.10 shows the differences in the presence of autonomy, care, and divinity themes in core goal structures as a function of both age (Figures 4.10a and 4.10b) and level of education (Figures 4.10c and 4.10d). Figure 4.10a shows changes in the proportion of individuals whose protocols made reference to autonomy, care, and divinity themes across age. Autonomy themes were highest in the youngest age group, and declined steadily with age until the 55-plus age group, at which point they increased slightly. In contrast, care themes were less prevalent among 18- to 25-year-olds, but increased and followed the same age-related pattern as autonomy themes beginning with the 26- to 35-year-old group. Divinity themes occurred in a minority of the protocols at each age, and showed no age-related changes. A fourth theme—dependence upon others—decreased steadily over the life span. These data suggest an age-related pattern. Young adults were most concerned with the pursuit of autonomy goals in the presence of support by loved ones (i.e., parents, family). Over the course of young adulthood, care themes increased and autonomy themes decreased in prominence, converging at Age 26 to 35 and following the same age-related trajectory after that point.

Figure 4.10b shows changes in the proportion protocols organized around singular moral orientations (e.g., autonomy alone; care alone or divinity alone). As indicated in Figure 4.10b, pure types were rare in the sample, and showed no age-related difference. In contrast, the

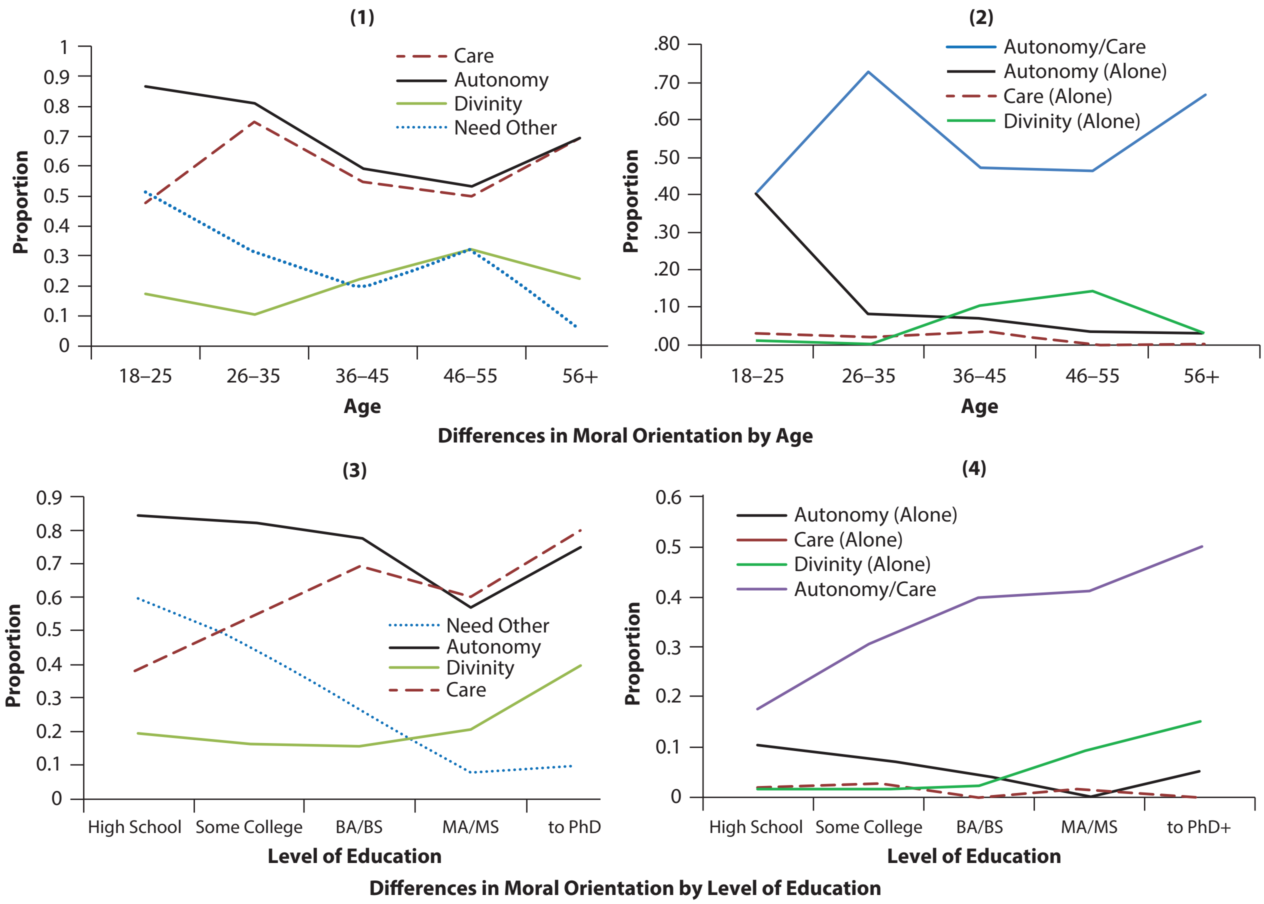

Figure 4.10 Changes in moral themes across the life span.

proportion of core goal structures containing references to both agency *and* care concerns increased between 18 and 25 years to 26 and 35 years, and then fluctuated between .50 and .70 throughout the remaining life course. Figures 4.10c and 4.10d depict these same data as a function of level of education instead of age. As indicated from the figures, although similar, the pattern of changes is more pronounced when analyzed across level of education. As indicated in Figure 4.10c, the presence of divinity/spirituality themes increased among individuals with the highest level of education. Figure 4.10d, shows a steady increase in the protocols containing both autonomy and care themes with increasing levels of education.

The developmental level of core goal structures for each individual was determined using dynamic skill theory. Core role structures showed developmental variation as a function of both age and educational level. The correlation between developmental level and age was .64 (partial correlation controlling for educational level was .34); between developmental level and level of education .65 (partial correlation controlling for age was .34. The correlation between age and level of education was .67 (all $p < .001$).

The study of moral action provides a microcosm for understanding the development of integrative structures of action. It brings together thinking, feeling, strong evaluation, socialization, and culture. The development of structures of moral action shows both order and variability. Order in the development of moral structures is indicated by increasing differentiation and integration in configurations of moral thinking, feeling, and acting. Variability is indicated in the form of diverse trajectories in developmental pathways, such as those that we have described in the development of moral activity. The moral world reflects a variegated landscape of concerns about autonomy, virtue, care, and other areas involving strong evaluation. However, there are no pure pathways in the development of moral action. Although moral development moves in the direction of increased differentiation and integration, structures of moral action integrate multiple themes depending upon local circumstances.

A MICRODEVELOPMENTAL ANALYSIS OF THE COACTIVE CONSTRUCTION OF EVERYDAY SKILLS

At its core, the concept of *constructive processes* is richly coactive, multiply nested, and fundamentally interdependent. In the following, we focus on coactive processes that operate at the individual and social levels of functioning. Using tools for analyzing the development of joint action (described earlier), we will examine the microdevelopment (Granott & Parziale 2002) of shoe-tying skills as they emerge through richly coactive exchanges between a boy and his nanny. To perform an analysis of how shoe-tying skills develop within joint action, we begin by performing a *task analysis* (Fischer, 1980) of the developmental outcome in question (i.e., tying a bow knot). We then track developmental changes in the differentiation and integration of component acts involved in learning to tie shoes and how these changes arise through the process of coactive scaffolding within the person ←→ environment system.

A task analysis involves (a) breaking down a given task or skill into its part actions and processes and (b) identifying the particular ways in which individual parts are coordinated or related to compose the task in question. Figure 4.11 provides a *task analysis* of the structure of the sensorimotor actions involved in tying shoes. As indicated in Figure 4.12, one can parse the structure of tying a bow knot into a series of part steps, each of which is composed by an integrated configuration of actions.

Having performed a task analysis and identified the parts of a developing skill, the next step is to track the *formation* and *integration* of the parts as they emerge in moment-by-moment social interaction over time. These steps are illustrated by the results of a study assessing the microdevelopment of shoe-tying skills in a 5-year-old boy and a 22-year-old caregiver. Over the course of several days, the caregiver was videotaped as she taught a 5-year-old boy to tie his shoes. For each episode (segment of coordinated activity), (a) the nature and number of task parts successfully and unsuccessfully attempted by the child and (b) the type and level of coregulated scaffolding provided by the teacher were identified. Figure 4.12 tracks changes in the developmental scaffolding of the child's shoe-tying skill over time.

Inspection of Figure 4.12 reveals several important points. First, as indicated in the top panel, the developmental trajectory is nonlinear. Although the developmental

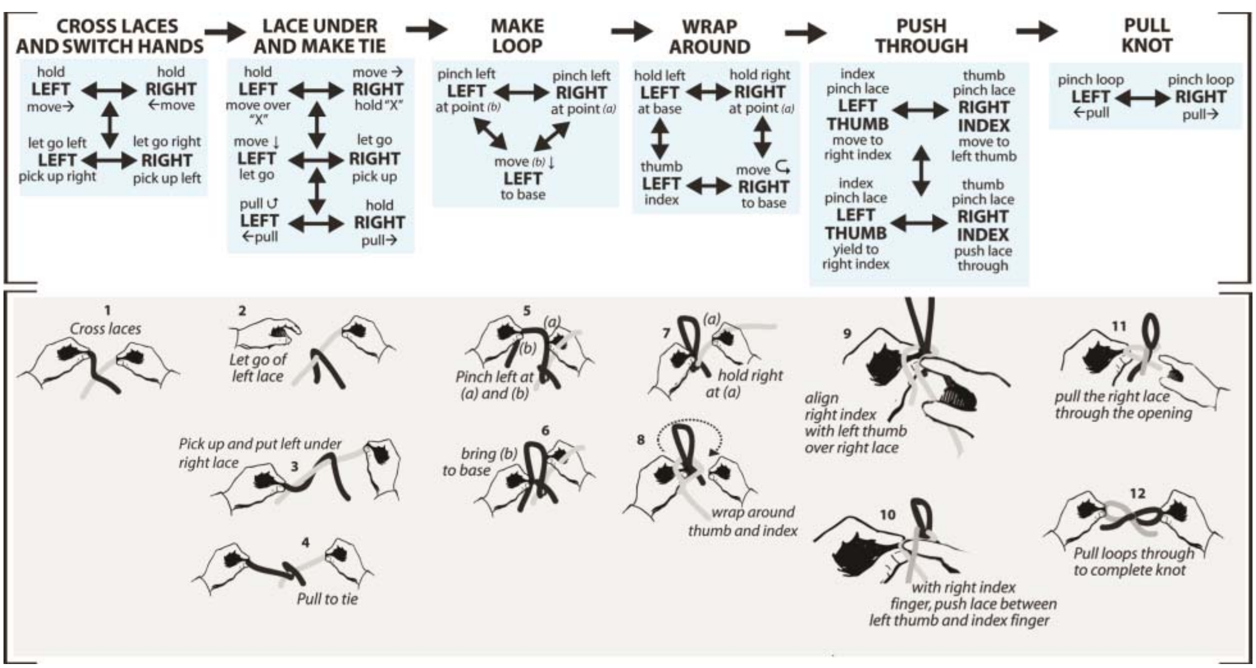

Figure 4.11 Task analysis for tying a bowknot (shoe tie).
Note. Diagrams on top panel consist of skill diagrams describing each component part of the task of tying a bowknot. Skill structures operate at the level of compounded sensorimotor systems. Diagram on the bottom panel indicate the nature of the specific movements involved in each step.

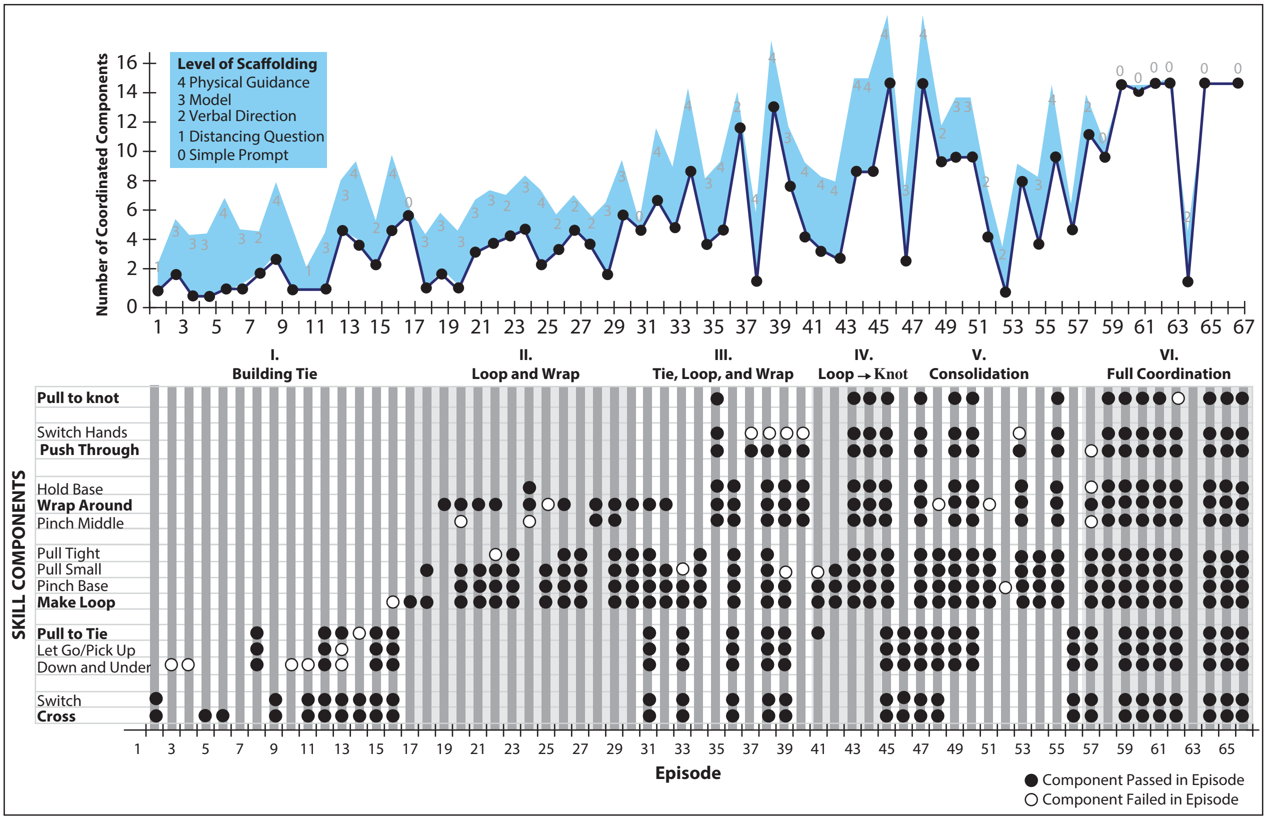

Figure 4.12 Developmental changes in the structure of teaching and learning to tie shoes.
Note. Top panel indicates (a) microdevelopmental changes in the number of task components coordinated by the child and (b) the level of scaffolding provided by the teacher in each conversational turn. The bottom panel identifies the specific task components attempted (failed) and completed (passed) on each.

level of the boy's actions increase over the course of the exchanges, the level of complexity rises and falls, sometimes showing dramatic fluctuations from one segment or exchange to the other. The organization of this trajectory is illuminated by an examination of the actual content of the child's actions over the course of his learning. Inspection of the bottom panel of Figure 4.12 indicates that the boy's skill developed in a series of six cascading phases. These phases are characterized by a cascading pattern of forward and backward movement in which the child gains initial mastery of different subskills before moving forward to coordinate the subskills into successively higher-order structures. Specifically, as indicated in Figure 4.12, first, the dyad worked together to develop skill in the initial act of *building a tie*. Having gained initial mastery over the tie, the dyad then moved to build skills for *making the loop* and executing the *wrap around*. During the third phase, the dyad worked to bring together these two subskills into a higher-order structure (*tie-loop-wrap-push through*). In the fourth phase, the dyad worked on mastering the skill to construct the final knot (*loop-wrap-push through-pull to tie*), before working to consolidate unstable during the fifth phase (*tie-loop-wrap-push through-pull to tie*). During the final phase, the dyad practiced the entire sequence to mastery.

The top panel of Figure 4.12 shows the pattern of social scaffolding that occurs between the teacher and learner in relation to the level of the child's developing skill. The teacher alternated among five of the nine levels of scaffolded support (see Table 4.1) over the course of teaching and learning (i.e., prompts, distancing, verbal direction, modeling, and hand-over-hand physical guidance). Throughout the course of teaching and learning, the child's actions were supported by a relatively high level of scaffolding. In most episodes, the teacher was actively involved in explaining, modeling, or providing physical guidance to direct the child's learning. Exceptions to this rule occurred during some, but not all, transitions between one subskill and a shift of focus toward building a new one, and when the child gained full mastery of the entire skill.

Social scaffolding was not the only form of scaffolding to occur throughout the teaching and learning process. Both *task-scaffolding* and *ecological scaffolding* (see Table 4.1) were operative. One example of ecological scaffolding concerns the origins of the learning sequence identified in Figure 4.12. Although the organization of the sequence of learning was neither fixed nor linear over the sessions, neither was it arbitrary. At many points in the process, the organization of the particular learning activity was constrained by the *ecology of the task itself*. For example, although some steps in the sequence must be executed in real time before others (e.g., *making a loop* must precede *wrapping a lace* around the loop), the order of acquisition of other subskills was free to vary. For example, once the child had completed the act of *making the initial tie*, a choice point emerged. The dyad could either move forward to the next step (*making a loop*) or return to the beginning, remake the tie and then move on. However, completing the subskill of *making the tie* occurs at a distinctive juncture. The sight of the completed tie invites or "affords" (Gibson, 1977) a transition to the next step.

Similar processes occur throughout the learning sequence. After the subskill of *wrapping a lace around the loop* was initially acquired, the child's attempt to *hold the lace in place* (around the loop) was unstable and difficult to sustain. However, the next subskill in the sequence (*push through*) requires stability in holding the loop in place. As a result, to move on and learn the *push through*, the ecology of the task all but requires the learner to move backward in order to move forward: the boy must *reloop the lace*, work on *holding the lace* stably in place, and then focus on the *push through*. This requirement "naturally" creates conditions in which *making the loop* and *wrap around* receive more practice than other steps. In this way, the *process of development itself* emerges as a product of the intercoupling of teacher, learner, task, and object. The task structure determines how the learning proceeds.

COCREATING THE DEVELOPMENTAL PROCESS: NEGOTIATING MEDIATIONAL MEANS

It is easy to think of learning to tie shoes as merely a sensorimotor skill. Shoe tying involves physically manipulating laces in order to tie them into a knot. It is also tempting to think that a child can learn to tie shoes simply by imitating the act modeled by others. However, learning to tie a knot is a complex process that requires the use of sign activity to mediate and direct sensorimotor movements. We have already seen that the task of learning to tie shoes is richly structured by the task itself. However, it is also deeply organized by the language that is used to build symbolic representations by partners to regulate their sensorimotor actions. Simultaneously, in moment-by-moment action, sensorimotor action and its effects on the world modify the very representations that we use to direct action. The richness of the coactive processes through which everyday action emerges is easy to miss, especially in research in which the variables of interest are aggregated measures collapsed across context.

An analysis of the changing structure of dyadic action can illuminate the richly coactive nature of the processes by which individual skills develop. Figure 4.13 tracks changes in the joint structure of action during the early phases of learning. When teaching and learning to lace shoes, both the teacher and the child typically operate at (at least) two developmental levels simultaneously, namely the representational and the sensorimotor levels. At the representational level, the child and adult use language to represent and direct meanings and relations; the *sensorimotor* level indicates the use of structures of sensorimotor action to move and tie laces. In Figure 4.13, representational structures are depicted in the upper portion of the dyadic skill diagrams; sensorimotor structures are indicated in the lower portion of the diagram and are displayed against a gray background. The complexity of the teacher's and the learner's actions tend to fluctuate among three levels of skill development. All sensorimotor actions operate at the level of sensorimotor systems (Sm3, see Figure 4.2). Representational actions tend to fluctuate between single representations (e.g., "that's your left hand"; Rp1) and representational mappings (e.g., "put your left hand *over* your right hand," Rp2).

Figure 4.13 identifies the process of teaching and learning how to put one lace under the other in order to complete the initial tie (Steps 2 and 3 in Figure 4.11). Inspection of these changes reveals three important points: First, it is possible to identity precisely the joint structure of the representational and sensorimotor actions involved in the development of shoe tying. Second, the use of *mediational means* (sign activity) employed by the teacher and the learner are crucial components of the process of learning to tie shoes. Third, mediational means themselves arise through the coactive interplay among teacher, task, object, and learner. Through the dynamic modification of mediational means, not only do structures of thinking

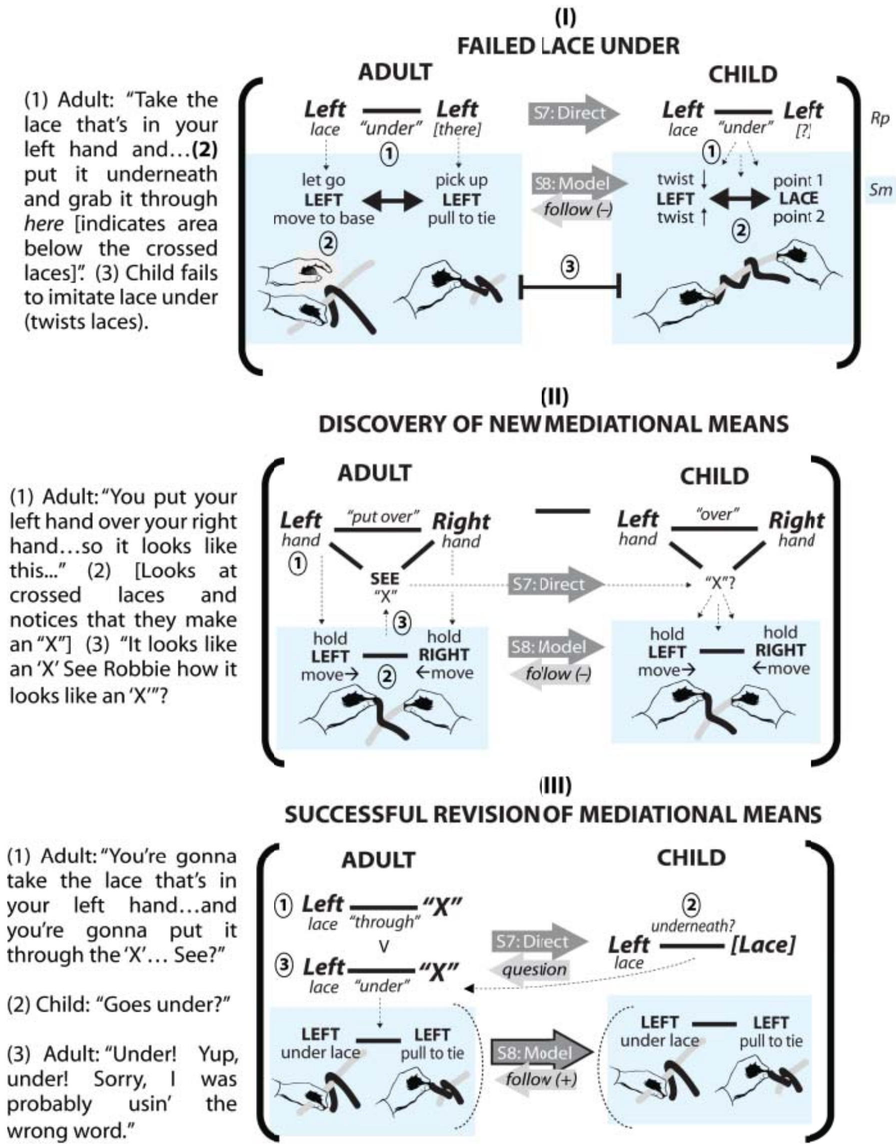

Figure 4.13 The coconstruction of mediational means (shoe-tying).

Note. Figure shows a series of dyadic action diagrams that specifies the evolving structure of joint action that occurs between the adult and child over the course of teaching the "lace under." The structure of the adult's action is indicated on the left portion of each diagram; the structure of the child's actions is indicated on the right. Unshaded structures indicate activity at the representational (Rp) level of functioning; shaded diagrams indicated the structure of sensorimotor action (Sm). Dotted arrows indicate the sequence of action and control over time.

and action develop over time, *the process of learning and development itself emerges and develops over time*.

As the teaching and learning process began, the child had already mastered the simple skill of crossing the laces. Building on this skill, Panel (I) in Figure 4.13 shows the structure of the child's first failed attempt to complete the initial tie (Steps 2 and 3 in Figure 4.11). Using a high level of scaffolding (Sc8), the teacher modeled the act of bringing one lace under the other. At the level of representational mappings, the teacher directed the child to "take the lace that's in your left hand and . . . put it *underneath* and grab it through *here* [indicating the area below the crossed laces]." However, despite the teacher's modeling, the child was unable to grasp the referential meaning of the term *underneath*. Instead of putting one lace *under* the other, the boy twisted one lace around the other, thus failing to complete the tie. The disparity between the teacher's modeling and the child's failed attempt is indicated at Point 3 in Panel (I) of Figure 4.13.

Panel (II) of Figure 4.13 illustrates the importance of *task scaffolding* in the coactive revision of the mediational means that the teacher uses to teach the task. Given the child's failure, the teacher untied her shoe and began to model the sequence of shoe tying from the beginning. As indicated in Panel (II), through the process of *task scaffolding*, the teacher discovers a new strategy for teaching the child how to put one lace under the other. At Point (1), the teacher modeled (Scaffolding Level 8) the act of crossing the laces. In so doing, she offered the directive (Sc7), "You put your left hand over your right hand . . . so it looks like *this*." At Point (2), the teacher paused and looked at her own crossed laces. *Noticing that her own crossed laces took the shape of an "X,"* she said, "It looks like an 'X.' The teacher then began to use the concept of "X" to mediate her instruction. As indicated at Point (3), the teacher directed the child by saying, "See Robbie how it looks like an 'X'? At this point, the child crossed his own laces. The idea of invoking the "X" to teach the child to put one lace under the other was not something that was planned beforehand. Instead, *it emerged as discovery* based on the teacher's *own actions in the task itself*—namely that of crossing her laces. Thus, the mediational means emerged coactively through the process of *task scaffolding*.

As indicated in Panel (III) of Figure 4.13, the teacher continued to use the notion of the *X* as an alternative to the concept of *underneath* to mediate her instruction. At Point (1) of Panel (III), the teacher said, "You're gonna take the lace that's in your left hand . . . and you're gonna put it *through the 'X'* . . . See?" Again, however, the child failed to comprehend meaning behind the teacher's use of the phrase *through the 'X.'* Confused, the child twice failed the lace under component of the task. As indicated at Point (2), on his third attempt, the boy moved his lace as if to experiment with where to put it, and asked, "goes under?" Apologizing, at Point (3) the teacher said, "Under! Yup, under! Sorry, I was probably usin' the wrong word." Having differentiated between *through the X* and *under the lace,* the child was able to put one lace under the crossed laces.

Over the course of these three episodes, the teacher discovered and refined the mediational means she used to represent the spatial relation to complete the *lace under*. The change in mediational means is indicated in Figure 4.14. After the teacher discovered that crossing the laces created an "X," her use of mediational means shifted from "*underneath/here*" → "*through the X*." After the

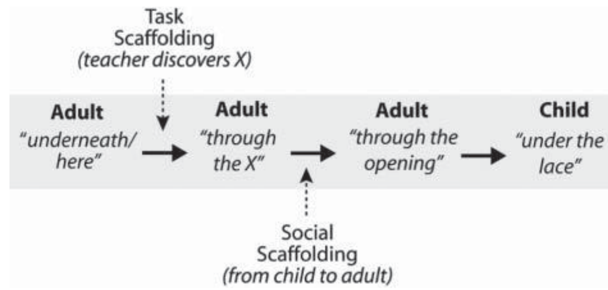

Figure 4.14 Development of mediational means.

child expressed confusion about the concept of "through," the teacher differentiated between the concepts of *under* and *through*. In specific, she invoked *under* with reference to *laces* (i.e., "Put the left *lace under* the right *lace*") and *through* with reference to the concept of an *opening* (i.e., "Put the left lace *through* the *opening*"). The novel use of the term *opening* identifies the area under the crossed "X" as the target of action.

The language invoked to mediate instruction and task completion are integral parts of the developmental processes. As such, it follows that central aspects of the process of development—the mediational means—emerged coactively over the course of teaching and learning. Thus, not only do the structures of development emerge over time, the process of change itself emerges and develops over time. As a result, it becomes difficult to separate the *structures* of development (i.e., skilled action) from the change process that organize development (i.e., coactive scaffolding; differentiation and integration). Structures of psychological activity and the processes by which those structures develop operate as flip sides of the same process.

CONCLUSIONS

We live in a complex world. It is composed of complex and dynamically emergent systems that exhibit both striking order and dramatic variability. It is the job of developmental scientists to understand the origins of such order and variation. As scientists, our work is necessarily informed by our conceptions of what it means to be a science. Science is committed to some form of *determinism*, the belief that events are both orderly and caused. Science is also committed to grounding assertions in empirical evidence, and, within the constraints of inescapable conceptual frameworks, to following where the data lead. As developmental scientists, we find ourselves at a juncture that should engender theoretical reflection. It we take the concepts of coactive emergence seriously, developmental science must address the conflict between an orderly determined world on the one hand and limited powers of prediction on the other. Predicting the course of human action is similar to predicting the weather. Over long periods, we are able to predict gross changes in human behavior. Just as we know that summer will eventually arrive after spring, we know that the capacity for symbol use will arise in some form after 2 years of sensorimotor-affective experience. In contrast, in the short term, just as we know that dark clouds will continue to move in our direction if they are near us rather than if they are far away, it is easier to predict what people will do in the coming minutes or hours than in the coming years. From the perspective of classic Cartesian-Split-Mechanistic science, such a state might seem discouraging. For the neopositivists of Cartesian science a central goal was to what will happen next and the ability to predict what comes next falls short of this goal.

Although scientists still committed to the traditional neopositivist values of prediction and control may lament this state of affairs, from an alternative view, our inability to predict what comes next may actually call for celebration. Our limited powers of prediction may not be a failure of our science, but instead may signal the inherent dynamism of the developmental process itself. If this is so, then we are served best by following the results of our inquiries where they seem to be leading us. In this case, they seem to suggest the importance of understanding the dynamics of coactive emergence. The concept of coactive emergence provides a framework for understanding what we have been trying to understand for so long—how novel and more powerful structures arise from existing and less powerful structures. Embracing the concept of coactive emergence suggests a new way of thinking about developmental science. Rather than seeking answers to the problem of origins by seeking to identify the assumed fixedness of *is*, it might be better to shift our mind-set toward the *dynamics of possibility*—understanding how novel forms emerge as systems self-organize under shifting developmental circumstances.

Trading a mind-set of prediction for a mind-set of possibility has important implications for our science. If order is an emergent product, it is possible we can understand the origins of order by identifying the circumstances under which coactions among systems occur. However, if order is an emergent product, it is also possible that variations in system functioning will create conditions under which something different will emerge. Novel developmental circumstances may foster the coactive production of novel and unanticipated forms. This principle applies to both individual development as well as the process of evolution. For the past century, evolutionary theory has relied on the explanatory staples of mutation, natural selection, and recombinant genetics to understand the process of evolutionary change. For years, we have lived with the difficulty of understanding how these quasi-random evolutionary processes—even over the course of millions of years—could bring about the stunning order of complex living systems. Modern epigenetic systems theory provides a framework for understanding how novel evolutionary forms can arise coactively, even in the absence of changes in the genome (Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume). According to Gottlieb (2002), the epigenesis of novel forms of *individual* behavior is key to understanding this process. When such novel gene-environment coactions recur across generations, new genome-epigenome-environment relations create novel possibilities for new developmental forms, even in the absence of changes in the genome. Such possibilities arise because of the untapped potential already existing within the genome for coactions with the epigenome and novel environmental circumstances. Novel genome-epigenome-environment relations can exploit this novel potential, leading to novel forms in the absence of genetic mutation.

However, to develop the promise of dynamic, relational, and epigenetic systems approaches to development, it will be necessary to continue to attend to several important conceptual and methodological issues. The first concerns the need for both precision and scope on the elaboration of developmental theory. Precision comes in the form of local theoretical models of local psychological and developmental processes (e.g., cognitive, affective, perceptual development). The testing of local models has been the primary mode developmental science for over a half-century. Equally important, however, is the elaboration of broader models of psychological development akin to those formulated by Piaget, Vygotsky, Erikson, and others. The continued elaboration of such models serves important functions in psychological science. They remind us that all observation is embedded in pretheoretical assumptions and beliefs that organize more local theory and research. They allow us to address broader questions at the level of individual person in addition to local questions at the subpersonal level of isolated psychological functions. Further, the synthesis of local research into general of psychological development provides a framework for understanding how different categories of psychological processes function in relation to each other. This not only provides a way to understand how local research fits into a larger framework, it also helps researchers become aware of how diverse psychological processes have implications for understanding a researcher's local research area, which is essential for the effectiveness of developmental analysis.

A second class of theoretical concerns involves issues related to the concept of development. As the weaknesses of general stage models of development have been revealed, many researchers have focused on the analysis of *age-related* rather than *structure-functional* changes in psychological processes (see Overton, Chapter 2, and Witherington, Chapter 3, this *Handbook*, this volume, for extended discussions of structure-function change). Although psychological development does not proceed as a linear, stage-like progression of structural changes, human behavior is nonetheless *structured*. As we have demonstrated repeatedly in this chapter, development involves dynamic transformations in the structure-function of behavior. Not all age-related changes are *developmental* changes. The concept of development is a directional one; it implies progressive movement toward one or another actual or idealized developmental outcome. Developmental movements are those that involve increasing differentiation and hierarchic integration of component parts over time. The skill scale described earlier provides a common measure for assessing changes in differentiation and integration of psychological structures as they develop within particular contexts and domains. Although the common scale is broadly applicable to assessing development in any given psychological domain, development assumes different shapes both within and between domains, contexts, people, and cultural groups. Again, development exhibits both order and dynamic variability.

Finally, although the focus of developmental science is on the nature of individuals, most psychological research focuses primarily on establishing relations at the level of the group or population. However, it is often unclear how relations established at the level of the group relate to the development of individuals. Over the past decades, evidence has accumulated that demonstrates the difficulty of drawing inferences about individual behavior from research conducted on groups (e.g., Molenaar & Nesselroade, Chapter 17, this *Handbook,* this volume; Nesselroade & Molenaar, 2010). Evidence suggests that more often than not, population insights represent only a small subset of individuals at best; at worst, they are statistical artifacts representing no one (Estes, 1956; Rose et al., 2013; von Eye, 2009; von Eye, Bergman, & Hsieh, Chapter 21, this *Handbook*, this volume). In developmental science, to create stable measures of behavior, researchers often base assessments of individuals on aggregate estimates of individual behavior by collapsing across multiple contexts. Although such data is helpful in differentiating groups of children who are more and less likely to produce target behaviors over time, they ignore the role of context in the production of target behavior at the level of individuals. It is not possible to understand the structures and processes of individual development simply by focusing on changes in group averages over time. To understand how novel structures emerge in development, it will be necessary to design research (see Molenaaar & Nesselroade, Chapter 17, this *Handbook*, this volume; Nesselroade & Molenaar, 2010; Ram & Grimm, Chapter 20, this *Handbook*, this volume; von Eye, Bergman, & Hsieh, Chapter 21, this *Handbook*, this volume) assessing how individual behavior emerges coactively in real time within the person ←→ environment system.

SUMMARY AND CONCLUSIONS 198
REFERENCES 199

Biology has genetic, epigenetic, developmental, ecological, and evolutionary components. In addition to the scientific fields contributing to biology the philosophy of science also frames the field. As is the case with all the sciences, progress in biology depends on advances in theory building, empirical research, and modeling. Development, as one of the central processes of biology, has been the focus of both empirical and theoretical attention for centuries. Research techniques and methods used in biology to study development have evolved dramatically over the past several decades, generating a wealth of detailed empirical data. Metatheoretical frameworks, theories, and modeling have likewise advanced, calling into question established interpretations and assumptions about development, including the relation between genotype and phenotype, the nature and extent of heredity, the links between development and evolution, and the biological bases of behavior and cognition (e.g., see R. M. Lerner & Benson, 2013a). This chapter reviews the history and current status of biology's view of development and discusses the broader implications of this view for a psychobiological systems view of human development.

DEVELOPMENTAL THEORY IN THE HISTORY OF BIOLOGY

Development is the fundamental phenomenon of biology. It is also one of biology's most challenging problems.

The writing of this chapter was supported in part by NSF grant BCS 1057898 awarded to R.L. We thank Richard Lerner, Willis Overton, and James Tabery for their constructive comments.

What greater mystery could there be than the growth of something as complex as a human, made up of thousands of billions of cells organized into multiple organs, glands, muscles, and other body parts, from a relatively simple and formless tiny egg? How can it be that a single fertilized cell is able to give rise to an embryo and then, through many cycles of cell growth and division, an adult? The history of biology's evolving view of the remarkable process of development can be traced to debates begun more than 2,500 years ago between those who believed that all an organism's features are present prior to development at conception (*preformationism*) and those who believed that an organism's features do not preexist but rather come into existence progressively over the course of development (*epigenesis*). For example, according to the Hippocratic school of ancient Greece, each fertilized egg was thought to contain all the organized structures of the adult organism, but in miniature form. Development simply involved growth of this preformed homunculus. From this perspective, development did not involve an increase in overall complexity during the course of the individual's lifetime, as all the parts and organs were present and in their proper form from the outset. Based on his observations of animal embryonic development, Aristotle (384–322 BC) questioned this preformationist framework, noting in his text *The Generation of Animals* that in their earliest stages eggs appeared formless and only gradually did embryonic structure take shape. He argued that adult parts were not present at the beginning of development, but rather appeared sequentially as development proceeds. From this view, individual development included differentiation as well as growth.

However, the Aristotelian view of development, which eventually came to be known as *epigenesis*—a term coined by C. H. Waddington (see van Speybroeck, 2002)—faced the considerable problem of explaining how form emerges from formlessness. How, for example, do chicken eggs become chickens and frog eggs become frogs if both frog and chicken eggs are seemingly formless from the start? To deal with this thorny issue, Aristotle proposed that organisms have souls that internally direct the epigenesis process toward proper adult form (Maienschein, 2012).

Aristotle's general conception of development remained in play well into the 17th century. As a result of the increasing availability of microscopes, heated debate arose in the late 17th century regarding the plausibility of preformation versus epigenesis views of embryological development (Moore, 1993). The refutation of a strict homuncular view of preformationism was given a substantial boost in the middle of the 18th century with the careful observations of embryonic development by Caspar Friedrich Wolff (1733–1794), who was able to document that different organ systems differentiate and take form consecutively over the course of prenatal development. He emphasized that when organs first become observable, they do not appear in their final form. For example, the intestine of the chick embryo starts as a flat sheet and then becomes a tube. Wolff's findings were confirmed and extended decades later by Karl Ernst von Baer (1792–1876), whose detailed descriptions of the embryological sequences of fish, birds, and mammals in his 1828 monograph *On the Development of Animals, with Observations and Rejections* provided an initial map of the process of differentiation, further documenting and providing support for the epigenesis view that development proceeds from the general to the more specific. Von Baer stressed that development in vertebrate species could be universally characterized as progressing from the homogeneous to the heterogeneous. Further, in keeping with Aristotle's original insight, he provided compelling evidence that every step in development is only possible through the conditions preceding it.

Scientists of the 17th and 18th centuries (including von Baer) who advocated the epigenesis view of development continued to espouse the existence of a life force (akin to the Aristotlean soul) that directed the course of development. As a result, the epigenesis view remained linked to *vitalism*, a doctrine that held that living organisms contained an immaterial and immeasurable life-force responsible for form, growth, and animation. In contrast, the hypothesis of preformationism managed to avoid the issue of vitalism; if structure was present from the very beginning, then there was no problem of how to derive form from a formless state (Moore, 1993). As empirical evidence from improving technologies advanced, there was a concerted effort among embryologists in the 19th century to show how the alleged functions of vital forces could be explained in terms of physical processes consistent with a materialist philosophy.

By the second half of the 19th century, experimental embryologists and other biologists interested in development and heredity were attempting to find some middle ground between epigenesis and preformationism perspectives (Maienschein, 2012). One popular solution, exemplified by Weismann's *germ-plasm theory* (Weismann, 1893; see also de Vries, 1889), involved proposing that the individual characters of adults were specified by material particles present in germinal cells, rather than existing in miniature form at the start of development. This idea was originally proposed by Charles Bonnett (1720–1793), an 18th-century preformationist who in his 1762 book *Considerations on Organized Bodies* had argued that what was preformed was not the organs and other body parts in miniature, but rather organic particles or "germs" corresponding to and determining their growth. Although these material units of heredity eventually acquired a variety of different names at the hands of different biologists (e.g., Darwin's *gemmules*, Galton's *strips*," Weismann's *determinants*, de Vries's *pangenes*), it was generally agreed that these particles were somehow responsible for the phenotypic traits of the individual organism, representing a kind of material preformationism.

Moreover, in Weismann's germ-plasm theory it was assumed that these internal determinants were protected from any effects arising from the experience of the organism during its own lifetime. Weismann (1893) believed this was necessarily the case because the separation of the germ cells from all other cells of the body (what he called the *somatic line*) occurred so early in the course of the individual's development that what happened to somatic cells over the individual's ontogeny had no opportunity to effect the make-up of the germ cells. As a result, only changes in the *germ line* (contained in the sperm and egg) could contribute to heredity and ultimately to evolution. From this view, the fertilized egg contained all the necessary information for the development of the organism and this information was insulated from any environmental influences occurring during the individual's own lifetime.

Weismann's narrow conception of development and heredity had an enormous impact on the direction of theoretical biology for many decades. As the philosopher Griesemer (2002) has pointed out, Weismann's views provided the basic causal structure used to articulate ideas about genotype and phenotype, heredity and development, and evolution and selection for most of the 20th century. For psychology, Weismann's views provided a foundation for distinguishing between inherited and acquired behaviors (Johnston, 1995). In particular, his germ-plasm theory supported a distinction between those behaviors that are intrinsic to the organism (and assumed to be the result of *natural selection*) and those behaviors that were the result of the effects of experience (presumably through some form of learning). This distinction assumed that some behavioral patterns could be prespecified in the germ plasm, independent of environmental factors and already determined at conception. This assumption would influence thinking about both brain and behavioral development for much of the 20th century.

The material preformationist view of Wesimann was bolstered by the work of Gregor Mendel, whose research on the laws of inheritance in garden peas (resurrected some four decades after its initial publication in 1865) suggested to him that heredity came packaged in discrete units that were combinable in predictable ways. Mendel proposed that each of these discrete units or factors was associated with a particular phenotypic trait or character, a one-to-one correspondence between heredity factors and the structure or properties of the organism. Further, he proposed that each character was represented in the fertilized egg by two factors, one derived from the father and the other from the mother. These internal factors were thought of as self-contained packets of inheritance, passed on from generation to generation. Mendel's research thus provided a basis for making a conceptual dichotomy between the characters and qualities of individual organisms (later called the *phenotype*) and the factors or "units" of heredity that passed from parent to offspring in reproduction (later called the *genotype*).

During these early years of the 20th century a number of biologists worked to solidify the view that heredity and the resulting stability and variability of phenotypic traits observed across generations involved the passing on of discrete internal factors or "determinants" situated somewhere in the structure of fertilized cells. These hypothetical internal factors were termed *genes* by the Danish botanist Wilhelm Johannsen in 1909 (see Johannsen, 1911), and during the early decades of the past century it was still not clear whether these genes were fictitious or real (Keller, 2000), but to a large extent the material basis of genes did not matter. Genes were simply "units of heredity" used as intervening variables to explain Mendelian patterns of heredity of offspring phenotypes based on parental phenotypes (Griffiths & Stotz, 2006).

The celebrated discovery of the double helix by Watson and Crick (1953) solidified the material basis of genes as deoxyribonucleic acid. The pairing of the two strands of the double helix of DNA was thought to be the instructions for phenotypic development and the exclusive process for replicating the essential units of inheritance. As a result, development came to be increasingly characterized across the biological sciences as the process by which genotypic specification is translated into the phenotypes of individuals, including their anatomy, physiology, and behavior (Dobzhansky, 1937; Mayr, 1942, 1982). Influences above the level of the gene were thought to play a relatively minor role in developmental outcome. Stotz (2006) provides a succinct overview of this widespread perspective:

> For the largest part of the past century we came to see genes as a material unit with structural stability and identity, with functional specificity by means of their template capacities that encode information, and with intergenerational memory; we came to see genes as the designator of life and the site of agency and even mentality (in containing a plan or a program for and asserting control over developmental processes). (p. 914)

The mysterious and elusive vital force advanced by proponents of epigenesis in the 18th and early 19th century was thus gradually replaced by an equally mysterious and elusive *genetic program* believed to guide the process of development. This gene-centered perspective had at its core an underlying false premise that went unquestioned by many psychologists and biologists over the course of the 20th century: that the bodily forms, physiological processes, and behavioral patterns of organisms could be specified *in advance* of the organism's development. Indeed, the notion of a preformed program that resides in the genes and is directly responsible for an individual's phenotypic characteristics came to dominate much of 20th-century biology's concern with both developmental and evolutionary processes (Keller, 2000; Lickliter & Honeycutt, 2009; Oyama, 1985; Robert, 2004).

EVOLUTIONARY THEORY AND GENOCENTRISM

During the 19th century, the study of heredity and development were considered one science. Almost all theories of heredity of the time (including Darwin's) assumed that to understand heredity one must also understand development. In other words, explaining why traits or characteristics are similar between parent and offspring requires one to understand how those characteristics develop over individual ontogeny (Amundson, 2005). In this view, inheritance (heredity and development together) was about the reproduction of similarity across generations (Gerson, 2007). Further, since heredity was involved in evolution, it was thought that evolution was to be understood in terms of changes in developmental processes.

The widespread acceptance of Weismann's germ-plasm perspective on the nature of heredity and development and the rediscovery of Mendel's research suggesting that the inheritance of some traits or characteristics could be predicted with reference to internal factors transmitted in reproduction contributed to developmental issues becoming increasingly divorced from concerns with heredity and evolution in the early decades of the 20th century. If genes contained the necessary information for phenotypic traits, and if circumstances during individual development could not directly influence the traits or characteristics of offspring, then any role or influence of development in heredity and evolution had to be minimal. According to the evolutionary biologist John Maynard Smith (1982), "one consequence of Weismann's concept of the separation of the germ line and soma was to make it possible to understand genetics and hence evolution, without understanding development" (p. 6).

The architect of the chromosomal theory of heredity, Thomas Hunt Morgan (Morgan, 1917; Morgan, Sturtevant, Muller, & Bridges, 1915), contributed to this growing separation of heredity and development by drawing a sharp distinction between transmission genetics and developmental genetics. Morgan viewed *transmission genetics* as critical to evolutionary concerns, because it dealt with the hereditary transmission of (at the time, still hypothetical) genes, whereas *developmental genetics* (including embryology) focused on how genes were expressed during development and had little to say about evolution. This perceived separation of heredity and evolution from development was eventually solidified by the *Modern Synthesis* of evolutionary biology, crafted by animal and plant geneticists in the 1930s and 1940s (Mayr & Provine, 1980). This new framework, a synthesis of neo-Darwinian, Weismannian, and Mendelian concepts, promoted a narrow definition of evolution as "a change in the genetic composition of populations" (Dobzhansky, 1937). Following a line of thinking most clearly articulated by R. A. Fisher (1930), a species or a population became a collection of discrete Mendelian genes existing in different frequencies (so called *gene pools*) that were the objects of evolutionary change. Evolution was thus assumed to be changes in genes, rather than changes in developmental processes.

Watson and Crick's discovery of the structure and function of DNA in 1953 served to reaffirm the genocentric position of the Modern Synthesis—if genes are DNA, and copying errors for DNA to RNA to protein are the source of genetic variation, then evolution must indeed be "changes in gene frequencies in populations." A succinct overview of these basic tenets of the Modern Synthesis was provided by David Futuyma (1986) in his influential textbook: *Evolutionary Biology*:

> The major tenets of the evolutionary synthesis, then, were that populations contain genetic variation that arises by random (i.e. not adaptively directed) mutation and recombination; that populations evolve by changes in gene frequency brought about by random genetic drift, gene flow, and especially natural selection; that most adaptive genetic variants have individually slight phenotypic effects so that phenotypic change are gradual; that diversification comes about by speciation, which normally entail the gradual evolution of reproductive isolation among populations; and that these processes, continued for sufficiently long, give rise to changes of such great magnitude as to warrant the designation of higher taxonomic level (genera, families, and so forth). (p. 12)

Note that in this widely accepted view of evolution, it was assumed that the process of development as well as the environment in which the organism develops have little to do with the changes in gene frequencies thought to drive evolution. The special privileges assigned to genetic factors effectively divorced heredity (as genetic transmission) from development, and developmental influences from evolutionary processes. These divisions fostered the view that developmental analyses could add little or no explanatory value to evolutionary theory. Development was increasingly viewed as merely the reading out of genetic programs that were assumed to be the products of natural selection, and the rules governing the evolution of populations were assumed to be distinct from those governing individual development. As a result, the Modern Synthesis focused on population genetics, an approach that concentrated on the traits or characteristics of adults in populations and virtually ignored questions about how these characteristics were actually realized during the course of development. This strategy essentially "black boxed" the process of development, thereby peripheralizing developmental and behavioral scientists from the concerns of evolutionary biology. Attempts to explain evolution in terms of developmental processes were widely considered "an error of misplaced reductionism" (Maynard Smith, 1985).

PSYCHOLOGY AND NATIVISM

The internally driven and decidedly predetermined view of development commonplace in 20th-century biology was also widely embraced in psychology. In the first half of the century, several generations of psychologists relied on the notion of internally driven *maturation* as a causal explanation for physical growth, behavioral development, and cognitive skills (e.g., Bayley, 1951; Gesell, 1929; Witty & Lehman, 1933). Genes were thought to prescribe not only bodily structures and physical appearance, but also the fundamental form of human cognitive processes. Arnold Gesell's (1945) conception of human development, in which early behavior expands through "the innate processes of growth called maturation" is a well-known example of this theoretical framework.

The legacy of the maturational framework continues to play out across the psychological sciences (see Bateson, Chapter 6 and Overton, Chapter 2, this *Handbook*, this volume, for extended critiques of the concept "maturation"). For example, the assumption that aspects of development involve a programmed unfolding of genetic information, relatively independent of environmental factors, is still evident in contemporary developmental psychology, as the following quotes drawn from several developmental psychology textbooks makes clear:

- To those who emphasize *nature*, development is largely a process of maturation, the biological unfolding of the individual according to a plan contained in the genes (the hereditary material passed from parents to child at conception). Just as seeds turn into mature plants through predictable process, humans "unfold" within the womb (assuming that they receive the necessary nourishment from their environment). (Sigelman & Rider, 2012, p. 7)
- To grasp the meaning of development, we must understand two important processes that underlie developmental change: maturation and learning. Maturation refers to the biological unfolding of the individual according to a species-typical biological inheritance and an individual person's biological inheritance. (Shaffer & Kipp, 2010, pp. 2–3)
- *Nature* refers to traits, abilities, and capacities that are inherited from one's parents. It encompasses any factor that is produced by the predetermined unfolding of genetic information—a process known as maturation. (Feldman, 2012, p. 11)
- The term nature refers to the biological forces that govern development. To a certain extent our development is preprogrammed our genes—traits inherited from our parents and ancestors. In childhood this program unfolds.... Nature provides the genetic program. (Cook & Cook, 2005, p. 5)
- Whatever the source of the egg and sperm, and wherever they meet, their merger is a momentous event: The resulting 23 pairs of chromosomes define a child's heredity—what he or she will do naturally. (Kail, 2012, pp. 42–43)

Although textbook authors must often gloss over more nuanced theoretical points for their relatively naive readers, these passages clearly demonstrate a commitment to the notion of predetermined aspects of human development and also promote the standard version of the nature (internal, biological, and hereditary factors) versus nurture (experiential and environmental factors) dichotomy, one in which the two are treated as separate sources of developmental information. As is reviewed in more detail later, the widespread use of this distinction in the 20th century made it possible to split heredity from development and developmental analysis from evolutionary analysis, as well as legitimize attempts to partition phenotypic characteristics into those that are genetically determined and those that are produced by environment.

Despite persuasive efforts within the psychological and developmental sciences to successfully integrate conceptions of nature and nurture over the last several decades (e.g., Gottlieb, 1997; R. M. Lerner, 1978, 1991, 2006; Moore, 2002; Overton, 1973, 2004, Chapter 2, this *Handbook*, this volume; Oyama, 1985; Richardson, 1998; Sameroff, 2010; Stiles, 2008), developmental psychology has not yet successfully come to terms with various versions of the nature-nurture debate (Goldhaber, 2012; Lewkowicz, 2011; Spencer et al., 2009). Within the domains of perceptual and cognitive development, this struggle has often centered on the issue of to what extent humans are innately—see Bateson, Chapter 6, and Overton, Chapter 2, this *Handbook*, this volume, for the problematic nature of the term *innate*; also Mameli & Bateson (2011)—prepared to interpret and act on the world and to what extent they rely on learning and experience (see Blumberg, 2005, and Samuels, 2002, for contrasting views). "Nativistic" perspectives on perception and cognition typically rely (often implicitly) on the argument of the poverty of the stimulus: The developing organism displays too much knowledge, or too much skill for experience or learning to be an adequate explanation. Thus, nativists propose that there is a core set of innate—here the term *innate* meaning "biologically determined" rather than its strict definition "present at birth"—concepts that provide the foundation for later learning (e.g., Carey & Markman, 1999; Landau, 2009; Spelke & Kinzler, 2007). These core concepts are thought to be present in early infancy in the absence of obvious experience and are thus presumed to be biologically prespecified. For example, Spelke and Newport (1998) have argued for the differential roles of biology and experience, suggesting that a solution to the nature-nurture debate is the "thesis that human knowledge is rooted partly in biology and partly in experience and . . . that successful explanations of the development of knowledge will come from attempts to tease these influences apart" (p. 323).

In this chapter, we show how current biological research does not support these types of divisions or dichotomies. A major goal of this chapter is to make the case that if there is any lesson to be learned by developmental scientists from advances in the biological sciences, it is that "biology" and "experience" are completely fused and cannot be meaningfully separated or teased apart. In what follows, we outline and apply *developmental psychobiological systems* (DPS) to the enduring challenge of mapping out the relational causes of development, and we examine its relevance to the study of human development (see Overton, Chapter 2, this *Handbook*, this volume, for the close association between DPS and *relational developmental systems*).

Rather than viewing nature (genes or heredity) and nurture (environment or experience) as separate sources of information during development, DPS recasts nature and nurture in terms of product and process (Figure 5.1). The structure (anatomy, skills, habits, preferences) of an individual at any given time represents one's nature, and nurture is the process that organizes, maintains, and transforms one's nature (Oyama, 1985, 2002). From this view, organisms inherit *resources* for development, not trait or characteristics or specifications for traits or characteristics (Johnston, 2009; Overton, 2010, Chapter 2, this *Handbook*, this volume). DPS thus emphasizes that the pattern of internal and external factors involved in development and their temporal and spatial relations cannot be specified or predetermined in a genetic program (Griffiths & Tabery, 2013). Simply put, development is an historical process, not a programmed one. At whatever stage of the life cycle we identify a particular characteristic or capacity, a history of development already lies behind it. This hard won insight took most of the last century to achieve.

DEVELOPMENTAL PSYCHOBIOLOGICAL SYSTEMS

Before reviewing the central tenets of DPS, it is important to point out that DPS is a *meta*theoretical position or orientation (Godfrey-Smith, 2001). All scientific endeavors reflect some kind of metatheoretical assumptions about the relevant subject matter and how to study it (see Overton, 2006, 2013, Chapter 2, this *Handbook*, this volume) and DPS provides what we believe are productive assumptions for the scientific study of development in ways

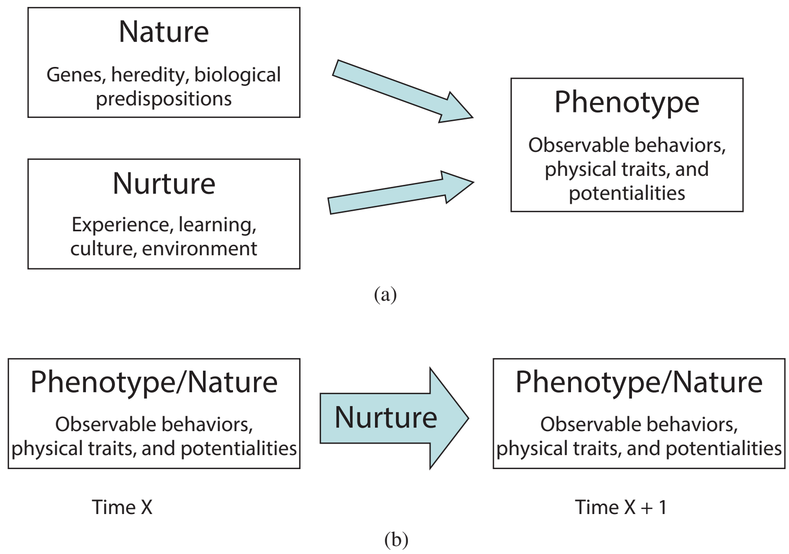

Figure 5.1 Contrasting views of nature—nurture relations. (a): Traditional conceptions of nature and nurture promote the two as separate sources contributing to phenotypic outcomes. (b): The developmental psychobiological systems view proposes that nature is best viewed as the dynamic product of the process of nurture, broadly defined to include all relevant developmental resources.

that are biologically plausible and that avoid misleading oversimplifications. Moreover, with its emphasis on process, activity, change, emergence, and self-organization, DPS is a *relational* metatheory of development (R. M. Lerner, 2006; R. M. Lerner & Benson, 2013a; Overton, 2006, 2010, 2013). DPS is, in fact, what Overton (2013, Chapter 2, this *Handbook*, this volume) has termed a *midrange metatheory,* functioning between the ontological and epistemological assumptions of a relational worldview and the specific concepts of any particular theory.

The roots of DPS trace back more than 50 years ago to a group of psychobiologists (many associated with the American Museum of Natural History) concerned with the role of experience in the development of behavior across a range of vertebrates and invertebrates (e.g., Denenberg, 1964; Gottlieb, 1971; Kuo, 1967; Lehrman, 1953, 1970; Levine, 1957; Moltz, 1963; Rosenblatt, 1969; Schneirla, 1956, 1966; Tobach & Schneirla, 1968; Turkewitz, 1977; see also Aronson, Tobach, Lehrman, & Rosenblatt, 1970). This research tradition was primarily concerned with the development of species-typical behavior of animals in their natural habitats, with a particular interest in the behavioral and psychological adaptations distinctive to each species and how these adaptations were modified in response to changing internal and external conditions. Because most species-typical behaviors were presumed to be innately (i.e., "biologically") determined at this time (Lorenz, 1937, 1950), DPS largely coalesced as a reaction to the widespread notion of genetically determined "instinctive" behavior (Lehrman, 1953; Schneirla, 1956).

CONCEPTUAL AND EMPIRICAL OBJECTIONS TO NATIVISM

In the early 20th century it was generally accepted that humans and other animals possess a basic set of unlearned (presumably inherited) instincts at birth (although others might appear at later ages). William James promoted the importance of instincts in his influential *Principles of Psychology* (1890) and William McDougall (1909) famously identified 12 major human instincts, including curiosity, gregariousness, and self-assertion (his list would grow to 17 several decades later). Psychologists of this era were divided on the types and number of instincts, but few questioned their existence. Even students of animal learning viewed instinct as a powerful influence on behavior. Edward Thorndike (1918), for example, proposed that,

> Any man possesses at the very start of his life—that is at the moment when the ovum and spermatozoön which are to produce him are united—numerous well defined tendencies for future behavior. Between the situations in which he will meet and the responses he will make to them, preformed bonds exist. It is already determined by the constitution of these two germs, that under certain circumstances he will see and hear and feel and act in certain ways. (p. 2)

Like most other psychologists, Thorndike wanted to experimentally separate that which was learned from that which is original in the nature of animals, including humans "to get the association process free from the helping hand of instinct" (Thorndike, 1911, p. 30).

By the 1920s the instinct concept had become a source of heated debate in psychology (Bernard, 1921; Carmichael, 1925; Dunlap, 1919; Kantor, 1920; Tolman, 1923), where criticisms of the instinct concept centered on its vagueness and circularity and on its nondevelopmental stance that instincts were determined by heredity, whereas other behaviors were the result of learning (see Johnston, 2009). Adding fuel to this debate was Zing-Yang Kuo (1898–1970), who proposed that not only were there no instincts in the traditional sense, but that the very distinction between instinctual versus learned characteristics was fallacious and served to stifle developmental analysis (see Honeycutt, 2011). Kuo noted that the instinct concept provided a "finished psychology," in the sense that it assumed an explanation of the origins of behavior by simply giving it a label. Lehrman (1953) captured the core of this shortcoming more than 60 years ago:

> Any instinct theory which regards "instinct" as immanent, preformed, inherited or based on specific neural structures is bound to divert the investigation of behavior development from fundamental analysis and the study of developmental problems. Any such theory of "instinct" inevitably tends to short-circuit the scientist's investigation of intraorganic and organism-environment developmental relationships which underlie the development of "instinctive behavior." (p. 359)

Kuo (1930, 1938) supported his theoretical position by the results of his various lines of comparative research. For example, he challenged the "rat-killing" instinct in cats by raising kittens in a variety of different social environments. Some kittens were raised with or without an adult cat, and some kittens were raised with rodents (rats or mice). Every few days each kitten was given the opportunity to chase and kill an unfamiliar rodent. After 4 months of testing, more than 90% of those kittens raised with adult cats killed a rodent compared to less than half of those kittens raised in groups without adults. More strikingly, less than 10% of those kittens raised with rodents had killed a rodent by 4 months of age. Indeed, these rodent-raised kittens showed numerous attachment-related behaviors (e.g., separation anxiety) to their rodent cage mates. In addition, Kuo took those kittens that did not kill rats and exposed them to an adult cat that killed a rodent in their presence. This experience had a profound impact on kittens raised without adults (100% killed rodents) but had a much smaller effect on those raised with rodents (10% killed rodents). Clearly, the development of the so-called rat-killing instinct, far from being unlearned or built-in, depended on the early raising conditions and experiences of kittens. If one is to speak of a rat-killing instinct, then one must also speak of a rat-loving instinct as well, at which point the instinct concept itself becomes useless. As Kuo (1930) succinctly put it: "nothing is more natural than for the cat to 'love' the rat . . . and if one insists that the cat has an instinct to kill the rat, I must add that it has an instinct to love the rat, too" (p. 35).

Kuo's raising experiments underscored the *probabilistic* nature of behavioral development. Over the course of development, each individual encounters its own unique array of experiences, opportunities, and constraints, thereby making some behavioral outcomes more likely to be supported and maintained and others prevented or eliminated. The enormous range of the *possible* becomes the *actual* behavior we observe as a result of the organism's real-time active experience, its developmental history, and the nature and features of its developmental context. Artificial divisions and descriptive labels like nature and nurture (and related dichotomies such as instinct versus learning) fail to capture these underlying dynamics of individual development and in so doing hinder progress in understanding the ways and means of basic life processes (Keller, 2010).

The shortcomings identified by Kuo in regard to instinct are equally problematic for more modern nativist notions regarding the causes of behavior (i.e., maturation, biological predispositions, developmental programs), as these accounts of development presuppose the very phenomenon that is to be explained. Thelen and Smith (1994) have pointed out that most major theoretical systems associated with the study of human development have had a common teleological core that implicitly assumes an "end state" before the process of development even begins (see also Overton, 2010, Chapter 2, this *Handbook*, this volume). In this sense, nativism is a thoroughly nondevelopmental concept, and as previously noted, effectively serves to sidestep empirical developmental analysis. Echoing the earlier claims of Lehrman and Kuo, Stotz (2008) argues that

> The main problem with all allegedly explanatory categories and concepts of behavior, such as instinctive, learned, or genetically programmed, is that they block further investigations into real ontogenetic and evolutionary causes of a behavior just by their very nature of purporting to explain while really doing nothing but labeling it. (p. 365)

For example, claims that aspects of behavior or cognition are prespecified assume that such "primitives" are not subject to development. As a result, studies conducted to document innate (i.e., biologically determined) abilities or knowledge at best only provide information about *what* individuals can do and *when*. The *how* question is overlooked by invoking the presumed action of genetic programs, instructions, or predispositions. Similar problems arise by calling something environmentally determined or "due to learning." In either case, this kind of simple determinism glosses over the complex developmental dynamics involved in the generation of all an organism's characteristics. A DPS orientation encourages researchers to focus on *how* phenotypes actually develop, and emphasizes that any explanation of phenotypic development will involve a system of interrelated factors that become causally relevant by their coactions (see Bateson, Chapter 6, this *Handbook*, this volume, for a similar analysis from an ethological perspective).

A common misunderstanding used to challenge a DPS orientation is to conflate DPS's denial of preformationism (i.e., innate [i.e., biologically determined] preferences or "core" knowledge) with the extreme empiricist position that individuals begin life as "blank slates" (Pinker, 2002). Animal and human newborns are not blank slates; they display an array of biases, preferences, and proclivities following birth. However, like any other trait or characteristic of an organism, these biases and predispositions must develop (Harshaw & Lickliter, 2011; Moore, 2009; Spencer et al., 2009). To claim that predispositions are "biologically given" or "innate" is a thoroughly nondevelopmental point of view that says nothing about the developmental origins of these early behaviors.

The Roles of Experience

To move away from simple (internal or external) models of determinism requires a reformulation of what is meant by experience. Traditionally, the way in which experience was thought to affect the development of behavior was through various forms of learning (Johnston, 2009). However, as pointed out by a number of prominent developmental psychobiologists during the last half century (e.g., Gottlieb, 1976; Kuo, 1967, Lehrman, 1953, 1970; Schneirla, 1956), it is important to keep in mind that *experience* is not synonymous with *learning*, but rather refers much more broadly to function or activity (Overton, 2006, Chapter 2, this *Handbook*, this volume), and is construed very broadly to include the electrical activity of neurons and their processes, neurochemical and hormonal secretion, the use of muscles and sensory systems, and the behavior of the organism itself. Thus, the term *experience* is also not synonymous with *environment*, but rather refers to functional activity at the neural, physiological, and behavioral levels of analysis.

Importantly, experience may contribute to development in subtle and often nonobvious ways, as was elegantly demonstrated by Gottlieb's decades-long research project on the development of species identification in ducklings (reviewed in Gottlieb, 1997). Ducklings have to hear their own or broodmates' prenatal vocalizations to show species-specific responsiveness to their respective maternal call following hatching. Ducklings denied this normally occurring experience failed to show a preference for their species-specific maternal call. The finding that prenatal experience plays a formative role in the development of species-typical behavior provided empirical support for Gottlieb's notion of *probabilistic epigenesis* (1971, 1991, 2007), a core tenet of the DPS framework, which holds that because of the rich traffic of bidirectional influences within and between levels of analysis, individual development cannot have a predetermined trajectory.

Integrative Levels: Situated Relational Causality

For all multicellular organisms, there is a hierarchy of integrated levels, including genes—cells—tissues—organs—organ-systems—organism—populations. Another core tenet of the developmental psychobiological systems approach is that developmental causation is both "bottom up" and "top down" (see Overton, Chapter 2 and Witherington, Chapter 3, this *Handbook*, this volume). Genes and all other levels of the hierarchy are recognized as part of a complex system, in which the cytoplasm can influence the genes, extracellular hormones can influence the cell nucleus, external sensory stimulation can influence the genes, hormones can be influenced by the external environment, and so on (Gottlieb, 1997, 1998). From this framework, the influence that any component may have on other parts can extend to higher or lower levels, or remain at the same level. The relations between components are bidirectional or reciprocal (←→), whereby one component that affects another can be influenced by it in turn. Within this context it has generally been useful to differentiate all additive forms from these reciprocal relations by referring to the latter as *coactions* (Gottlieb, Wahlsten, & Lickliter, 2006). We continue this tradition here—except when *interaction* appears in a quote or is appropriately used—and will understand *coaction* as similar to other relational terms used to describe nonadditive influences. These include the concepts of *reciprocal determination* (Overton & Reese, 1973), *fusion*, (Greenberg, 2011; Partridge, 2011), *relational bidirectional* (←→) *causality* (R. M. Lerner, 2006), *relational causality* (Gottlieb & Halpern, 2002; Overton, 2006), and *circular causality* (Witherington, 2011).

An appreciation of the importance of integrative levels is not a new concept in biology (e.g., Novikoff, 1945; Russell, 1930; Schneirla, 1949, 1956; von Bertalanffy, 1933; Woodger, 1929; see also Greenberg & Tobach, 1984), but was not widely applied during most of the past century due to the prevalence of the gene-centric approach to development outlined earlier. This pattern has shifted in recent decades, due in large part to advances in molecular genetics, endocrinology, neuroscience, and developmental biology. As we review later, across biological and psychological domains there is a growing emphasis on the importance of genetic-environmental coactions, requiring complicated systems analyses to address the multiple part-whole dynamics underlying the process of development (Kohl, Crampin, Quinn, & Noble, 2010; Noble, 2010).

More than 50 years ago, the embryologist Paul Weiss (1959) provided a simple but useful diagram (Figure 5.2) of the hierarchy of reciprocal influences he thought to be involved in the process of development. His diagram represents a hierarchically organized system of increasing size, differentiation, and complexity, in which each component affects, and is affected by, all the other components at its own level as well as at lower and higher levels. Weiss's arrows of influence thus not only go upward from the gene, eventually reaching all the way to the external environment through the activities of the organism, but also return from the external environment through the various levels of the organism back to the genes. In this model, functional coactions occur both within levels and at the interfaces of the various levels of the hierarchy.

For example, the causal interconnections that have been found to underlie the expression of reproductive behavior in the ring dove (*Streptopelia capicola*) illustrate the rich network of internal and external factors involved in their courtship, nest-building, egg-laying, incubation, and parental care. Our knowledge of ring dove reproductive behavior, based in large part on studies by Lehrman (1964, 1965) and Michel (1986), recognizes the historical, contingent, and dynamic nature of phenotypic outcomes by demonstrating that: (a) hypothalamic, pituitary, and gonadal functions, essential for the range of reproductive

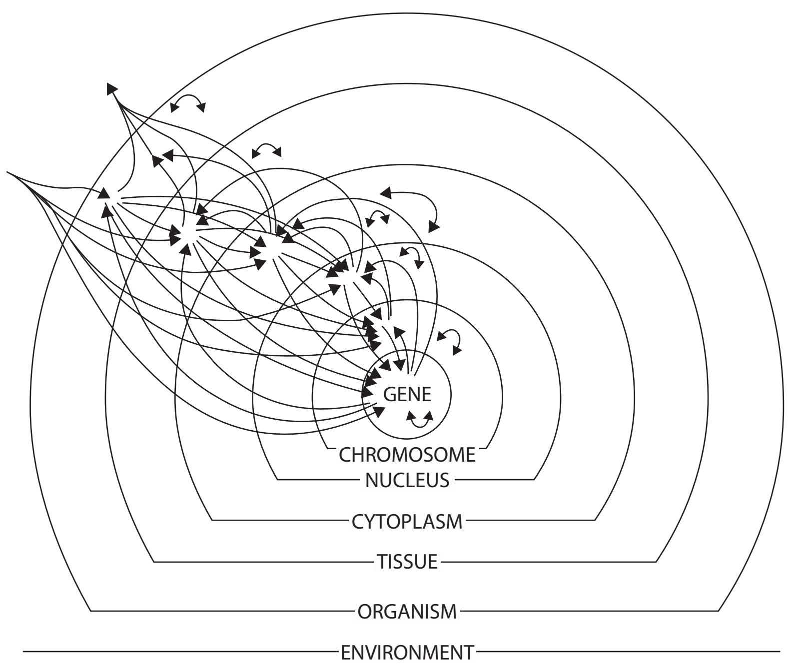

Figure 5.2 Embryologist Paul Weiss's representation of the hierarchy of reciprocal influences involved in development. Weiss's hierarchy spans from the lowest level of organization (gene) to the highest level (external environment). As such, the diagram represents a hierarchically organized system of increasing size, differentiation, and complexity, with feed-forward and feed-backward traffic within and across levels of organization.

Source: From "The Significance of Biology for Human Development: A Developmental Psychobiological Systems View" (p. 215), by G. Gottlieb, D. Wahlsten, and R. Lickliter, in *Theoretical Models of Human Development*, R. M. Lerner (Ed.), Volume 1 of the *Handbook of Child Psychology*, 6th ed., W. Damon and R. M. Lerner (Editors-in-Chief), 2006, Hoboken, NJ: Wiley.

behaviors seen in ring doves, are largely determined by the social and physical stimuli associated with the reproductive cycle (i.e., the long days of spring, the presence and activities of the mate); (b) changes in levels of circulating hormones influence the dove's sensitivity to specific social and physical stimuli (i.e., the presence of a nest, the activities of the newly hatched young); and (c) the dove's prior reproductive experience alters the pattern and regulation of behavior by its influence on the sensitivity of the dove's nervous system to specific hormones and to social and physical stimuli (see Michel & Moore, 1995, for further discussion).

Taken together, the coactional traffic between neural function, hormones, behavior, and environmental resources involved in the reproductive behavior of the ring dove highlights the difficult but critically important task of developmental analysis—filling in the bidirectional details among the specific internal and external factors contributing to the generation of any phenotypic trait or character. An understanding of the ring dove's reproductive behavior was not achieved by examining only neurological, endocrine, or physiological levels of analysis; it also required detailed information about the organism's physical and social milieu. In keeping with another basic tenet of the developmental psychobiological systems approach, the causes of reproductive behavior in the ring dove can be said to be distributed across several levels of organization. In any given aspect of the reproductive process, some factors might be more central and predominate more than others, but the variety of factors at play always operate in a context in which their effects are dependent on their relation with other factors. Understanding development thus requires, as suggested earlier, a relational concept of causality (Gottlieb & Halpern, 2002; Overton, 2006, Chapter 2, this *Handbook*, this volume).

The relational integrative framework illustrated in Weiss's diagram (Figure 5.2) is fundamental to developmental psychobiological systems (Gottlieb et al., 2006; Griffiths & Tabery, 2013; Hofer, 1981; Michel & Moore, 1995) and as we explore later, is now being successfully applied across multiple levels of inquiry across biology, including genetics, epigenetics, neuroscience, and evolutionary biology. The insight that the causes and control for development do not reside in any one factor or component, but rather reside in the nature and dynamics of the relations among factors *internal* and *external* to the organism has shifted thinking about development away from the internally based, prespecified framework prevalent for most of the past century and toward an appreciation of development as a *situated process* that is dependent on resources distributed across the organism-environment system. In other words, control of development is exerted by the regulatory dynamics of the gene-in-a-cell-in-an-organism-in-an-environment system (Oyama, 1985; Robert, 2004). Recognizing that development is a process that is fundamentally "situated" represents a major shift in thinking from the largely decontextualized, internally driven view of development that dominated the life sciences for most of the past century.

The contemporary developmental psychobiological systems framework (e.g., Ford & Lerner, 1992; Gottlieb, 1997; Griffiths & Gray, 1994; Griffiths & Tabery, 2013; Johnston, 2009; Lickliter & Berry, 1990; Michel, 2010; Moore, 2002; Overton, Chapter 2, this *Handbook*, this volume; Oyama, 1985; Oyama, Griffiths, & Gray, 2001) extends this core principle and emphasizes that because of the reciprocity of influences within and between levels of analysis within the organism-environment system, attempts to partition developmental outcomes into those attributable to the genes and those that are the result of the environment is simply not possible. Attempts to dichotomize developmental causality into "nature" and "nurture" effectively ignore the multiple levels of influence, resources, and coactions between genes and behavior (Gottlieb 2007; Johnston & Edwards, 2002; Meaney, 2010), thereby isolating developmental psychology and its concerns from developmental genetics, developmental biology, and developmental neuroscience (Gottlieb et al., 2006). A particular aim of developmental psychobiological systems approach has thus been to replace the simplistic metaphor of a genetic program with a more accurate account of genetic and nongenetic influences on development.

Situating Genes in the Developmental System

Schaffner (1998) outlined five concepts that DPS applies to the relations between genes, development, and behavior. These include: *parity,* the idea that genes are not privileged but rather are one part of an integrated developmental system; *nonpreformationsim*, the idea that we will not find the "information" for characteristics in genes, as all phenotypic characteristics are generated by the process of development; *holism*, the idea that genes have meaning only in the context of other genes and their cellular, extracellular, and extraorganismal environment; *indivisibility*, the idea that the separate effects of genes and environment on characteristics cannot be identified in any meaningful sense; and *unpredictability*, the idea that it is not possible to predict *a priori* an organism's characteristics, as they are emergent in the process of development. These five core concepts are consistent with a *relational* metatheory of development (Overton, 2006, 2013, Chapter 2, this *Handbook,* this volume), with its emphasis on process, activity, change, emergence, and self-organization.

An example from the study of anatomical development serves to illustrate this shift in emphasis. From the gene-centered view dominant over much of the past century, limb development was seen as a relatively straightforward process—genes were thought to provide the specific instructions for the growth and development of bone and muscle, thereby accounting for the observed stability of form and function within a species and across generations. Evidence from developmental biology indicates a more complicated and distributed explanation. In vertebrates the *active movement* of the embryo is required for the normal or species-typical development of bone, joints, muscles, tendons, and ligaments (Müller, 2003). For example, the fibular crest is a leg bone that connects the tibia to the fibula in most bird species. It allows the force of the iliofibularis muscle to pull directly from the femur bone to the tibia bone. This direct connection between the femur and tibia is important, as it allows the reduction in size of the femur bone seen in birds when compared to mammals. Developmental biologists have shown that when chicken embryos are prevented from moving within the egg during periods of their prenatal development, this bone fails to develop (Müller & Steicher, 1989).

Under the normal conditions of prenatal development the bird embryo is subjected to ongoing stimulation from a host of factors, including gravity, thermal gradients, amnion contraction, maternal stimulation, and also self-stimulation of its own muscles, joints, and sensory systems as it moves and positions itself in the egg (or in the case of the mammalian embryo, the uterus). For example, in the chick embryo the first muscle contractions are observable by the third day of incubation. The prenatal environment (and later the more complex postnatal environment) thus provides a range of stimulation and activity that turns out to be essential for normal anatomical, physiological, and behavioral development (see Gottlieb, 1997; Lickliter, 2005, for behavioral examples). In the example of skeletal development, the *use and exercise* of the chick embryo's leg turns out to influence gene expression, the activity of nerve cells and their processes, as well as the release of various neurochemical and endocrine secretions during prenatal development. All of these factors and their coactions are necessary resources for the normal development of the skeleton of the young bird, starting with the patterned deposition of cartilage-forming cells, the precursors of the bones (Streicher & Müller, 1992). Similar processes are undoubtedly at play in human fetal development.

The complex coactions between genes, gene products, self-stimulation, and external influences involved in avian skeletal development illustrates a basic feature of the process of development appreciated by most biologists and developmental scientists—what a gene does in the sense of what it provides development depends on the expression and activity of other genes, as well as nongenetic factors internal and external to the organism. In other words, genes are not exempt from influences at other levels of analysis and are, in fact, dependent on them for initiating and terminating a sequence of activity. The same contingency applies to the influence of any other factor or developmental resource (e.g., hormone level, neural activity, sensory experience, social coaction). The anthropologist Tim Ingold (2004) has noted that,

> If genes interact with anything, it is with other constituents of the cell, which interacts with other cells in the organism, which interacts with other organisms in the world. It is out of this multilayered process that the capacities of living beings emerge. In other words, these capacities are outcomes of the whole *developmental system* comprised by the presence of the organism, with its particular genetic and cellular composition, in its environment. (p. 217)

A common misunderstanding of the DPS approach is to conflate its "parity thesis" (the tenet that genes are not privileged sources of developmental information) with the notion that genes are relatively unimportant or play a limited role in the achievement of many phenotypic outcomes. The developmental biologist Scott Gilbert (2003), for example, has argued that because DPS places all developmental factors (e.g., genes, cells, environments) on the same informational level, it makes an error of not distinguishing between those factors that are instructive versus those that are merely permissive. Instructive information, he argues, is typically a function of genomes. To illustrate this point, Gilbert draws on the classic work of the experimental embryologist Hans Spemann (1869–1941), who transplanted the jaw-forming region of an early frog gastrula into the jaw-forming region of a salamander embryo (and vice versa). Following these experimental manipulations, the young salamanders developed frog-like jaws and the frogs developed salamander-like jaws. Gilbert argues that this remarkable morphological specificity is best explained by the genome of salamanders and frogs.

To single out genes as the source of species-specificity in this example is, however, misleading. Spemann transplanted jaw-forming *tissues*, not just genes. Moreover, the instructive power of jaw-forming tissue is itself contingent on a variety of other factors. What would be the outcome if the jaw-forming tissue was excised and transplanted at earlier or later points during embryogenesis? What if the jaw-forming region of a frog gastrula was transplanted to a different (non-jaw-forming) body region of the salamander embryos? The DPS framework emphasizes that the property of morphological specificity (as well as physiological or behavioral specificity) depends on a complex system of nested temporal and spatial factors distributed well beyond the genome. To make this claim does not mean that frog and salamander genes are unimportant; they are critical to the process of jaw formation. However, formation of these structures is a function of the process of development, not simply “information” provided by the genes. Given that development is always the result of a series of elaborate temporal and spatial coactions within and between levels that are inherently context dependent (e.g., Coen, 1999; Nijhout, 1990; Noble, 2006), DPS holds that it is not possible to meaningfully assign “instructive” control to any one variable of the developmental system.

In the next sections, we review and provide some examples supporting this developmental point of view using findings drawn from genetics, epigenetics, neuroscience, ecology, and evolutionary biology. Our overview is not intended to be thorough and is highly selective, as our examples have been screened through the authors’ own interests and with an eye to the interests and concerns of developmental scientists.

GENES, EPIGENETICS, AND DEVELOPMENT

Earlier we briefly traced the history of the gene concept in biology and noted how genes were assigned a privileged role in development throughout most of the past century. Genes were thought to direct the development of the organism and nongenetic environmental factors were deemed necessary for normal development, but only in the sense that they supported or in some way triggered the unfolding of genetic information. As a consequence, it was assumed that an understanding of the structure of the genome and the mechanisms of gene regulation were both fundamental to an understanding of development and also sufficient for this understanding (Nijhout, 1990). Moreover, genes were assumed to be the sole source of biological heredity. From this view of development, the instructions for building organisms were present in their genes and genes were also the exclusive means by which these instructions were transmitted from one generation to the next.

These traditional assumptions about genes have been seriously challenged by evidence drawn from molecular genetics, cell biology, and the rapidly growing field of epigenetics. Not to be confused with *epigenesis*, which refers to the causal coactions that bring about embryonic form, *epigenetics* is a term used by molecular and developmental biologists to refer to modifications of gene activity in the absence of any alteration to DNA sequence. More broadly, epigenetics is used to refer to developmental and hereditary influences arising from environmental effects (Ho, 2010; Meaney, 2010). The developmental biologist Conrad Waddington first described epigenetics more than 70 years ago as the branch of biology that studies the causal coactions of genes with their environment that bring the phenotype into being (Waddington, 1942; see also van Speybroeck, 2002). The genetic, molecular, and cellular details of phenotypic development were poorly understood at that point in time. Based in part on his experimental work with fruit flies, Waddington came to question the canonical view that there was a simple correspondence between genes and phenotypic characteristics and proposed that only an understanding of the coaction of genes with each other and with the internal and external environment of the organism could successfully account for phenotypic development. Waddington was advocating a new conceptual framework for the study of development and evolution, one that emphasized changes in what he termed *developmental systems*. From this view, the contribution of the genome always depends on the influence of the features of its surrounding contexts, beginning with the cytoplasmic environment provided by the mother’s egg at conception. Waddington’s efforts to integrate genetics, development, and evolution was well ahead of the prevailing consensus of his time and was motivated by what he viewed as the inability of population genetics to provide a workable model of the operation of genes in development and evolution (Hall, 2001).

Contemporary epigenetics includes the study of how patterns of gene expression are passed from one cell to its descendants, how gene expression changes during the differentiation of one cell type into another, and how environmental factors can modify how genes are expressed. Contrary to Weismann's influential doctrine of the "encapsulated" genome that dominated 20th-century biology, contemporary epigenetic research has provided abundant evidence demonstrating that genetic activity is regularly influenced by neural, behavioral, and environmental events, both in real time as well as across the course of development and across generations (see Charney, 2012; Gottlieb, 1998; Hallgrimson & Hall, 2011; Jablonka & Lamb, 2005; Jablonka & Raz, 2009; Keller, 2010; Meaney, 2010, for multiple examples). As a result of these findings, many biologists have moved away from the notion of genes as the primary or privileged cause of phenotypic characteristics to one of genes as cooperative players in a complex hierarchical web of regulation (e.g., Bateson, Chapter 6, this *Handbook,* this volume; Bateson & Gluckman, 2011; Gilbert & Epel, 2009).

For example, studies with fish, birds, and mammals have demonstrated that social stimulation can also lead to changes in brain and behavior through effects on the genome (Robinson, Fernald, & Clayton, 2008). Some of the first demonstrations of gene response to social stimuli came from studies of immediate early genes in songbirds (Clayton, 2000; Mello, Vicario, & Clayton, 1992). Immediate early genes (IEGs) are a class of genes that are rapidly expressed in response to particular forms of environmental stimulation (as opposed to genes that are expressed only when other genes induce them to contribute to protein production). For instance, in the male zebra finch, the singing of another male bird induces the expression of *egr-1* (also known as *zif-268)*, a transcription factor-encoding gene, in a region of the bird's auditory forebrain involved in hearing. Other types of social coactions have been found to effect the expression of *egr-1* in other regions of the songbird brain and can vary based on the immediate context of the experience. Expression of *egr-1* can be induced by brief social experiences (with effects seen within minutes) and can immediately enhance or suppress the transcription of other genes. Many other transcription factor-encoding genes in addition to *egr-1* have subsequently been shown to increase or decrease their expression in the male zebra finch auditory forebrain within 30 minutes of the onset of an unfamiliar male song (Replogle et al., 2008).

These types of findings have fostered a deeper appreciation across both biology and psychology of the responsiveness of gene activity to internal *and* external regulatory influences. As Nijhout (1990) pointed out some years ago,

> A single genotype can produce many different phenotypes, depending on the contingencies encountered during development. That is, the phenotype is the outcome of a complex series of developmental processes that are influenced by environmental factors as well as by genes. Different environments can have an effect on the outcome of development that is as profound as that produced by different genes. (p. 445)

Our understanding of how this is so has advanced significantly in recent years, due in large part to advances in genomics and epigenetics.

The Relational Gene

Traditional molecular genetics defined a gene as a protein coding sequence of DNA nucleotides. More specifically, a "gene" referred to a DNA sequence that is transcribed to produce a messenger RNA molecule that in turn is processed to produce a protein or a functional RNA. Advances in molecular genetics over the past several decades have called this definition into serious question and suggest it will have to be replaced with a different explanatory framework (see Keller, 2000). As we review later, we now know that genes may be coded in pieces that need to be combined, the same DNA sequence can result in different proteins due to alternative splicing, and gene regulation can span multiple genes.

Before a gene can be transcribed, a "reading frame" must be established to determine where transcription begins and ends. Some genes are known to overlap, so that depending on the state of the surrounding context, the same region of DNA can be read in different ways. For example, under one set of conditions a particular region might be used as a promoter (involved in initiating transcription), whereas under a different set of conditions that same region may be read as a coding region (part of the template used in protein synthesis, see Stotz, 2006). Thus, it is the surrounding context and system of RNA factors that in some sense brings a "gene" into being. Neumann-Held (1999) captured this dynamic quality of the genome, arguing that "there is no fundamental way by which the classical . . . gene concept could be applied to DNA segments. One focuses at the same bit of DNA, and different structures and functions can appear. One focuses on different levels of the expression process . . . and again different structures and functions appear" (p. 125).

Once a gene sequence is transcribed from DNA to mRNA, a complex series of events takes place before the mRNA exits the nucleus of the cell. The transcribed RNA contains numerous, noncoding nucleotide sequences (*introns*) that must be removed, leaving only coding sequences (*exons*), which are spliced together and used in protein synthesis. However, depending on the state of the surrounding conditions, RNA can be edited in alternative ways, bringing about different proteins. In one extraordinary case, an mRNA transcript of a single fruit fly gene can be spliced into over 38,000 different protein variants (Schmucker et al., 2000). It has been estimated that about 65% of human genes undergo alternative splicing (Leipzig, Pevsner, & Heber, 2004). To complicate matters even further, it has been found that two gene sequences are sometimes combined to create a single mRNA transcript that is used to build novel proteins, and in still other cases, exons from different mRNA transcripts can be combined in a single transcript (called *trans-splicing*; see Gerstein et al., 2007).

Even after the translation process, contextual factors continue to play an informative role in the construction of proteins. Once amino acids have been strung together, proteins must fold into a particular shape, and this shape determines its particular function. It used to be thought that proteins and their shape and function were coded by contiguous stretches of DNA arranged on the chromosome like beads on a string. The sequence of amino acids (specified by DNA) is certainly an important factor involved in protein folding, but numerous other factors have also been identified in determining protein shape. For example, study of the production of glucocorticoid receptor protein variants has revealed at least eight different versions of the glucocorticoid receptor *a* protein, each produced from the same gene and the same mRNA (Lu & Cidlowski, 2006). Importantly, this diversity is not associated with variation in nucleotide sequence, but rather is dependent on the cellular context within which the gene is activated. According to Meaney (2010),

> Both the form and the function of the protein product are defined by context. The function of the gene can only be fully understood in terms of the cellular environment in which it operates. And the cellular environment, of course, is dynamic, changing constantly as a result of signals from other cells, including those that derive from events occurring in the external environment. (p. 48)

Given the number of factors, events, and contingencies involved in synthesizing proteins, it no longer seems meaningful to say that genes code for protein synthesis. This has led some to redefine genes as *relational entities or processes that include DNA and a host of other factors involved in the production of proteins by cells* (see Gonzalez-Pardo & Alvarez, 2013; Neumann-Held, 1999; Stotz, 2006).

It should be clear from the discussion thus far that it is not possible to identify what DNA segments constitute a gene, let alone predict what proteins a particular gene might contribute to, without knowledge of the cell structure and the state of its surround. Whether a gene is transcribed, to what extent, and what kinds (and amounts) of proteins are produced are all contextually contingent, involving a host of other molecules besides DNA. As Stotz (2008) put it, "The factors that interactively regulate genomic expression are far from background conditions or supportive environment; rather, they are on a par with genetic information since they co-specify the linear sequence of the gene product together with the target DNA sequence" (p. 364).

Epigenetic Processes and Gene Regulation

Difficulties in demarcating the boundaries between gene and environment are exacerbated when we take into account how gene transcription is regulated and maintained by cellular processes over time. Genes are not self-expressive and the presence of a gene as part of an individual's genotype does not mean that it will necessarily be transcribed (Charney, 2012; Slavich & Cole, 2013). We now know that there are complex cellular processes that lie between the gene, its expression, and the functional outcome associated with the gene's product. These cellular processes, often referred to collectively as the *epigenome*, the complex biochemical regulatory system that silences or activate gene expression, began to be studied in the mid-1970s as researchers focused on how cells that have differentiated (for example, into liver cells or brain cells) remain differentiated over time and transmit their specialized state to daughter cells. In addition, effort was devoted to understanding the processes involved in X-chromosome inactivation (when one X chromosome is silenced in XX females) and gene imprinting (when genes are silenced based on parent of origin). Subsequent studies (see Martin & Zhang, 2007) detailing the processes by which genes could be expressed or not expressed led to the discovery of several cellular processes by which genetic expression could be regulated (see Figure 5.3).

To understand the regulatory mechanics of gene transcription, one must first appreciate how chromosomes

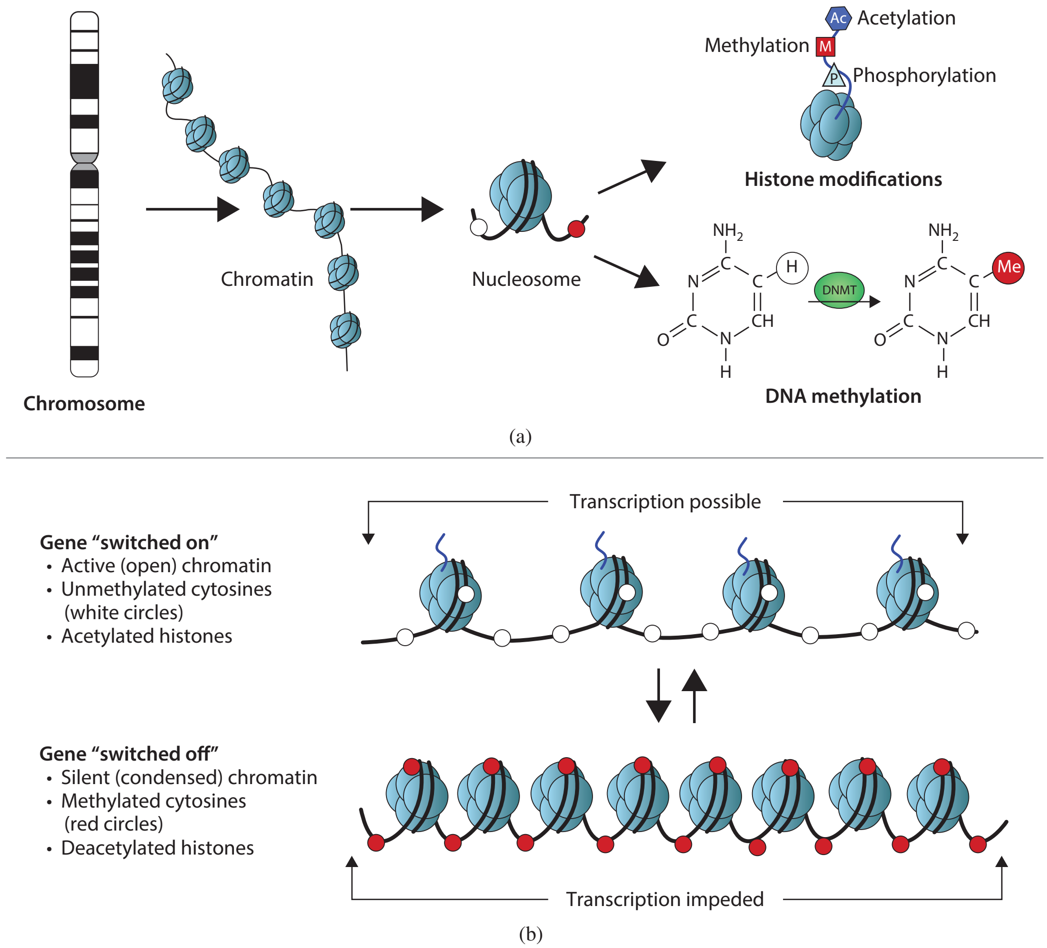

Figure 5.3 Schematic of epigenetic modifications that influence gene expression. A depiction of DNA methylation, histone modification, and their effects on gene activation. (a): Strands of DNA are wrapped around histone octamers, organized into chromatin. DNA methylationn provides a unique epigenetic signature that regulates chromatin organization and gene expression. (b): Genes are expressed when the chromatin is open (*active*) and are inactivated when the chromatin is condensed (*silent*).

Source: From *Basic Principles of Genetics*, by P. Luong, 2009. Retrieved from http://cnx.org/content/m26565/1.1/

are packaged within cell nuclei. In humans, the 23 pairs of nuclear chromosomes span approximately 2 meters of DNA (Sultan & Day, 2011). As a result, nuclear DNA does not float freely in the nucleus but is compacted and entwined around core histone proteins that are densely packed together in structures called *chromatin*. More specifically, negatively charged nuclear DNA is wrapped around (and attracted to) positively charged histone proteins in a series of beadlike structures (nucleosomes). For transcription factors to gain access to DNA to initiate gene transcription, chromatin must be chemically altered to loosen the connection between DNA and histone proteins. This alteration involves the addition or removal of molecules (e.g., acetyl or methyl groups) via enzymes on the histone proteins, thereby altering the overall charge (see Meaney, 2010). Depending on how this charge is altered, the connection between DNA and histone proteins can be loosened or strengthened, thereby making DNA regions more or less accessible for transcription (Figure 5.3).

Space limitations preclude a review of all of the known processes, so in what follows, we focus on *DNA methylation*, the most studied of the chromatin modification processes. Methylation takes place when a methyl group attaches to the nucleotide base cytosine. Methylated cytosine attracts methyl-binding proteins that act as a physical barrier to the gene. The presence of methylated cytosine does not influence the structure of a protein if the gene is transcribed, but it does influence the likelihood that a gene will be transcribed (Jablonka & Lamb, 2005). Methylation patterns (and other chromatin systems) are reproduced in daughter cells during the replication of DNA, and thus appear to play an important role in differentiation and cellular memory. Specific cell types acquire their precise and well-defined functions through the process of differentiation; this process is largely directed through the process of DNA methylation, resulting in the expression of some genes and the silencing of others, and leading to the formation of differentiated neurons, blood cells, liver cells, and so on, which are identical in terms of their DNA sequences but differ in their epigenetic profiles (Gudsnuk & Champagne, 2011).

Environmentally Induced Epigenetic Effects on Development

Epigenetic processes are known to be responsive to environmental input, and these responses can bring about significant morphological differences, even in genetically identical individuals. As a case in point, genetically identical bee larvae differentially fed relatively high amounts of royal jelly develop into the more complex and fertile queen bees rather than sterile and less sophisticated worker bees. Kucharski, Maleszka, Foret, and Maleszka (2008) provide evidence that royal jelly yields its effect by influencing methylation patterns. For example, they were able to create adult bees with queen characteristics in the absence of royal jelly by silencing an enzyme that methylates a single gene, *dynactin p62* in the newly hatched larvae.

Initially, it was thought that plasticity of epigenetic modifications was limited to very early embryological development; however, this assumption has been challenged by evidence indicating environmentally induced epigenetic variation across the life span (Champagne, 2010; Slavich & Cole, 2013). For example, Fraga and colleagues (2005) found that significant differences in DNA methylation and histone acetylation patterns among monozygotic human twin pairs take shape over the first several decades of life. Interestingly, twins who spent less time together during their lives or who had different medical histories showed the greatest differences in their methylation and histone profiles. Further, the older the twin pair, the more different they were when compared to younger twins. For example, a 50-year-old pair of twins had 4 times as many differently expressed genes as did a 3-year-old pair (Fraga et al., 2005). Research has shown that divergent methylation patterns between twin pairs can be found at birth, indicating the importance of prenatal factors to gene activation (Ollikainen et al., 2010).

Advances in neuroscience and psychobiology have shown that epigenetic modifications play important roles in learning, memory, and cognition (see Graff & Mansuy, 2008; Sultan & Day, 2011; Sweatt, 2010, for reviews). One of the first suggestions that epigenetic processes are involved in learning and memory came from a study examining histone acetylation in the insular cortex, a brain region involved in novel taste learning (Swank & Sweatt, 2001). Subsequent research has also addressed the importance of histone acetylation and DNA methylation in object recognition and spatial and contextual memory. For instance, experiments with rodents have shown that the formation and recall of contextual fear memories (the association between a specific environment and an aversive stimulus) can be improved or impaired by drugs that act on enzymes involved in the methylation of histones (Levenson & Sweatt, 2005).

In a groundbreaking series of studies with rodents, Meaney and colleagues (see Champagne, 2010; Meaney, 2010; Zhang & Meaney, 2010, for reviews) have provided detailed evidence that the social environment during early development can affect physiological and behavioral response to stress in adulthood. Meaney and colleagues found that low levels of maternal licking and grooming during early postnatal development results in rat pups that grow up to show enhanced fearfulness and an increased hypothalamic-pituitary-adrenal response to stressful events when compared to pups that receive high levels of maternal licking and grooming. These differences are maintained in part by different levels of glucocorticoid receptors in the hippocampus. Weaver and colleagues (Weaver, Diorio, Seckl, Szyf, & Meaney, 2004) went on to identify more than 900 genes in the hippocampus that appear to be regulated by levels of maternal care. Using microarrays to monitor changes in hippocampal gene expression, they found 253 transcripts that were upregulated and 50 transcripts that were downregulated in rat pups of high versus low LG mothers. Following both drug manipulations and cross-fostering, a related study found that these epigenetic changes emerged during the first week following birth and regulated expression of these genes over the course of the life span (Weaver, Cervoni, et al., 2004).

Evidence has also linked epigenetic processes to stressful events in the prenatal environment. For example, Mueller and Bale (2008) found that adult male rats born to mothers who had experienced gestational stress showed changes in the expression of corticotropin-releasing factor (CRF) and glucocorticoid receptor genes and increased HPA-axis responsivity. In particular, prenatal stress exposure resulted in significantly reduced methylation in the CRF gene in both the hypothalamus and amygdala of adults.

In humans, newborns of mothers who experienced depression during the third trimester of pregnancy showed increased methylation of the glucorticoid receptor gene when compared to infants born to symptom-free women. This increase in methylation was positively correlated with salivary cortisol levels in response to stress at 3 months following birth (Oberlander et al., 2008). Methylation of this same gene in adult clinical (depressive and bipolar) samples has also been positively correlated with amount and severity of childhood abuse (Perroud et al., 2011). A study also reported a relation between depression in pregnant women and methylation of the serotonin transporter gene promoter in their newborns (Devlin, Brain, Austin, & Oberlander, 2010), providing further evidence that human gene activity is not impervious to environmental influences, but rather is a regulated and reactive component in the cellular system that is itself a regulated and reactive component in the individual's larger developmental system.

The implications of epigenetic processes for biological and psychological development are as yet not fully known, but clearly are significant (Gonzalez-Pardo & Alvarez, 2013; Masterpasqua, 2009; van Ijzedoorn, Bakermans-Kranenburg, & Ebstein, 2011). Epigenetic processes are increasingly recognized as a key means by which early life events can have long-lasting effects on neurobiology and behavior (Roth, 2012), and emerging evidence suggests that epigenetic factors may underlie various forms of disease and psychopathology (e.g., Graff, Kim, Dobbin, & Tsai, 2011; Isles & Wilkinson, 2008; Stuffrein-Roberts, Joyce, & Kennedy, 2008). For example, Cole and colleagues (Cole et al., 2007) identified 209 genes that were differentially expressed in circulating leukocytes from individuals reporting high versus low levels of subjective social isolation (loneliness), including genes involved in immune activation, transcription control, and cell proliferation. Impaired transcription of glucocorticoid response genes and increased proinflammatory transcription control pathways were identified in socially isolated individuals, indicating genome-wide activity can be altered in response to perceived levels of social connection. There is also growing evidence that epigenetic processes have a role in several psychiatric disorders, including depression and schizophrenia. For example, reductions in the expression of *reelin* and GAD1 genes, known to be involved in synaptic function and memory, in the hippocampus and cortex of schizophrenic patients have been consistently reported in postmortem studies (Costa et al., 2002; Grayson, Chen, Dong, Kundakovic, & Guidotti, 2009).

Transgenerational Epigenetic Inheritance

Epigenetic changes are known to be at play across the life span (see Slavich & Cole, 2013; Sweatt, 2010) and growing evidence also indicates that changes in response to an environmental event in one generation may in some cases be transferred to subsequent generations (Harper, 2005, 2010; Jablonka & Lamb, 2005). Most of the known transgenerational effects are associated with altered diet, toxin exposure, or temperature changes, although there have been reports of some transgenerational effects stemming from altered sensory conditions and behavioral patterns. In most cases the specific process responsible for the trangenerational effect remains unknown, but in some cases, the effects have been attributed to altered methylation patterns.

One of the first demonstrations of transgenerational epigenetic inheritance came from the study of coat color variations associated with the A^{vy} allele in *Agouti* mice (Morgan, Sutherland, Martin, & Whitelaw, 1999; Waterland & Jirtle, 2003). The expression of this allele typically results in a yellow coat color and a strong tendency toward obesity and diabetes in this strain of mice. However, when *Agouti* females are fed a diet high in folic acid and vitamin B12 (both of which are high in methyl donors) before and during pregnancy, their methyl-rich diet effectively silences the *Agouti* allele in their developing embryos. As a result, females fed on the altered diet give birth to mostly thin, brown furred pups, whereas control mice not fed the altered diet give birth to pups that are mostly fat and yellow furred (and as adults have higher susceptibility to obesity, diabetes, and cancer). The methyl supplements that the mouse embryo received from the mother during prenatal development modified the embryo's epigenome, effectively preventing the *Agouti* gene from being expressed. In contrast, embryos whose mothers received no methyl supplementation showed no such silencing effects. Importantly, these results were observed in genetically identical mice.

There are numerous additional findings documenting transgenerational developmental effects of diet. For example, Zamenhoff and colleagues (reviewed in Zamenhoff & van Marthens, 1978) found that prenatal exposure to protein-deficient diets in rats is associated with stunted growth patterns of offspring, even when the offspring are themselves raised on standard diets. Zambrano et al. (2005) have shown that such transgenerational effects of protein restriction on growth in rats vary according to sex and the timing of the dietary restriction (during pregnancy and/or lactation). Although the specific processes remain unclear, these observations clearly indicate that what happens in one generation can have lasting, systematic consequences on offspring in subsequent generations.

Research has also begun to address possible transgenerational effects of altered diets in humans. A study by Pembrey et al. (2006), using the Avon Longitudinal Study of Parents and Children, explored the effects of food supply on offspring and grandchild mortality risk ratios. They found that the paternal grandfather's food supply (based on estimates from local harvest and food price records) was linked to the mortality risk ratios of grandsons, whereas the paternal grandmother's food supply was linked with granddaughters' mortality risk ratios. Importantly, these transgenerational effects were only seen when low food supply exposure occurred before the prepubertal periods of both grandparents, or during the fetal development of the grandmother. Such findings suggest that the environment can induce epigenetic changes in the sex chromosomes, which are then passed on to offspring (and in turn, their offspring). In other words, sex chromosomes can apparently be marked across generations according to the parent of origin, suggesting a process for the intergenerational transmission of modifications of gene expression via the gametes. The understanding of the ways and means of epigenetic variation and inheritance is still in its infancy and additional longitudinal analyses and research are needed to confirm *germline dependent* epigenetic inheritance in humans. Applying a multigenerational perspective will undoubtedly add to an understanding of the processes by which the consequences of adverse experiences do not remain limited to the individual experiencing the adversity, but may also be transmitted to their nonexposed children, grandchildren, and beyond (see Harper, 2005).

A dramatic example of how toxin exposure can lead to trangenerational effects has been documented by Anway, Cupp, Uzumcu, and Skinner (2005), who exposed pregnant female rats to the pesticide vinclozolin (widely used on vineyard grapes and known to be an androgen antagonist) during the period of gestation when their embryos were undergoing gonadal differentiation. Male offspring of these mothers showed decreased spermatogenic capacity and decreased male fertility. These effects were found to persist across four generations, with no further vinclozolin exposure. These changes were not associated with any changes in DNA sequence, but rather were associated with DNA methylation at specific genes involved in spermatogenesis. Further research found that in each generation males whose ancestor had been exposed to the toxin showed an increase in cancer, prostate and kidney disease. When tested in a partner preferences paradigm, females that were three generations removed from the one-time toxin exposure discriminated and preferred males that did not have a history of toxin exposure; males did not exhibit such a preference when tested with exposed females (Crews et al., 2007). Modification of DNA methylation by toxin exposure thus altered mate choice not only in the exposed generation, but also in several generations removed from the one time exposure.

Taken together, these various results from both animal and human studies support the notion that the scope of what constitutes inheritance across generations includes factors above the level of genes and these factors are certainly not complete at the moment of fertilization. All organisms depend on the transgenerational presence of a large number of highly specific and essential developmental resources, including temperature, photoperiod, particular types and amounts of foods, and parental care. In other words, organisms inherit *resources* for development, not traits or characteristics. This insight is foundational to a fully realized psychobiological systems view of development. What is inherited across generations is a structured developmental system that includes components internal (e.g., genes, cytoplasm, cells) and external (e.g., diet, light cycles, conspecifics) to the organism. DPS recognizes that the recurrence from generation to generation of the specific resources and coactions that make up an organism's physical, biological, and social environments are as causally informative to the development and transmission of phenotypic characters as are genes contained within this system. A central concern of DPS is thus the identification of the developmental resources that allow for the repeated assembly of phenotypic characteristics, both within and across generations (see Caporeal, 2003; J. Lerner et al., 2012; Overton, 2010, Chapter 2, this *Handbook,* this volume, for further discussions of system resources).

The relational and dynamic nature of the genome, coupled with a growing appreciation of the pervasiveness of epigenetic regulation of gene expression throughout the life span, clearly has significant implications for psychology (Gonzalez-Pardo & Alvarez, 2013), developmental science (Gottlieb, 1998; Meaney, 2010), and in particular, the assumptions, methods, and goals of quantitative behavioral genetics (Charney, 2012).

Implications for the Methods and Assumptions of Quantitative Behavioral Genetics

Quantitative behavioral genetics has long been organized around a concern with determining how much differences in heredity (i.e., genes) and differences in environment relate to differences in behavior (e.g., Plomin, 1990). Research in quantitative behavioral genetics has involved two basic assumptions: first, with a combination of genetic and behavioral methods, the contribution of genetic and environmental factors to behavioral characteristics can be intelligibly partitioned; second, it is possible to identify specific genes that determine phenotypic characteristics, including psychological disorders (e.g., Plomin, Owen, & McGuffin, 1994). Starting with a conceptual and statistical framework provided by Francis Galton in the last decades of the 19th century (Galton, 1874), quantitative behavior geneticists have employed a range of research designs, including animal breeding studies and kinship studies, in their attempts to quantify the relative contributions of genotypic and environmental differences to the total phenotypic variation of a particular characteristic in a particular population.

This emphasis on partitioning the causal determinants involved in development has a long and storied history over the course of the past century (see Keller, 2010; Moore, 2013, for recent overviews) and continues to be evident in contemporary behavioral genetics (e.g., Plomin, DeFries, Knopik, & Neiderhiser, 2013), despite the growing body of evidence reviewed above demonstrating the fundamentally fused interdependence of genes and environment. This emphasis on partitioning has directed the focus, methods, and assumptions of the field, many of which have been called into question by advances across the biological sciences.

Animal Breeding Studies

One of the earliest and most widely employed methods to estimate the relative contributions of heredity and environment to phenotypic characteristics involved breeding studies with animals. The logic of animal breeding studies is seemingly straightforward: If a given characteristic can be selectively bred for across generations, then that characteristic must be determined by genetic factors. This assumption has been widely applied in livestock breeding programs since the 19th century, where a wide range of phenotypic characteristics associated with appearance, efficiency, and productivity are "artificially selected" through selective breeding across generations. This assumption has also been evident in scientific concerns with behavioral characteristics, including perceptual and cognitive skills. For example, beginning in the 1920s the psychologist Robert Tryon engineered two strains of rats that diverged in their ability to solve various mazes (reviewed in Tryon, 1940). He selectively bred together rats that showed the fewest errors in solving complex mazes, while also interbreeding rats that showed the most errors, to create strains of "maze bright" and "maze dull" rats. In the following decades numerous researchers created similar strains of rats and mice using selective breeding for various maze-solving measures (see Wahlsten, 1972). Because the environments between strains were kept relatively constant across generations (and between strains) in these designs, the differences in performance in the maze by different strains were attributed to heredity. More generally, this approach assumed that differences between animals of the same inbred strain are caused by environmental factors and differences between animals of different strains are caused by genetic factors (Belknap et al., 1998). This assumption can be valid only if the effects of genes and environment are strictly additive (Gottlieb et al., 2006).

The strictly genetic basis of strain differences was eventually challenged as a growing number of studies demonstrated the context dependent nature of observed strain differences. For example, Cooper and Zubek (1958) bred for bright and dull rats as Tyron had done decades earlier, and once the strain difference was established over many generations, they transferred some of the offspring from the "bright" and "dull" lines to either an enriched or impoverished raising environment. When these transferred rats were later tested for their maze-solving abilities, they found no differences between the two strains when both were raised in the impoverished or in the enriched condition. Similar elimination of strain differences following environmental alterations were subsequently reported by Hood and Cairns (1989), who bred mice raised in social isolation following weaning for low or high frequency of attacking intruders. Once the strain difference in aggressive behavior was established over multiple generations, they raised some offspring in social groups (rather than in isolation) following weaning and found that the observed strain differences in aggressive behavior disappeared. Hood (2005) went on to show that these strain differences could be eliminated by social raising even after 39 generations of selective breeding for aggressive behavior.

Because each highly inbred strain is genetically different from other strains, and because each member of a specific strain has nearly identical genes, it is possible to test samples of different strains across a range of different environmental conditions and establish a graphical *norm of reaction* (NoR, see Sarkar, 1998). Such graphs are intended to represent the phenotype of organisms of a particular genotype as a function of their environment. More formally, the norm of reaction is defined as the set of ontogenetic trajectories produced by a genotype in response to naturally occurring or experimentally imposed environmental variation (Schlichting & Pigliucci, 1998). Establishing a norm of reaction is not usually possible for organisms that have not been highly inbred, limiting its broad applicability, but in some cases a NoR can be determined as an average across genetically different individuals if random assignment to condition is employed (Gottlieb et al., 2006).

Although NoRs can be used to help identify environmental and strain-related effects on the development of phenotypic characteristics, we argue that it is doubtful that such studies can successfully identify strictly or solely genetic effects. This is the case because inbred strains differ not only in their genotypes but also in their behavioral, physiological, and anatomical phenotypes, and as Gottlieb (2003, p. 339) cautioned, "much of what passes for gene-environment interaction is actually organism-environment interaction." In keeping with this insight, we argue that what is actually measured in NoR studies is how different phenotypes (strains) respond to different environmental manipulations. Phenotypes should not be treated as a proxy for underlying genotypes, because phenotypes themselves can play a causal role in observed strain differences.

Researchers engaged in this type of work are well aware of how some phenotypic factors (for example, maternal behaviors) can contribute to strain related differences and they typically take measures (for example, cross-fostering) to control for such possible confounds. However, such postnatal manipulations do not control for potential prenatal factors contributing to observed strain differences. For example, egg yolk factors have been found to contribute to phenotypic differences between broiler and layer chicken strains (Ho, Reed, & Burggren, 2011). When the yolk environments between these two strains were switched so that broiler chicken embryos developed in layer chicken yolk environments (and vice-versa), the manipulated embryos showed significant differences in body mass, heart rate, and general rates of development when compared to controls.

In rodents, pregnant females from different strains can differ in body size, litter size, gestation period, amount of food intake, activity levels, and/or hormone levels, all of which could potentially contribute to strain-related differences in physical and behavioral development. To illustrate this point, consider the work of McLaren and Michie (1958), who conducted a study on anatomical development in mice using an embryo transfer procedure they helped pioneer. They were interested in explaining why some strains of mice tend to have mainly five lumbar vertebrae (C3H/Bi) versus six lumbar vertebrae (C57BL/How). When they implanted fertilized eggs between females of these two strains, they found the number of lumbar vertebrae in female offspring tended to match the foster mother's strain rather than the genetic mother's strain, indicating a uterine effect on number of lumbar vertebrae. This remarkable study was among the first to suggest that a strain-specific phenotype (in this case, the uterine environment) contributes to the realization of strain-specific characteristics.

In related research, Cowley, Pomp, Atchley, Eisen, and Hawkins-Brown (1989) transferred mouse embryos between a smaller sized strain (SWR) and larger strain (C3H). To eliminate postnatal effects, all transferred embryos were raised after birth by isogeneic C6BF1 females. They found that SWR mice gestated in C3H females showed significantly heavier body weights (and had longer tails) than untransferred SWR embryos. Similar effects on body weight were found by transferring embryos between different strains of deer mice (Roth & Klein, 1986). Francis, Szegda, Campbell, Martin, and Insel (2003) reported an additional prenatal effect on *behavior* in mice strains using embryo transfer procedures. They transferred mice of the B6 strain (C57BL/6J) into foster dams of a different strain (BALB). They found that B6 mice that developed in BALB uteri and were raised by BALB dams behaved liked BALB mice in a variety of behavioral measures of exploration (open-field tests), anxiety-related behaviors (plus-maze performance), and water maze behaviors. However, the effect could not be attributed to only prenatal factors alone, as neither B6 mice embryos that only developed prenatally in BALB mice and were then raised by B6 dams nor B6 mouse pups that were only raised by BALB dams after birth showed the BALB pattern of behavior. In the latter group, the B6 pups (raised by BALB dams after birth) were transferred to B6 dams for gestation, so they did not receive a prenatal manipulation. As the authors suggest, these results indicate that some of the observable phenotypic differences between mouse strains must be attributed to aspects of both prenatal *and* early postnatal environments.

Taken together, the findings on prenatal and postnatal maternal effects on strain differences call into question whether animal breeding studies can actually tease apart genetic contributions to development, particularly in light of the complex epigenetic processes known to be at play during early development. As Gottlieb (1991) noted, the norm of reaction is “essentially non-predictive because . . . each new environment is expected to have a different influence on developmental outcomes that cannot be stated in advance of actual empirical investigation” (p. 5). This is not to say that such studies lack value. Comparing the development of different strains across a range of prenatal and postnatal environments can help identify and define the complex network of factors involved in behavioral and morphological development. However, if the goal of such research is to identify phenotypic effects associated with genotypes independent of nongenetic factors, this strategy is bound to fail.

Kinship Studies

The primary method of quantitative behavioral genetics has been some form of the kinship study, the goal of which is to determine whether individual differences in characteristics are associated with degrees of relatedness. The simplest form of these studies compares how offspring resemble other biological relatives of varying degrees (parents, siblings, cousins, half-siblings). The logic of this type of study is relatively straightforward: If a characteristic is caused by hereditary factors, then we should see a greater concentration of the trait or characteristic among members of the same family, proportional to their degree of genetic relatedness (Joseph, 2010). However, shared environmental factors often confound these studies, so to better estimate genetic influences behavior geneticists typically employ the adoption method, in which behavioral measures of adopted individuals are compared to measures obtained from their biological and adoptive parents. Genetic effects are inferred when adopted people are more similar to their biological than to their adoptive relatives. Even more commonly, behavior geneticists rely on twin studies in which correlations (or concordance rates) between monozygotic and fraternal twins are compared. Genetic influences on traits or characteristics are then inferred when monozygotic (MZ) twins are more similar than are dizygotic (DZ) twins.

Francis Galton pioneered the examination of the relative roles of nature and nurture in the late 19th century by the use of human twin studies. Using surveys he provided parents, he found that twins who were similar at birth (i.e., by nature) tended to remain similar despite changing circumstances, whereas twins dissimilar by nature tended to remain dissimilar despite similar environments (Burbridge, 2001). Based on the results of his surveys, Galton concluded that nature was far more important than nurture in the development of human characteristics. Galton’s research and his conclusions were fundamentally flawed in hindsight (he did not distinguish between monozygotic and dizygotic twins, nor did he consider any role of prenatal factors), but the notion that the study of twins could serve as a valid method to distinguish between the effects of heredity and environment gained strength in the early decades of the 20th century and continues to stand as the primary means by which genetic influences on human characteristics are inferred by behavior geneticists (e.g., Bouchard, 2004; Lang, Livesley, & Vemon, 2006; Plomin, 1990).

However, like family studies more generally, adoption and twin studies are challenged by a number of confounding variables and questionable assumptions (see Joseph, 2006; Moore, 2013). For example, adoption studies deviate from a random-effects design as a result of selective placement of children into types of homes that tend to fall within a restricted range of intelligence levels, education, and other sociocultural variables (Richardson & Norgate, 2006). In studies of twins reared apart, not only are their environments not entirely dissimilar (i.e., they grow up in similar times and locations), the twins are often aware of one another and have had long-lasting relationships (Charney, 2008).

More problematic are the underlying assumptions that provide the foundation for comparisons across individuals. For example, the assumption that the adoption method can effectively separate heredity and environment presumes that the prenatal environment has no role in individual differences and that the uterine environment is essentially the same across all women (Gottlieb et al., 2006). This is certainly not the case. The state of the mother’s health, diet, stress level, and teratogenic exposure are widely known to have a major effect on the neural and physiological development of her fetus (Bateson & Gluckman, 2011). Thus, monozygotic twins separated at birth and reared in different households could both show low IQ because of prenatal alcohol exposure or prenatal malnutrition. Moreover, monozygotic twins who share a chorion and placenta are known to be more similar on various physical and psychological measures than are monozygotic twins that do not share chorions and placenta (Phelps, Davis, & Schartz, 1997; Prescott, Johnson, & McArdle, 1999), suggesting that some identical twins may be more similar than other twin sets as a result of shared prenatal environments.

Further, in most twin studies it is assumed that the postnatal environments of monozygotic twins are equivalent to the postnatal environments encountered by fraternal twins (the "equal environments assumption," EEA). Rutter (2006) noted that to infer that genetic factors explain MZ versus DZ twin differences, "one has to assume that all the contrast between MZ and DZ pairs can be wholly attributable to genes because the environmental variation within MZ pairs should be much the same as within DZ pairs" (p. 41). Surprisingly little research has been conducted to validate this foundational assumption, and what little support there is could just as easily be used to argue against the notion of the EEA (Beckworth & Morris, 2008; Joseph, 1998, 2006; Richardson & Norgate, 2005). Research has shown that in childhood identical twins are more commonly dressed alike, share the same playmates, more often share bedrooms, and are treated more similarly by others (Scarr, 1968). In adolescence, identical twins spend more time together and have more friends in common than fraternal twins, and when these social variables were included in a multivariate analysis, apparent genetic effects were significantly reduced or eliminated (Horwitz, Videon, Schmitz, & Davis, 2003). The paucity of reliable supporting evidence and known violations to the EEA led Joseph (2010) to conclude that there is "little reason to accept that the twin method has measured anything other than the more similar treatment, greater environmental similarity, and closer psychological association experienced by MZ versus same sex DZ pairs" (p. 581).

Given the range of problems and confounds associated with kinship studies, we argue that it is difficult to interpret their results. Although relatives frequently have characteristics in patterns that would be predicted by genetic theories, these patterns also match predictions made by theories of nongenetic causation as well. In fact, all of the patterns of correlations used to support a genetic argument (that characteristics run in families, that monozygotic twins are more similar than dizygotic twins, that monozygotic twins separated at birth are similar) can be explained just as readily from an environmentalist perspective. Of course, the environmentalist position, like the genetic point of view, fails to appreciate the fundamental interpenetration of genes and environment elegantly demonstrated by findings from contemporary epigenetic research.

Heritability Estimates

Since its inception, the goal of behavioral genetics has been to measure the extent to which variation in a phenotype in a population can be accounted for by genetic variations (Gottlieb, 1995; Gottlieb et al., 2006). These "heritability" estimates are constructed on the basis of *additive models* that assume genetic and environmental effects on any given phenotype are separate and statistically independent. Researchers working in this tradition generate heritability estimates ranging from 0% to 100%, and assume that as the percentage increases towards 100%, the importance of genetic influences on the characteristic in question correspondingly increases. In humans, the most common method for heritability studies is to compare the similarity of identical twins with the similarity of fraternal twins. The roots of the heritability statistic date back to the efforts of the geneticists Ronald Fisher and Sewall Wright, who in the early decades of the 20th century sought to make biometric models of continuous variation in characteristics in populations congruent with Mendelian genetic principles (see Feldman, 1992; Griffiths & Tabery, 2007). Fisher assumed that continuous traits in a population were influenced by a large number of segregating genes, each with miniscule but additive effects. When summed, Fisher showed that these genetic contributions could bring about a normal distribution of that phenotype in the population. In 1918, Fisher introduced the analysis of variance (ANOVA) to statistically separate the phenotypic variability of a population into genotypic and environmental components, and their interaction.

According to an ANOVA, the total amount of phenotypic variability in population for a given trait or characteristic (V_P) can attributed to the additive contributions of genetic variation in that characteristic (V_G), environmental variation (V_E), and their interaction ($V_{G\times E}$), which results in the following equation:

$$V_P = V_G + V_E + V_{G\times E}$$

However, V_G can be subdivided into variation attributable to the additive effects ("breeding value") of genes (V_A), which are thought to be responsible for the relations between parents and offspring, as well as dominance effects (V_D), and interactive (epistatic) genetic effects (V_I) resulting in the following equation:

$$V_P = (V_A + V_D + V_I) + V_E + V_{G\times E}$$

Broad-sense *heritability* (H^2) refers to the proportion of total variance of a characteristic in a population attributed to all genetic components (V_G/V_P). Most quantitative behavioral geneticists are interested in narrow-sense *heritability* (h^2), which refers to the total proportion of variance in a characteristic in a population statistically attributed to additive genetic variance ($V_A + V_P$). This estimate is thought to be useful in predicting offspring outcomes or how well a trait or characteristic might respond to selective pressure in certain environments (Feldman, 1992; Wade, 1992).

The statistical problems with calculating heritability have been discussed at length elsewhere (see Bailey, 1997; Charney, 2012; Lewontin, 1974; Vreeke, 2000; Wahlsten, 1994; see also Bateson, Chapter 6, this *Handbook*, this volume), but suffice it to say that in calculating narrow heritability, quantitative behavioral geneticists make an unwarranted assumption: they assume a completely additive model, so the values of V_D, V_I, and $V_{G \times E}$ are treated as nonexistent and set at zero (Stoltenberg & Hirsch, 1998). As we have reviewed earlier, this assumption is no longer biologically plausible and calls into question any meaningful interpretation of h^2. Further, the epigenetic research we reviewed earlier challenges the statistical assumption that variation in characteristics can be fully explained by two sources of influence (genetic and nongenetic) and their coaction (see Charney, 2012; Molenaar, Boomsma, & Dolan, 1993; Moore, 2013; Wahlsten, 1994, for further discussion). Given that we now know that much of what genes do is to react to signals from the internal and external environment, the idea of dividing developmental influences into genetic and environmental factors no longer seems biologically possible (Gottlieb, 2003).

Molenaar et al. (1993) emphasize that there exists a third (nonlinear, epigenetic) source of phenotypic variation (historically called "developmental noise") in biometric models independent of genetic and environmental factors. Molenaar et al. (1993) review a wealth of evidence for this third factor, beginning with Sewall Wright's (an originator of the heritability statistic) analysis of fur coloration in guinea pigs over 90 years ago. Wright (1920) found that this third source of variability accounted for 91% of the total variation observed. Molenaar (2007) has argued that the existence of this epigenetic factor challenges some fundamental assumptions of modern quantitative genetic analyses. In traditional biometric analyses it is assumed that the structure of variation at the population level is equivalent to the structure of variation at the individual level. To make this claim requires that one assume that that (a) all individuals (or units) in a population (or ensemble) are homogenous (i.e., obey the same dynamic processes), and (b) that the process under investigation is stationary (not time-dependent). Molenaar (2007; Molenaar & Nesselroade, Chapter 17, this *Handbook*, this volume) points out that neither of these assumptions is tenable in the study of developing individuals. Obviously, the latter assumption is violated when studying psychological processes (like learning or development) that vary across time. Moreover, the existence of nonlinear, epigenetic sources of variation challenges the homogeneity assumption. For example, in a study of EEG responses in dizygotic twin pairs in a visual discrimination task, Molenaar found substantial heterogeneity (subject-specificity) in EEG responses over time (Molenaar, Smit, Boomsma, & Nesselroade, 2012).

Besides its statistical assumptions, there are additional issues with the meaning and usefulness of heritability. Most notably, high heritability of a characteristic does not indicate that genetic factors are more important than environmental factors in the development of a characteristic. Likewise, low heritability of a characteristic does not indicate that genetic factors are less important (see Moore, 2013). A simple thought experiment serves to illustrate this point. Imagine a heritability analysis was conducted on Cooper and Zubek's (1958) maze bright and dull rats raised in only the standard laboratory environment. Because genetic background would reliably predict maze-solving scores and because there was no measured environmental variation, heritability would be very high. Now imagine we calculate the heritability of maze-solving skills in only the enriched condition. Because genetic background would not predict differences in maze solving, heritability would be zero. This example not only illustrates that heritability does not speak to the causes of characteristics, it also shows that the values (high, moderate, or low) of heritability depend on and are limited to the populations studied and the contexts in which they are calculated. In other words, any heritability estimate is specific and limited to a particular population at a particular time. Further, for most complex characteristics we can assume that there are additional environmental factors at play that are not measured (or controlled for) in standard heritability estimates. As Moore (2008) put it,

> Generalizing the results of a heritability study from a population of research participants to a much broader population requires confidence that the variation in developmental environments experienced by the broader population is no different than the variation in developmental environments experienced

> by the research participants. But, because we typically do not know which factors play important roles in the development of a particular characteristic, it is not possible to know if the variation in those factors is the same across the broader population as it was in the original population of research participants. (p. 338)

To make matters even more challenging, in human populations we cannot experimentally control either environments or levels of genetic variation, thereby rendering the interpretation of heritability estimates even more suspect.

Although heritability estimates can be useful in making some types of predictions (*does* like beget like) under constant conditions, it is important to emphasize that the statistic does not inform us about the causes or the relative importance of the various causes of characteristics (*how* like begets like). Some quantitative behavior geneticists endorse this point. Turkheimer (2011, p. 236), for example, proposes that behavioral genetics has "failed to offer much in the way of etiological insight into complex behaviors." To address this situation, some quantitative behavioral geneticists (e.g., Plomin, 2013; Plomin, Haworth, & Davis, 2009; but see Turkheimer, 2012) have proposed that advances in molecular genetic technologies will finally allow researchers to correlate specific genetic markers with specific phenotypes, thereby establishing the "missing link" between quantitative and molecular genetics.

Molecular Genetics and Behavior

In the past several decades there has been a rapid rise in studies aimed at correlating genetic variants with population trait or characteristic variation, due in large part to advances in technology that are becoming both more powerful and less expensive. The most common genetic variants tested are polymorphic regions of a gene, including differences in single nucleotide bases at specific loci. Millions of these *single nucleotide polymorphisms* (SNPs) have been identified. SNPs can be found in the coding or regulatory region of genes, making it possible to associate characteristics with actual functional genetic variants. However, in many cases SNPs serve as indirect markers that identify a nearby functional genetic variant that may contribute to a characteristic (Gray, Campbell, & Spurr, 2000). Researchers have turned to using genome-wide association studies (GWAS), in which hundreds of thousands of SNPs are examined from many thousands of participants. Wahlsten (2012, p. 479) claims that "the power of the method is so great that, if there is a genetic variant in a population with a noteworthy influence on some psychological or neural function, GWAS can find it."

Despite the power of these new technologies, there is growing concern that these studies may fail to deliver on the promise of finally linking quantitative behavioral and molecular genetics. For example, when associations between SNPs and characteristics are found, the effect size tends to be extremely low. As one case in point, one SNP thought to be involved in height accounted for only 0.3% of variation in height (Weedon et al., 2007). Even when combined with other studies that looked at a total of 40 SNPs, the combined effect explained about 5% of height variance (Visscher, 2008). These small effects were surprising given that height is consistently one of the most highly heritable characteristics by conventional methods of analysis. Because similar small effects have been documented across a range of other phenotypes with high heritability, there has been a growing interest in explaining this so-called missing heritability problem (Joseph, 2012; Maher, 2008; Manolio et al., 2009; Plomin, 2013).

Perhaps more problematic, however, is the failure to replicate reported findings. For instance, Caspi et al. (2003) reported evidence for an association between depression and two alleles ("short" versus "long") located on the serotonin transporter (5-HTT) gene. They found that symptoms of depression were greater for individuals possessing the short allele, but only for those persons dealing with many major life (e.g., financial, relational, and health) stressors. No genetic association was found for people experiencing fewer life stressors. Following its publication, this study was met with much acclaim in both the scientific community and popular press, as it seemed to link a functional genetic variant with a common psychological profile, as well as show how genes can interact with life experience. However, in the ensuing years, the association between the short allele and depression reported by Caspi and colleagues has been called into question (see Zammit & Owen, 2006). In some studies, researchers found no association between these alleles and depression, others found gender-specific effects, and some studies reported finding effects in the opposite direction (i.e., greater depression associated with the long allele). These discrepancies led Zammit and Owen (2006, p. 201) to caution that "although heralding much promise, the extent to which this fascinating area of research will enhance our understanding of psychiatric disease remains to be seen." A meta-analysis of 14 studies by Risch et al. (2009) found no evidence of a relation between the presence of short and long alleles and depression (but see Karg, Burmeister, Shedden, &

Sen, 2011, for an opposing view and meta-analysis). Further, genome-wide association studies have to this point failed to find any reliable genetic association with depression (Ripke et al., 2012; Wray et al., 2012).

Similar failures to replicate have been found in the hunt for genetic associations with other psychological characteristics and disorders. For example, Chabri and colleagues (2012) attempted to replicate associations of 12 SNPs with measures of general intelligence using three independent data sets totaling nearly 10,000 individuals. Only one SNP (*SSADH* rs2760118) in one of the three data sets achieved marginal significance, and even this weak association was suspect given that the alleles of this SNP were found to have different associations with intelligence in one of the other data sets (i.e., the genotype associated with higher intelligence in the former was found to be associated with lower intelligence in the latter, though in both cases they were not statistically significant). Failures to replicate have also been found for various SNPs and memory (Need et al., 2008), personality (see Munafo & Flint, 2011, for review), and Parkinson's disease (Evangelou et al., 2010) to name a few (see Wahlsten, 2012, for additional examples).

How are we to make sense of these failures to find an association between psychological characteristics and gene variants? Some molecular biologists seem to be of the opinion that genetic associations exist, but are still too rare to detect or that the methodologies available are not suited to deal with gene-gene interactions that may be responsible for the small reported relations (e.g., Haig, 2011; Zuk, Hechter, Sunyaev, & Lander, 2012). On the other hand, it could be that the search for genetic associations of complex characteristics is simply bound to fail. Joseph (2012), for example, argues that "the issue researchers are grappling with is not missing heritability but missing *genes*, and there is good reason to believe that these 'missing' genes are actually 'nonexistent' genes" (p. 80, emphasis in the original). In other words, there simply are no genes independently responsible for depression, schizophrenia, intelligence, or temperament/personality.

One interesting suggestion to the "missing heritability" problem is to include epigenetic and environmental inheritance systems into the analysis (Danchin et al., 2011; Furrow, Christiansen, & Feldman, 2011). From the DPS perspective, this approach rightly recasts heritability as a developmental issue that requires developmental analysis. This approach can potentially enhance our understanding of the distribution of phenotypes in a population, as well as provide insight into how this population might respond to selective pressures. However, incorporating environmental and epigenetic inheritance systems into heritability statistics will necessarily remain limited, in that they remain correlational attempts to account for variation in populations. As such, they cannot inform us about the identity of the relevant factors or processes by which genes and nongenetic factors actually influence the development of characteristics in individuals. Lehrman (1970) and Lewontin (1974) have each provided a particularly lucid account of the distinction between analysis of variation (as used in behavior genetics) and the analysis of causes (as used in developmental science).

Given the limitations of gene association studies, we suggest more effort be placed on studying gene expression and its consequences in developing organisms. Indirect measures of gene transcription (via measures of RNA) using microarrays and other techniques have successfully linked gene activity with specific characteristics, as seen in Weaver et al.'s (2004) research on the long-term effects of maternal behavior in rodents discussed earlier. Modern techniques also allow for more direct manipulations of genes (e.g., selectively mutating, inserting, silencing, or deleting genes) to assess genetic contributions to development. Many human psychological phenomena cannot be studied in this way, but given the similarities between humans and other animals, much can be gleaned by understanding the basic neurobiology of brain development and function in model organisms whose genomes we can directly manipulate (Wahlsten, 2012).

For example, Lim, Wang, Olazábal, Terwilliger, and Young (2004) transferred a vasopressin receptor gene (*V1aR*) found in the affiliative and monogamous prairie vole (*Microtus ochrogaster*) into a specific region (ventral pallidum) of the ventral forebrain of juvenile male meadow voles (*Microtus montanus*), which typically display asocial and promiscuous sexual behavior. Following the gene transfer, normally asocial male meadow voles showed increased vasopressin receptors in this brain region and increased pair-bonding behaviors similar to those seen in prairie voles. In this case, a single gene yielded a powerful influence on functionally important and complex social behaviors.

Findings such as these, however, should not be used to promote a new form of genetic determinism. As the authors of the study astutely point out, "a single gene does not act alone in the control of complex social behavior; it must ultimately be placed within preexisting biological pathways that then interact with socioecological factors, developmental pathways, and stochastic events in the lives of organisms" (Lim et al., 2004, p. 757). In other words, it is important to identify candidate genes that can strongly impact how particular behaviors develop, but this is only the first step in understanding *how* such genes actually contribute to development. Kaplan (2006) has summarized this key insight as follows:

> Every trait of an organism is the result of the interaction of various genes and environments during the developmental process. In order to be successful, organismal development always requires the presence and coordinated actions of various kinds of resources (genetic, epigenetic, and environmental, to name a few), so it makes no sense to ask if a particular trait is genetic or environmental in origin. Understanding how a trait develops is not a matter of finding out whether a particular gene or a particular environment causes the trait; rather it is a matter of understanding how the various resources available in the production of the trait interact over time. (p. 50)

Because of the variability of relevant resources across different environments and because only a portion of the genome is expressed in any individual (due to its specific developmental context and experience), what is actually realized during the course of individual development represents only one of many possibilities. As we pointed out earlier, this insight is a core tenet of the developmental psychobiological systems perspective—because of the multiplicity of levels, factors, and coactions involved and because of its history-dependent and situated nature, neither physical nor behavioral development can have a predetermined trajectory (Gottlieb, 2007). Contrary to the assumptions of classical quantitative behavior genetics, DPS emphasizes that to understand the presence, maintenance, or transformation of any phenotypic trait, it is necessary to study its development in the individual. Given that all phenotypes, including behavior and cognition, have a specific developmental history that explains their emergence, a developmental mode of analysis is required to fully explain their structure and function.

Atchley and Newman (1989) highlighted several types of resources—genetic, maternal, and environmental—that impact the stability and variability of developmental outcomes. Their model for integrating genetics with developmental analysis recognizes that multiple factors, including contingencies in mating (which create the developing organism's genome) and contingencies of the maternal environment (cytoplasmic and uterine in the case of mammals) in which the individual develops mediates variability and stability in developmental outcome. As a result, understanding the developmental pathways of morphological, physiological, and behavioral phenotypes requires knowing the dynamic and contingent processes of internal and external factors operating over the course of individual ontogeny.

Application of this insight is increasingly apparent in the neurosciences, where advances across several levels of analysis, including genetics and epigenetics, are changing our understanding of the relations between experience, brain, behavior, and human development. These advances are making clear that attempts to reduce psychological phenomena to neuroanatomical, neurochemical, neurophysiological, or genetic factors misrepresents the key role of other levels of influence involved in the dynamics of brain development, as well as behavioral and cognitive development (Cicchetti & Curtis, 2006; Dalton & Bergenn, 2007; Greenberg, 2011; Overton, 2004; Tucker, 2007).

EXPERIENCE, EPIGENETICS, AND NERVOUS SYSTEM DEVELOPMENT

The human brain is a massively complex system with a hierarchy of tightly integrated levels of organization, from synapses and cells to neural circuits and brain regions. It contains at least a million billion synapses and thousands of miles of neural wiring, forming a dense web of cellular connections that has yet to be completely mapped (Sporns, 2011). In keeping with the dominant view of development in play during most of the past century, brain structure and function was long viewed as the product of a genetically predetermined maturational process (see Hamburger, 1957; Thompson et al., 2001). Until a few decades ago, many scientists assumed that the brain was somehow hard wired and that neuronal connections were predesignated to perform fixed functions. Moreover, the relation between brain and development was viewed as unidirectional—the structural maturation of the brain was thought to be the primary cause of both behavioral and cognitive development. For example, Lenneberg (1967) argued that neural systems that are involved in higher cognitive functions, including language, develop as a result of a maturational blueprint, and that specific brain regions are genetically "prespecified" for specific cognitive functions. More generally, the Nobel Prize winner Roger Sperry (1971) proposed that "one could now see how it could be entirely possible for behavioral nerve circuits of extreme intricacy and precision to be inherited and organized prefunctionally solely by the mechanisms of embryonic growth and differentiation" (p. 32). The behavior geneticist Ronald Wilson (1983) boldly claimed that "the brain is the ultimate structure underwriting human behavioral development" and its "precise wiring is coded in the DNA" (p. 313). Some have claimed that human brains contain hundreds or even thousands of separate, genetically determined neural circuits (modules) that are specialized to respond to specific objects or events (e.g., faces, language, potential mates; see Samuels, 1998, 2002).

These bottom-up views of brain development ignore the fact that neural factors, like genetic factors, are always part of the individual's integrated developmental system. A wealth of evidence emerging from the neurosciences over the last several decades has established that a unidirectional framework is simply not up to the challenge of understanding the complex links between genes, brain, behavior, and the physical, biological, and social environments in which individual development occurs (see Dalton & Bergenn, 2007; Mareschal, Johnson, Sirois, Spratling, & Thomas, 2007; Marshall, Chapter 7, this *Handbook*, this volume; Stiles, 2008). Although it is not possible to adequately review this research effort in a few pages, here we briefly discuss findings from selected studies that collectively serve to illustrate the multifaceted, activity-based nature of brain development, a process guided and constrained by the rich bidirectional traffic among genetic, epigenetic, and environmental factors.

Prenatal and Postnatal Experiential Influences on Brain Structure and Function

In his classic text, *The Organization of Behavior*, Donald Hebb (1949) famously proposed that an organism's experience—its actions/activity—could alter brain structure and function. His idea of how learning and memory could arise from changing coactions among neural connections was among the first proposals that provided a feasible way in which learning and memory might be explained at the neural level. Further, Hebb's proposal suggested that *plasticity* is a fundamental property of neural systems (see Cicchetti & Curtis, 2006; Nelson, 1999, for further discussion). Given the technological constraints of his day, Hebb and his colleagues were only able to provide indirect empirical support for this notion (e.g., Hebb, 1949). The role of individual experience on regulation of neuronal activity and development was more directly supported by subsequent research concerned with the possible implications of environmental enrichment for brain structure and function. In the 1960s, Rosenzweig, Krech, Bennett, and Diamond (1962; Rosenzweig, Love, & Bennett, 1968; see Renner & Rosenzweig, 1987, for a review) were able to demonstrate effects of environmental enrichment on rodent brain anatomy and chemistry. Greenough and colleagues (e.g., Greenough & Chang, 1988; Markham & Greenough, 2004) extended this groundbreaking work, showing that variations in both the type and timing of environmental conditions can affect patterns of synaptic connectivity in the developing rodent brain. Hubel and Wiesel's (1967) classic work on the development of ocular dominance columns in cats likewise demonstrated the importance of both type and timing of experience on the development of cortical organization. We now know that there are many ways in which neuronal functioning (including neurogenesis, synaptogenesis, myelination, axonal sprouting, and vascular changes) can change in response to specific experiences. According to Zatorre, Fields, and Johansen-Berg (2012), "the brain is the source of behavior, but in turn it is modified by the behavior it produces. This dynamic loop between brain structure and brain function is at the root of the neural basis of cognition, learning and plasticity" (p. 528).

The degree to which experience can play an inductive role in brain organization has been elegantly demonstrated in the work of Mriganka Sur and colleagues, who have explored the effects of experimentally rewiring young ferret brains (see Newton & Sur, 2004; Sur, Angelucci, & Sharma, 1999, for reviews). Typically, the medial geniculate nucleus (MGN) of the ferret's thalamus receives auditory input from the superior colliculus and projects to the auditory cortex. However, when the input connections to the MGN are experimentally severed in young ferrets, retinal projections innervate the MGN, as well as the lateral geniculate nucleus (LGN, an area normally innervated by retinal projections). As a result, the response properties of the MGN in rewired animals resemble those of the LGN. Likewise, the rewired primary auditory cortex functionally and structurally resembles the primary visual cortex. These data indicating that both auditory and visual neurons can change their physical characteristics and assume functions of the visual cortex and vice versa clearly challenge any notion that brain structure and function can be exclusively driven by intrinsic maturational factors.

Effects of prenatal experience on brain structure have been reported by Rao et al. (2013), who demonstrated that activation of a light-response pathway in the retina of the mouse fetus must occur during gestation to produce normal eye development. Under the typical conditions of development, photons of light penetrate the uterine wall and activate the protein melanopsin in the fetus, which is critical for initiating and directing the development of blood vessels and retinal neurons in the eye. When activated, this light-sensitive pathway holds local expression of vascular endothelial growth factor (VEGFA) in check, suppressing the number of blood vessels that form in the retina. These blood vessels are critical for the high metabolic demands (including large amounts of oxygen) of retinal neurons. Dark raising mouse dams during the later stages of pregnancy fostered a large expansion in blood vessel growth in their embryos, resulting in abnormal retinal development in their pups. It appears that prenatal light exposure is critical for preparing the eye for vision, both by regulating retinal neuron number and initiating the pattern of ocular blood vessels.

Similar effects of prenatal experience—keeping in mind that experience refers to the actions/activity of the organism—have also been reported for functional outcomes. For example, during the later stages of prenatal development the avian embryo is oriented in the egg such that its left eye is occluded by the body and yolk sac, whereas the right eye is exposed to diffuse light passing through the egg shell when the female is intermittently off the nest during the incubation period. This differential prenatal visual stimulation resulting from the embryo's invariant postural orientation in the egg has been shown to facilitate the development of the left hemisphere of the brain in advance of the right hemisphere. Further, this light-induced developmental advantage for the left hemisphere has been shown to influence the direction of hemispheric specialization for a variety of postnatal behaviors, including visual discrimination, spatial orientation, feeding behavior, and various visual and motor asymmetries (reviewed in Rogers, 1995). Altering the normal pattern of light stimulation available during prenatal development can modify this typical pattern of brain and behavioral development (Deng & Rogers, 2002). For example, a left spatial turning bias is seen in the large majority of quail chicks following hatching (> 85%; Casey & Lickliter, 1998). This species-typical turning bias can be reversed by occluding the right eye and stimulating the left eye with light prior to hatching. Further, the induction of such lateralization can be prevented by incubating eggs in darkness or by providing the same level of light stimulation to both eyes in the period prior to hatching (Casey & Lickliter, 1998). These findings suggest an equipotentiality for hemispheric specialization and indicate that late prenatal experience can have a significant influence on the stability and variability of functional lateralization.

Evidence also indicates that the activity of experience can contribute to structural and functional specialization in neural development following birth. For example, in rats differences in postnatal maternal stimulation is known to bring about differences in brain development and behavioral differences between male and female pups (see Moore, 2006). Rat dams typically engage in high levels of perineal or anogenital licking (AGL) of their pups in the first several weeks postpartum. Under normal conditions, males receive significantly more anogenital licking than do their female siblings during this period, due in large part to the chemical composition of their urine. Increased levels of anogenital licking of males has been shown to influence the retention of cells in the spinal nucleus of the bulbocavernosus (SNBC), which innervates the bulbocavernosis muscle involved in penile erections. At birth, both male and female pups have equivalent numbers of cells in the SNBC, but over time females lose most of these cells. In contrast, males retain these cells as a consequence of receiving higher levels of anogenital licking. Not surprisingly, males that receive little anogenital lickling following birth display numerous problems copulating as adults (Moore, 2006). Further, when female pups are injected with testosterone, they are licked as much as males, and as adults these females show many of the male behaviors involved in sexual reproduction. These results indicate that species-typical afferent input (AGL) can contribute to the sexual dissimilarity of nervous system morphology observed between males and females. Further, these results suggest that variation in maternal behavior can produce individual differences in neural processes among males that can affect their subsequent reproductive success.

The development of neuroimaging technologies (see de Haan, Chapter 18, this *Handbook*, this volume), particularly functional magnetic resonance imaging (fMRI) and diffusion tensor imaging (DTI), has provided researchers new and powerful tools for exploring the roles of experience on human brain structure/function relations. This body of research has confirmed and extended earlier findings based on histological studies and have provided an evergrowing information source about the relations among activity, experience, brain growth, and development. Although not without its critics, functional neuroimaging techniques are altering our understanding of brain-behavior relations and advancing our ability to observe developmental processes across relatively short time scales. As a case in point, using neuroimaging methods, Draganski and colleagues (2004) found that when adults learn to juggle over a 3-month-period, the repeated training leads to increased gray matter concentration in occipito-parietal regions of the brain involved in visual-motor coordination, reaching, and grasping. Further, these changes were apparent after as little as 7 days of training. Similarly, practice of a complex whole-body balancing task has been found to increase gray matter in frontal and parietal cortex after just two training sessions and changes in white matter regions after 6 weeks of training (Taubert et al., 2010). Hu et al. (2011) reported that children who received extensive training on an abacus (a traditional hand-operated calculator used for thousands of years in China) showed greater myelination in parts of the corpus callosum as well as other fiber tracts involved in motor and visuospatial function when compared to children who had not experienced regular use of an abacus. These types of findings, along with a wealth of supporting evidence available from similar neuroimaging studies (see May, 2011) highlight the remarkable capability of the brain for structural alteration in response to changes in activity and more broadly, environmental changes.

Luu and Tucker (1996) cogently commented some years ago that "to understand neuropsychological development is to confront the fact that the brain is mutable, such that is structural organization reflects the history of the organism" (p. 297). Just like the genome, the developing brain is an active and actively responsive system, and just as the notion of genetic programming of protein synthesis was found to be wanting, the notion of genetic programming of brain development likewise falls far short of explaining neural structure and function (Kolb & Gibb, 2011; Nelson, 1999; Stiles, 2008).

Situating Gene Activity in Brain Development

As early as the 1970s, research had revealed a greater variety of RNA molecules in the cortex of rats raised in complex as compared to simple or impoverished environments, suggesting that experience could affect the ways in which genes are expressed (Grouse, Schrier, Bennett, Rosenzweig, & Nelson, 1978). Since these initial discoveries, developmental neuroscience has been steadily advancing our understanding of the processes whereby early experience and environmental factors can influence neural and gene activity to result in the interindividual stability *and* variability of neural structure and function (e.g., Graff et al., 2011; Roth & Sweatt, 2011; Stiles, 2011; Sultan & Day, 2011). We now know that the structure and function of neural systems depends on dynamic historical processes that involve highly complex spatial and temporal patterns of coaction across genetic, neural, and environmental factors, and that epigenetic processes play a fundamental role in this process, with multiple feed-forward and feedback pathways (Cedar & Bergman, 2009).

An example of this distributed causality comes from work on gene expression during sleep/wake cycles in rats (Cirelli & Tononi, 2000). This research focused on the links between behavior, neuronal activity, and gene expression over short time scales. Using mRNA differential display and cDNA microarray technologies to screen for changes in gene expression in the cerebral cortex, Cirelli and Tononi were able to show changes in gene expression across behavioral states. They found that sleep and waking differ not only in behavior, metabolism, and neuronal activity, but also in the expression of distinct categories of genes, including those associated with glucose transport, neuronal plasticity, and protein folding. Cirelli, Pompieano, and Tononi (1996) also found that gene expression was influenced by the hormone norepinephrine from brain stem neurons that fire at very low levels during sleep and at high levels during waking. In this case, arousal level is tied to genetic expression by a specific hormone (norepinephrine) emanating from the activity of a specific neural structure (locus coeruleus), whose activity waxes and wanes in relation to the psychological state of the organism.

Epigenetic processes provide a means of dynamic gene regulation, allowing the nervous system to make both short-term and long-lasting changes at the level of neural circuitry and neurotransmission as a result of experience. Given that epigenetic processes pervade all aspects of development, it should not be surprising that these processes are involved in brain structure and function across the life span; current evidence indicates that epigenetic regulation of gene expression plays an important role in the development of the nervous system, synaptic plasticity, learning and memory, and the maintenance and survival of neurons (see Graff et al., 2011, for a review). As Hebb speculated more than a half-century ago, long-lasting changes in synaptic plasticity are one of the key processes underlying learning and memory, and a growing body of evidence indicates that histone modification and chromatin remodeling are regularly involved in the synaptic changes associated with various forms of learning and memory consolidation (Sultan & Day, 2011).

These types of findings suggest that the characteristics of epigenetic processes in the nervous system are similar to the processes involved in the differentiation of embryonic stem cells, in that they allow cells to respond and adapt to their environment, and keep a cellular memory of previous activity. In other words, the same processes that provide genomes with different identities or profiles during cellular differentiation are likely involved in generating different neural profiles of individuals in response to their life experiences (Szyf & Bick, 2013).

The advances in the neurosciences briefly reviewed earlier demonstrate the complex interplay of gene expression, cellular and hormonal activity, the physical environment, as well as the nature and patterns of social interaction, on the course of plasticity and learning across the life span. These findings emphasize the historical and situated nature of brain development and highlight the importance of research efforts focused on a fuller understanding of the particulars of experience and its varied contributions to neural and behavioral development. We have long known that experience has its effects on behavior by changing neural circuitry, including creating new synaptic connections and strengthening, weakening, or eliminating existing ones. We now know that these effects or implemented through changes in the expression of genes within the nuclei of nerve cells. These processes are proving to be far more complex and distributed than suggested by outdated notions of "genetic programs" or "biological maturation." It seems important to emphasize that the brain is *embodied and situated*; it develops and functions within a body that is itself situated in a physical and social environment (Mareschal et al., 2007; Marshall, Chapter 7, this *Handbook*, this volume; Overton, 2004, Chapter 2, this *Handbook*, this volume; Thelen & Smith, 1994). As a result, Greenberg (2011) notes that "it is the probabilistic, epigenetic, and self-organizing principles of development within a dynamic ecological context that shape the processes of differentiation and integration that characterizes a given individual's genetic, neurological, and behavioral attributes, rather than the other way around" (p. 182).

Greenberg's developmental insight also holds for our understanding of evolutionary processes. The relations between individual development, ecology, and evolutionary change have been the subject of renewed interest over the past several decades in several areas of biology, and as we discuss in what follows, has significant implications for developmental science.

INTEGRATING DEVELOPMENT AND EVOLUTION

Broadly speaking, three general concerns of biology over the past several centuries have been heredity, development, and evolution. Earlier we discussed how the perceived relation among these three concerns were initially forged in the 19th century and changed dramatically during the early decades of the 20th century, eventually giving rise to the Modern Synthesis of evolutionary biology (see Amundson, 2005; Bowler, 1989). In this section we review how the Modern Synthesis came to be applied to the psychological and behavioral sciences and explore the shortcomings of this application in light of advances in developmental and evolutionary theory. These advances are fueling new ways of thinking regarding the links between heredity, development, and evolution and leading to calls for a new "extended synthesis" in some quarters of evolutionary biology and beyond (e.g., Gissis & Jablonka, 2011; Jablonka & Lamb, 2005; Pigliucci & Müller, 2010). This extended synthesis has the developing phenotype rather than the genes as its primary focus, with a particular concern with identifying aspects of development that can lead to flexibility and adjustment when the environment or the genome changes (see West-Eberhard, 2003). As we explore later, this shift in emphasis affords a new way to conceptualize the role of behavioral development in evolutionary change and thus offers a potential avenue to synthesize psychology and biology in new and important ways.

The Modern Synthesis and the Behavioral Sciences

Proponents of the Modern Synthesis largely focused on the evolution of physical characteristics. Behavioral characteristics were thought to evolve in a manner similar to physical characteristics, but little empirical attention was devoted to this issue in mainstream evolutionary biology (but see Roe & Simpson, 1958) during the first half of the last century, in large part because behavior was not thought to contribute to evolutionary change (Bateson, 1988). However, in the 1960s and 1970s, the genocentric principles promoted by the Modern Synthesis began to be extended to the study of behavior, particularly in the field of sociobiology (Dawkins, 1976; Wilson, 1975, 1978).

Sociobiology

Sociobiology proposed that all animals, including humans, behave in ways that maximize their chances of transmitting their genes (directly or indirectly via kinship relations) to the next generation. With this in mind, sociobiologists argued that many social behaviors of animals, including humans (e.g., altruism, incest avoidance, mate preferences, parental investment, territorial aggression), could be best understood as genetically determined adaptations generated by the process of natural selection. As a result of this emphasis, sociobiology focused on the purported adaptive value of behavior (resulting from "ultimate" causes) and was not concerned with the "proximate" causes involved in the development of behavior (Griffiths, 2008; Lickliter & Berry, 1990). This "ultimate" perspective had at its core an underlying premise that went unquestioned by most researchers of this period, namely that the behavioral dispositions of organisms could be specified in advance of the organism's development. This postulate is at the heart of the genocentric view of development that dominated biological thought over the last century and that still remains prominent in some quarters of biology and psychology. Adult behaviors are seen to be the result of genetic programs, with little concern for the intervening resources, factors, or relations that construct the adult from the zygote.

Evolutionary Psychology

In the 1980s, many of these core assumptions of sociobiology were combined with aspects of cognitive science to forge a new field called Evolutionary Psychology (EP; Barkow, Cosmides, & Tooby, 1992; Cosmides & Tooby, 1987; Tooby & Cosmides, 1990; see also Buss, 1995). The original formulations of EP focused on human social and nonsocial behaviors (including perception and cognition) and set out to modify and extend the explanatory basis of sociobiology. Rather than focusing directly on behavioral adaptations, EP focuses on the "evolved cognitive mechanisms" thought to generate behavior. In particular, promoters of EP propose that modern human minds are composed of a large set of domain-specific cognitive modules that evolved by means of natural selection as adaptations to solve specific, recurring problems encountered in our ancestral environments. These modules are thought to guide and constrain a wide range of human perceptual and cognitive skills, including detecting cheaters, perceiving faces, learning language, guiding mate preferences and parenting strategies, among many others (Samuels, 1998; Sperber, 2001). Because all humans are thought to have the same set of modules, their totality represents human nature. To identify these modules and their origins, EP argues that we must consider the problems faced by our earliest hunter-gatherer ancestors during the emergence of *Homo sapiens* hundreds of thousands of years ago because, it is claimed, there has not been enough time for selection to modify the innate (i.e., biologically determined), modular nature of the human mind, despite significant changes in our living conditions over the past 10,000 to 15,000 years. Harris (2009) provides a succinct example of this view: "The mind we inherited from our ancestors was tested against alternative versions and won out against the competition because it was more successful in dealing with the challenges of hunter-gatherer life" (p. 30). In its strongest form, the EP viewpoint assumes that many human perceptual and cognitive processes, as well as some overall executive function, are preformed and triggered by species-typical experience (Pinker, 2002). Development is thus seen as the unfolding of programs or specifications that are already in place, imported into the life-cycle by means of the genome.

This framework has allowed most contemporary evolutionary psychologists (e.g., Buss, 1995; Tooby & Cosmides, 1990) to sidestep the accumulating evidence for the role of developmental processes involving specific mutually influential relations between individuals and contexts that occur at specific times (in ontogeny and history) and within specific places (see Elder, Shanahan, & Jennings, Chapter 2, this *Handbook*, Volume 4), in the realization of all phenotypic traits or characteristics by emphasizing that they are concerned with phylogenetic rather than ontogenetic causality. Proponents of EP argue that they focus on the "ultimate" causation of human behavior and its function or adaptive value, with the aim of understanding how human behavior was designed or shaped by natural selection over the course of evolution. This emphasis has resulted in minimal interest in developmental issues in most of the EP literature (but see Bjorklund, 2006; Bjorklund & Pellegrini, 2002; Frankenhuis, Panchanathan, & Barrett, 2013; Ploeger, van der Maas, & Raijmakers, 2008). The DPS perspective argues that sidestepping development is not justifiable because *development and evolution are two elements of one process* (Ioannidis, 2008; Lickliter & Berry, 1990; Lickliter & Honeycutt, 2003). EP's attempts to divide phenotypic causality into "proximate" and "ultimate" components misconstrues the fundamental link between development and evolution, in large part by assuming that processes that occur within the lifetimes of organisms following conception (diet, behavior, learning, social coactions) can have little if any influence on evolutionary change (see R. M. Lerner & Benson, 2013b; Walsh, 2013, for additional discussion). It has become increasingly clear that this is not the case (Gissis & Jablonka, 2011).

The problems associated with the underlying assumptions of EP (and sociobiology) can be traced in large part to the narrow genes-eye view of development and evolution promoted by the Modern Synthesis of evolutionary biology (Honeycutt & Lickliter, 2007; Lickliter & Honeycutt, 2003). The metatheoretical assumptions of the Modern Synthesis effectively split the internal world from the external world, and in placing priority on the former, promoted a predetermined and nondevelopmental explanation of physical and behavioral characteristics (Overton, 2006; Oyama, 1985; Richardson, 2013). As a result, with few exceptions, evolutionary psychologists have effectively ignored the findings that have emerged from genomics, molecular and cellular biology, and epigenetics and their implications for our understanding of heredity and evolution. In response to the charge of genetic determinism from many developmental scientists, evolutionary psychologists counter that they offer a detailed interactionist framework, as psychological adaptations require environmental input for their proper development and proximate activation (see Confer et al., 2010). In this form of interactionism, genes continue to be characterized as playing the primary or determinative role in the form and function of phenotypic characteristics and nongenetic or environmental factors are delegated to playing a necessary, but clearly supportive role. This perspective promotes a decidedly lopsided view of gene-environment relations and overlooks a wealth of converging evidence from the life sciences indicating the fundamental role of factors above the level of the genes to the origins, emergence, and maintenance of phenotypic outcomes across generations (e.g., see R. M. Lerner & Benson, 2013b).

The Developmental Challenge to the Modern Synthesis

The regulative and generative aspects of development revealed over the past several decades and reviewed in earlier sections of this chapter indicates that the natural selection of random genetic mutations (the cornerstone of the Modern Synthesis framework) simply cannot be sufficient to account for evolutionary change. A growing acknowledgment of this insight has fostered a renewed interest in development within evolutionary biology (as opposed to evolutionary psychology) and increasing recognition that changes in evolution reflect changes in developmental processes (e.g., Arthur, 2002; Gilbert, Opitz, & Raff, 1996; Gottlieb, 1992). This focus on the complexities of the dynamics of development is bringing together genetics, molecular, cellular, and developmental biology, neuroscience, ecology, and evolutionary biology to forge a more comprehensive explanation of the ways and means of the stability and variability of phenotypic characteristics (e.g., Gilbert & Epel, 2009; Hallgrimson & Hall, 2011; Lickliter & Harshaw, 2010; Müller & Newman, 2003; Richardson, 2013). As the philosopher Robert (2008) points out, taking a developmental point of view involves understanding that there is more to development than differential gene expression, that development is not a genes-*plus*-environment phenomenon, and that the causal analysis of development is required to understand evolution.

The developmental challenge to the Modern Synthesis has deep historical roots and involves contributions from numerous scientific disciplines (Gottlieb, 1992; Laubichler & Maienschein, 2007; Robert, 2004; West-Eberhard, 2003). As noted as far back as 1871 by Darwin's critic, St. George Mivart, phenotypic change must come about *before* natural selection is possible. In other words, variation must exist in a population before selection among the variants can occur. Mivart's insight that natural selection can only change the frequency or range of phenotypic variations already present in a population led Mivart to relegate natural selection a more minor role in evolution than Darwin had proposed and to argue that other factors must be at play that were capable of generating the variations upon which selection can then act. Mivart (1871) thought that these factors must somehow be based on the united action of internal and external forces that modified individual development, but he was necessarily vague as to how this might work, as Mivart and his contemporaries of 19th-century biology knew relatively little about details of development or the internal and external forces at play in evolutionary change. Nevertheless, Mivart's insight that the origins of new forms or characteristics must come about through changes in the process of development was a shift in thinking about the process of evolution, one that has received serious attention within the biological sciences in recent decades (e.g., Carroll, 2005; Gerhart & Kirschner, 1997; Gottlieb, 1992; West-Eberhard, 2003). This developmental challenge to the Modern Synthesis view of evolution has been coming from many disciplines, including developmental biology, ecology, animal behavior, and developmental science, and has suggested several processes of evolutionary change beyond simply changes in gene frequencies.

For example, following the thread of an idea proposed by Etienne Geoffroy Saint-Hilaire more than 100 years earlier, the embryologist Gavin de Beer (1940) argued that evolutionary change in the phenotype can only come about by changes in development. However, for de Beer and the few other theorists working on the relation between development and evolution during the first half of the last century (e.g., Garstang, 1922; Goldschmidt, 1940; Russell, 1930) alterations in development that were proposed to initiate evolutionary changes were thought to result from genetic modifications resulting from random mutation, drift, or recombination. Epigenetic processes were not seriously considered in discussions of evolutionary change (even by those focusing on the importance of development) because it was generally supposed that nongenetic factors could not be reliably replicated across generations and therefore could not provide for the heritable variation upon which natural selection could act.

This view has undergone considerable revision of late, due in large part to discoveries in molecular and cellular biology indicating that a variety of developmental resources beyond the genes reliably reoccur across generations. As discussed earlier, we now know that parents can transfer to offspring a variety of nongenetic factors that can directly influence phenotypic outcomes, including methylation patterns, chromatin marking systems, cytoplasmic chemical gradients, and a range of sensory stimulation necessary for normal development (reviewed in Harper, 2005; Jablonka & Lamb, 2005; Lickliter, 2005; Mameli, 2004). In mammals, where the embryo develops within the body of the female, these epigenetic factors can include noncytoplasmic maternal effects, including uterine effects (vom Saal & Dhar, 1992).

At conception, the human zygote inherits not just its genes, but also a structured cell, located inside a structured environment (the uterus), inside a female who is situated in a structured (and historically construed) physical and social environment. Changes in any of these factors could have potentially important implications for development as well as the course of evolutionary events. We propose that understanding how these various hierarchical levels change and how these changes are maintained and transformed across generations is central to a complete evolutionary analysis (see Figure 5.4). This is not a new perspective. Writing nearly 75 years ago, Waddington (1941) pointed out that,

> A theory of evolution requires, as a fundamental part of it, some theory of development. Evolution is concerned with changes in animals, and it is impossible profitably to discuss changes in a system unless one has some picture of what the system is like. Since every aspect of an animal is a product of development, or rather is a temporary phase of a continuous process of development, a model of the nature of animal organization can only be given in developmental terms. (p. 108)

In this light, the contemporary developmental psychobiological systems perspective recognizes the need to understand how combinations of genetic, hormonal, neural, physiological, behavioral, and social processes function synergistically as a system from which characteristics develop and are maintained within and across generations. A growing body of evidence indicates that a persistent change in any of the networks of coactions involved in the development of an organism can lead to anatomical, physiological, or behavioral modifications in that individual and in many cases in their offspring and grand-offspring as well (see Harper, 2005, 2010; Jablonka & Lamb, 2005, for examples). As a result, definitions of inheritance that

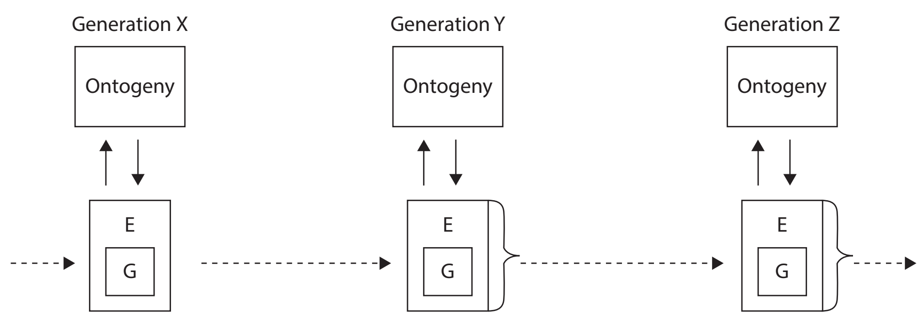

Figure 5.4 Probabilistic epigenetic model of development and heredity. The box containing genetic factors (G) is embedded within environmental factors (E) to represent the developmental system and illustrates that the effects of G and E are interdependent and causally contingent. The dashed arrows running between generations indicate that it is the developmental system that is "transmitted" across generations. The double arrows running between the ontogeny boxes and the developmental system boxes indicate that information going into ontogeny is itself a product of ontogenetic processes, which makes prespecification of outcomes impossible and allows events that occur during one generation to affect the developmental system made available to subsequent generations.

Source: From "Rethinking Epigenesis and Evolution in Light of Developmental Science" (pp. 30–47), by R. Lickliter and H. Honeycutt, in *The Oxford Handbook of Developmental Behavioral Neuroscience*, M. Blumberg, J. Freeman, and S. Robinson (Eds.), 2009, New York, NY: Oxford University Press.

do not include all components of the developmental system that are replicated in each generation and which play a role in the production or maintenance of the life cycle of the organism are bound to be less than complete (Figure 5.4; see also Gray, 1992; Mameli, 2005). Moreover, because some resources become available later in life (e.g., antibodies and bacteria in breast milk), inheritance is not complete at the moment of fertilization. In addition to genes, individuals inherit cell assemblies, an embryonic and fetal stimulative environment, and parents, peers, and the places they inhabit (Lickliter, 2005; Oyama et al., 2001; West & King, 1987). As emphasized throughout this chapter, gene-environment relations occur at all of these levels of the developmental system. At present, there is no overarching theory that adequately addresses the breadth of heredity processes at play in individual development and evolution. We believe such a theory is attainable, but has yet to receive the conceptual and empirical attention it deserves.

As we explore next, one of the most radical implications of a developmental point of view for evolutionary theory is the notion that *genetic changes often follow rather than initiate evolutionary change* (Gottlieb, 1992; Ho, 2010; Johnston & Gottlieb, 1990; West-Eberhard, 2003). From this view, environmentally induced change in an organism's behavior can provide an important process for how phenotypic plasticity might drive both genetic change as well as evolutionary change.

Behavior, Development, and Evolution

Over the past several decades a number of biologists and psychobiologists have proposed that behavior can potentially play a key role in evolutionary change (e.g., Bateson, 1988; Chapter 6, this *Handbook*, this volume; Gottlieb, 2002; Ho, 1998; Johnston & Gottlieb, 1990; Plotkin, 1988; Wcislo, 1989). Although the importance of behavior as an agent of evolutionary change is not a new idea (Baldwin, 1896; C. Lloyd Morgan, 1896), it has yet to be fully incorporated into evolutionary theory. Exploring the various roles of behavior in evolutionary change affords developmental scientists (and psychologists more generally) the opportunity to play an important role in shaping a new extended evolutionary synthesis.

The work of Gottlieb (1987, 1992, 2002) provided an innovative conceptual framework for understanding how changes in behavior could contribute to the evolutionary process. In Gottlieb's view of evolution, enduring transgenerational phenotypic change can occur at the behavioral, anatomical, and physiological levels before it occurs at the genetic level. His theoretically oriented perspective proposes that changes in development that result in a novel behavioral shift that recurs across generations can facilitate new organism-environment relations. These new relations, which can include "invasion" of novel environments, can bring out latent possibilities for morphological or physiological change. Eventually, a change in gene frequencies may also occur as a result of geographically or behaviorally isolated breeding populations. Thus, changes in behavior can be the first step in creating new phenotypic variants on which natural selection can act (Gottlieb, 2002).

In this view of evolutionary change, genetic change is often a secondary or tertiary consequence of enduring transgenerational behavioral changes brought about by alterations of normal or species-typical development. These developmental modifications often put individuals in new relations with their local environments, subjecting them to new selection pressures and increasing the likelihood of eventual change in the genetic composition of the population. This perspective introduces a plurality of possible pathways to evolutionary change, complementing genetic factors such as mutation, recombination, and drift.

In a seminal paper exploring the nature of the links between development and evolution, Johnston and Gottlieb (1990) provided an illustrative example of how new phenotypes may arise due to an enduring change in behavior before changes in gene frequencies. They describe a scenario in which a population of rodents whose normal diet consists of soft vegetation encounters a new food source of relatively hard but highly nutritious seeds. As the animals learn to sample and eventually increase the representation of seeds in their diet, a number of developmental effects of their new diet become evident, including possible changes in body size and composition, fecundity, age of sexual maturation, and indirect changes in morphology. For example, as the diet changes from soft vegetation to harder seed items, the mechanical stresses exerted on growing jaw tissues during development will change. Given that patterns of bone growth are known to be determined, in part, by forces exerted on the growing bone (Frost, 1973), the skeletal anatomy of the jaw will likely be different in the animals that experience hard versus soft diets early in life. Such changes in diet have, in fact, been shown to affect the jaw and skull of rats (Bouvier & Hylander, 1984).

In this example, behavioral change in members of a population (a preference for a new diet of hard seeds) leads to specific anatomical changes (modification of the jaw and teeth). Such changes can endure across generations, and as long as the new diet remains available, may eventually lead to changes in gene frequency as a result of long-term behavioral or geographic isolation among variants within the population. Following this line of thinking, West-Eberhard (2003) has provided a wealth of evidence suggesting that genes are probably more often followers than leaders in evolutionary change. From this view, the basis of phenotypic evolution cannot be reduced to population genetic events, but rather must include organisms' physical properties, self-organizing capacities, and responsive potential to external influences. Of particular importance in this concern is the recognition that variations in morphology, physiology, and/or behavior arising from modifications to the developmental process can place organisms in different ecological or functional relationships with their environments. If these phenotypic variations provide even slight advantages in survival and reproduction, then competitors without the novel phenotype will eventually decrease in frequency in the population, thereby contributing to evolutionary change.

Drawing on decades of work by developmental psychobiologists (see Michel & Moore, 1995), it seems clear that the conditions that best favor the expression of modified or novel phenotypes are species-atypical alterations in environmental conditions and contingencies that occur early in ontogeny (e.g., Blumberg, 2009; Gottlieb, 1971; Kuo, 1967; Levine, 1956). Shifts in behavior brought about by alterations to the developmental system can arise at any stage of the life cycle, but are generally more likely to occur earlier in individual development. This important point was highlighted by several evolutionary theorists during the last century (e.g., de Beer, 1940; Garstang, 1922; Goldschmidt, 1940; Waddington, 1975), who despite their different backgrounds and perspectives realized the significance of embryonic and neonatal periods of development for the generation of phenotypic novelties. These early periods of development are a time of rapid morphological, physiological, and behavioral change, and modifications to an individual's developmental system during this time can initiate a host of physical and behavioral changes, and in some cases (given the availability of appropriate developmental conditions) persist across subsequent generations. Developmental science has much to contribute in this area, particularly to exploring how previous developmental outcomes and current experiences in specific contexts combine to influence these processes.

For example, the observed behavioral changes reported in enriched rearing and early handling experiments (i.e., enhanced exploratory behavior, increased problem-solving abilities, resistance to stress) are types of behaviors that could support the seeking out and utilization of new habitats, leading to a host of other potential phenotypic novelties and setting the stage for possible evolutionary change. Gottlieb (1997) pointed out that animals that have had considerable variation in social and physical experiences early in life are more likely to seek out variation later in life, showing greater levels of exploratory behavior and novelty seeking than animals having more limited early experience. This sort of behavioral plasticity, the willingness to approach and explore novel objects, places, or situations, can increase the likelihood of particular individuals utilizing or migrating to new habitats, where they could encounter different types of functional demands. Although many changes in functional demands would be transient, others could be long lasting and persist across generations, revealing latent morphological or physiological variability not expressed in the original environment. How these processes work and the underlying biology involved remains poorly understood and developmental science can provide a developmental and ecological perspective to the ways and means of such transgenerational processes and their effects. It is important to emphasize that a developmental evolutionary approach involves unpacking developmental dynamics across numerous levels of analysis (genetic, epigenetic, behavioral, social, ecological) and time-scales (ontogenetic and transgenerational).

A related task for developmental science is to provide more detailed empirical evidence for the role of behavior as a leading edge in the evolutionary process. Changes in behavior brought about by changes in prenatal and postnatal rearing environments have been well documented in comparative psychology (e.g., Champagne, 2010; Kuo, 1967; Lickliter, 2005; Michel & Moore, 1995) but how such changes are significant to evolutionary issues has received relatively little empirical or conceptual attention. For example, differences in physical measures (e.g., body weight, endocrine responses) and behavioral measures (e.g., fearfulness) between groups of rats whose mothers or grandmothers were handled or not handled as pups have been reported for decades (e.g., Denenberg & Rosenberg, 1967). Despite the importance of these findings to both developmental and evolutionary concerns, the transgenerational effects of early rearing conditions on both physiological and behavioral responsiveness (including curiosity, novelty seeking, and emotional regulation) are only beginning to receive research attention and remain poorly understood. An experimental focus on how changes in experience can lead to genetic, morphological, or physiological alterations will help identify the specific biological and psychological processes potentially involved in the behavioral initiation of evolutionary change. This approach will necessarily be grounded in a view of behavior as both the *product* of development and as a component of the *process* by which development takes place (Stotz, 2008), and will require a multidimensional, process-oriented methodology that includes a variety of levels of analysis beyond the behavioral, including the environmental regulation of gene expression and cellular function and the effects of sensory stimulation on neural and hormonal responsiveness.

This multidimensional perspective on development and evolution provided by DPS highlights a persistent challenge for developmental theory—making sense of the relation among the various time scales over which change occurs. These time scales include *real time*, the immediate experiences and encounters of the individual with the extant physical, biological, and social environments, *developmental time*, the continuing influence of prior experiences and encounters on the individual's ongoing coaction with varied environments, and *evolutionary time*, the transgenerational effects of the individual's experiences and activities during ontogeny (Johnston & Lickliter, 2009). Improving our knowledge of the dynamics of developmental processes across these multiple time scales will undoubtedly contribute to a deeper understanding of the ways and means of both development and evolution.

SUMMARY AND CONCLUSIONS

Biology has been undergoing a significant shift in how to characterize the process of development over the past several decades. As in any science, the models and frameworks that form the foundation of our current knowledge have to be reevaluated and updated as new evidence is revealed. Just as the concepts of instinct and maturation, applied by generations of psychologists, have been shown to be simplistic and even misleading, several of the core concepts widely applied in biology during the last century to address the process of phenotypic development have likewise proven to be in need of revision. In particular, assumptions regarding the role of genes in development, heredity, and evolution (namely, instructions for building organisms resides in their genes, genes are the exclusive means by which these instructions are faithfully transmitted from one generation to the next, and there is no meaningful feedback from the environment or the experience of the organism to the genes) have been seriously challenged by demonstrations of the epigenetic regulation of gene expression and cellular function, in some cases across generations, as well as the varied effects of sensory stimulation and social coaction on genetic, neural, and hormonal responsiveness.

Consistent with the developmental psychobiological systems perspective outlined in this chapter, a major conclusion to be drawn from these advances in contemporary biology is that causation in biological systems runs in both directions: "bottom up" from the molecular level (including genes), and "top down" from all other levels, including cellular, tissue, organ, organism, and external physical, ecological, and social environments (Keller, 2010; Kohl et al., 2010; Noble, 2006, 2010; Richardson, 2013; Witherington, 2011, Chapter 3, this *Handbook*, this volume). These levels of organization reciprocally influence each other, and both the course of development and the impact of a change in development are thus contingent upon the state of the surrounding system. In other words, what happens at one level in a system (genetic transcription, neural activity, or behavior) depends on what is happening at other levels of the system (cellular environment, sensory environment, and so on). Further, all characteristics are jointly determined by internal and external developmental resources; *these are not competing alternatives*. So-called biological influences do not operate independently of (and cannot be meaningfully separated from) experiential influences. To argue otherwise both oversimplifies development and hinders further developmental analysis.

This growing appreciation of the complexities of developmental dynamics across biology has prompted some to call for a new evolutionary synthesis in the life sciences (e.g., Jablonka & Lamb, 2005; Keller, 2010; Pigliucci & Muller, 2010). Given that (a) biological form and function (from the genetic to the neural and anatomical levels) are routinely influenced by behavior, (b) that heredity includes specific features of physical and social environments, and (c) that behavioral changes can initiate and drive evolutionary change, it seems evident that the psychological sciences must have a key role in any such reformulation.

Much work lies ahead in creating a unified theory of heredity, development, and evolution. A comprehensive understanding of these phenomena and their relations across levels of biological complexity, from genes to cells to organs to organisms, has challenged generations of biologists and psychologists and is far from realized. That being said, it is certainly the case that genetics, neuroscience, and evolutionary biology have all undergone significant changes in recent years by the inclusion of a developmental point of view. The complexity of the bidirectional traffic across hierarchical levels inherent in the process of development being revealed through this inclusion highlights the dynamic fusion of biology and ecology and sets the course for future efforts aimed at a deeper understanding both developmental and evolutionary change. This task will require both description and experimentation, with the goal of explaining how each generation sets up the necessary developmental conditions and resources for the next and how specific changes in developmental conditions lead to specific changes in behavior, anatomy, physiology, as well as gene expression.

We began this chapter by asking what greater mystery there could be than how to explain the origins of form, function, and transformation within and across lifecycles. The complexity of this mystery is proving to be far greater than anyone anticipated. It may be the case that the number of variables, transactions, and contingencies involved from fertilized egg to functional adult may put a full understanding of the phenomenon of development beyond our comprehension. On the other hand, we have learned important lessons over the past century about how (and how not) to frame questions about development to address this complexity more accurately and profitably. The developmental psychobiological systems approach we have outlined in this chapter reflects these insights and provides a particularly useful and effective framework to address the scientific pursuit of human development.

REFERENCES 238

Human development presents many wonders, but one of the most remarkable is how a fully functional individual grows from a microscopic embryo. The processes that are involved have often seemed beyond understanding and, even now, much remains to be discovered. Nevertheless, the factual certainties have been known for a long time. The *robust* constancies of development are profound and real. Nobody will confuse a human with a rhesus monkey. At the same time, the *plasticity* of each individual is as remarkable as his or her robustness. Humans possess great capacity for change, a capacity that, as in other species, emerges very early in development. It does not follow, though, that two distinct processes can be cleanly separated, one leading to invariant outcomes and the other generating differences between individuals due to culture, education, and differences in experience. If this were true, it might be sensible to ask the question how much of behavior pattern is innate and how much is learned or more generally, how much is genetic and how much is due to the environment. This dichotomy, which was popular in the early days of ethology (e.g. Tinbergen, 1951) is neither true nor helpful and confuses folk psychology with real science.

In this chapter I review the profound changes that have taken place in how biologists think about behavioral development. I write as somebody with a degree in zoology and originally trained as an ethologist. It is difficult nowadays to define ethology. It was regarded as the biological study of naturally occurring patterns of behavior that are adaptive and typical of the species. Ethologists were strongly influenced by Darwinian thinking. In doing so, they have been contrasted with psychologists whose primary drive was to find universals and understand cognition and the human mind. A mistaken view held about ethologists has been that their work was solely conducted in the field. Many have been first and foremost experimentalists. Nevertheless much emphasis has been laid on simply watching the behavior of animals including children. Advice was given to the budding ethologist to produce an *ethogram* of all the behavior patterns of the subject under investigation. The assumption was that all members of the same species would behave in the same way. The assumption was clearly wrong because members of the same species, the same sex, and the same age sometimes differ dramatically from each other. Ethology, like psychology, broadened out, and made strong contacts with a great many different fields from the neurosciences to the developmental sciences, psychiatry, and anthropology.

Changes in my own interests also reflect the broadening character of ethology. As a boy I was a keen naturalist and wanted to study birds in the field. My first scientific paper, written when I was an undergraduate, was on the breeding biology and behavior of a rare Arctic bird, the Ivory Gull (P. Bateson & Plowright, 1959). However, my doctoral work was on behavioral imprinting, by which young birds form a strong attachment to the first conspicuous object they encounter. This research under Hinde was experimental and based in a laboratory (P. Bateson, 1966); it led to a lifelong interest in behavioral development and its underlying processes. On a 2-year postdoctoral position in California, I worked with the eminent neurosurgeon and neuropsychologist Karl Pribram. Subsequently, a substantial part of my research was with neuroscientists (e.g., P. Bateson & Horn, 1994; Horn, Rose, & Bateson, 1973). Later my developmental interest led me to work with epigeneticists who explained developmental phenomena in terms of the differential regulation of gene expression and, in particular, by epigenetic processes that lead to changes in gene expression without a change in nucleotide sequence. Despite or even because of these interests, I am strongly committed to reversing the reductionist trend and bringing the focus of developmental science back to the level of the whole organism (e.g. P. Bateson, 2005). This chapter surveys some of the contributions that ethology in its various guises, has made to an understanding of how humans develop and evolve and how these contributions are being integrated with modern studies of human development.

SETTING THE SCENE

The nature/nurture dichotomy is not merely a feature of popular science and folk biology and folk psychology. Many eminent biologists have accepted an *either/or* account of development. For example in his book *Sociobiology*, Wilson (1975) tacitly accepted this position. In a large collection of reviews of the book published in the journal *Animal Behaviour* in 1976, Wilson was attacked because he had not considered the interplay between the developing organism and its environment. In response to these criticisms he wrote that, in his view, development was a black box or module that could be decoupled when the relations between genes and the characteristics of the adult organism were considered (Wilson, 1976). The use of the nature/nurture distinction often involved a confusion of categories, since nurture was seen as a developmental process and nature was often viewed as the genetic origin of that process. For some, however, nature was viewed as the adult expression of a developmental process (P. Bateson & Gluckman, 2011). For others, though, nature was reserved for those features that developed robustly, unaffected by the vagaries of the environment, and nurture was used for those features that were plastic, greatly influenced by the conditions in which the individual developed.

The nature-nurture distinction runs through persistent arguments about the origins of human faculties. The 17th-century philosopher John Locke believed that all reason and knowledge was derived from experience. Charles Darwin's cousin, Francis Galton, expressed a strongly contrasting view about the development of human mental faculties, believing that education and environment produce only a small effect on the human mind and that most human qualities are inherited. The debate continues to the present day (see Downes & Machery, 2013). It extends across the full range of human faculties, styles of thinking, and behavior. The universalists claim that these faculties are shared by and intrinsic to all human beings. The relativists argue that all the cognitive characteristics of humans emerge from the culture in which they are embedded (see Lloyd, 2007). Reducing the problems of origin to either this or that is deeply unsatisfactory. Equally unhelpful, I argue, is the conflation of origins with developmental processes. Many others have taken the same view. In particular Gottlieb (1997), Johnston (Johnston & Edwards, 2002), Lickliter (Lickliter & Honeycutt, 2010, Chapter 5, this *Handbook*, this volume) and Oyama (1985) have argued strongly for a systems approach to development (see also the essays in the book edited by Oyama, Griffiths, & Gray, 2001). Developmental systems theory was also introduced to psychology by Ford and Lerner (1992) and later enlarged as relational developmental systems by Overton (2006) and later by Lerner and Overton (2008; Overton, 2013, Chapter 2, this *Handbook*, this volume; Overton & Lerner, 2012; Witherington, Chapter 3, this *Handbook*, this volume). Before focusing on how the robust features of development are integrated, I consider how ethological thinking has changed since the rise of ethology in Western Europe during the mid-20th century.

CHANGES IN THE ETHOLOGICAL APPROACH TO DEVELOPMENT

The notion of instinct became a focus of intense interest among the founders of modern ethology (Burkhardt, 2005), particularly Lorenz and Tinbergen. Lorenz had been struck by how behavior patterns that had looked so appropriate in the natural worlds to which the animals had been adapted looked odd when performed spontaneously outside of their normal context. A few days after hatching a hand-raised duckling touches with its bill a pimple above its tail and then wipes its bill over its down. Yet this pimple, which becomes an oil-producing gland in the adult, is not yet functional and the duckling would normally be made waterproof by the oily feathers of its brooding mother. Observations such as this led Lorenz to conclude that behavior patterns that were well-adapted by evolution to the biological needs of the animal are qualitatively distinct from behavior acquired through learning (Lorenz, 1965).

The classical ethologists emphasized how complex and coordinated behavior patterns develop without practice. Birds, for example, can usually fly without prior experience of flying. In one classic experiment, young pigeons were raised in narrow boxes that physically prevented them from moving their wings after hatching. They were then released at the age at which pigeons normally start to fly. Despite having had no prior opportunities to move their wings, the pigeons were immediately able to fly when released, doing so almost as well as the pigeons that had not been constrained (Grohmann, 1939). In a similar way, European garden warblers that have been hand-raised in cages nevertheless become restless and attempted to fly south in the autumn—the time when they would normally migrate southward. The warblers continue to be restless in their cages for about a couple of months, the time taken to fly from Europe to their wintering grounds in Africa. The following spring, they attempt to fly north again. This migratory response occurs despite the fact that the birds have been raised in social isolation, with no opportunities to learn when to fly, where to fly, or for how long (Gwinner, 1996).

Stable Features of Development

Lorenz, who had had his academic training in comparative anatomy, believed that behavioral activities could be regarded like any physical structure or organ of the body. They have, he argued, a regularity and consistency that relates to the biological needs of the animal, and they differ markedly from one species to the next. Indeed, the developmental progression from a single cell to an integrated body of billions of cells, combining to produce coherent behavior, is astonishingly orderly. Just as animals grow kidneys with a specialized biological function, adapted to the conditions in which they live, so they perform elaborate and adaptive behavior patterns without any previous opportunities for learning or practice. Particular behavior patterns are, Lorenz argued, like body organs in serving particular biological functions; their structure was likely to have been adapted to its present use by Darwinian evolution and depends on the ecology of the animal; and they develop in a highly coordinated and systematic way.

Certain aspects of human behavioral development recur in everybody's life despite the shifting sands of cultural change and the unique contingencies of any one person's previous history. Humans are remarkably similar to each other in many aspects of their behavior—at least, when compared with members of other species. With few exceptions, humans pass the same developmental milestones as they grow up. Most children have started to walk by about 18 months after birth, have started to talk by around 2 years and go on to reach sexual maturity before their late teens. Individual differences among humans seem small when any human is compared with any chimpanzee.

Human facial expressions have characteristics that are widely distributed in people of many different cultures. The emotions of disgust, fear, anger, and pleasure are read off the face with ease in any part of the world (Darwin, 1872; Eibl-Eibesfeldt, 1970; Ekman, 2009). An enormous archive of photographic records of human expressions in different cultures at different stages of economic development has been collected. The similarities in, for example, the appearance of the smile or the raised eyebrows are striking. The cross-cultural agreement in the interpretation of complex facial expressions is also remarkable. People from very different backgrounds agree about which emotions are being expressed. They also agree about which emotion is the more intense, such as which of two angry people seems the more angry.

The Innate School Marm

Even though Lorenz was a forceful advocate of the concept of instinct, he certainly did not deny the importance of learning. On the contrary, he gave great prominence to developmental processes, such as behavioral imprinting, by which birds formed their social and sexual preferences. However, Lorenz saw such learning processes as being under the control of what he referred to as the *innate school marm*. This metaphorical lady represents the highly regulated acquisition of information from the environment just when it is most adaptive for the individual to get it. He thought of instincts, whether they organized behavior directly or were the processes that changed behavior through learning, as inherited neuronal structures, which remained unmodified by the environment during development (Lorenz, 1965). Behavior resulting from learning was seen as being separately organized in the brain from the instinctive elements. At their most complex, then, instincts were thought to provide the basis by which the individual gathers particular types of information from the environment in the course of learning.

The acquisition of language by humans has been thought about in much the same way as Lorenz thought about the innate schoolmarm. In this respect Lorenz's ideas were remarkably similar to those of Chomsky (2000). It is obvious that the differences in spoken language between a French person and a German are not due to genetic differences. Therefore, apart from the act of speech itself, the proposed universal and instinctive characteristics of all humans are not going to be discovered in the surface organization of such behavior. In both Lorenz's and Chomsky's minds, however, the predispositions to behave in particular ways spring fully armed from the genome of each individual and were unaffected by experience.

Critique of Classical Ethology

Despite all the empirical evidence that some elements of behavior can develop robustly without opportunities for learning, the ethologists' notion of instinct attracted strong criticism in the 1950s from a group of American comparative psychologists who studied animal behavior and were strongly influenced by the thinking of Schneirla (1956). The critics laid out a quite different agenda in which a major focus was on behavioral development with no sharp distinction drawn between the specific and general consequences of experience (P. Bateson, 1976). The attack on the ethologists came most powerfully in an article by Lehrman (1953), who argued that

> The problem of development is the problem of the development of new structures and activity patterns from the resolution of the interaction of existing ones, within the organism and its internal environment, and between the organism and its outer environment. At any stage of development, the new features emerge from the interactions within the current stage and between the current stage and the environment. The interaction out of which the organism develops is not one, as is often said, between heredity and environment. It is between organism and environment! (p. 345; see also Lehrman, 1970)

This standpoint set the scene for a major change in the thinking of ethologists about development. Hinde was particularly influential in synthesizing the views of ethologists and comparative psychologists (Hinde, 1970). Advances in scientific thought in relation to the transactions between the individual organism and its environment had also occurred in the psychological literature (Lerner, 1984; Overton, 2006; Sameroff, 2010).

DIFFERENT PROBLEMS, DIFFERENT QUESTIONS

Children are studied in many ways because people become absorbed in different types of problem. Some want to know, for instance, how a particular character or system benefits the child, while others want to know how it works. The variety of different conceptual approaches to development is remarkable (Overton, 2013, Chapter 2, this *Handbook*, this volume). Clearly, then, a number of fundamentally different types of problems are raised when studying psychology and biology. Among ethologists, who study the biology of behavior, the most useful and widely accepted classification was formulated by the Nobel Prize–winning ethologist, Niko Tinbergen (1963). He had accepted Lehrman's critique of Lorenz's ideas about instinct. In a famous paper dedicated to Lorenz on his 60th birthday, he pointed out that four distinct types of problem are raised when studying behavior: current processes, ontogeny, function, and evolution (Tinbergen, 1963). These then relate to four different questions that can be asked about any feature of any organism including a child: How does it work? How did it develop? What is it for? and How did it evolve? Tinbergen's article followed shortly after Mayr's (1961) distinction between proximate and ultimate causation, and Tinbergen's biological function and evolutionary issues have often been characterized as "why questions" and current process and developmental issues as "how questions" (e.g., Klopfer & Hailman, 1972). However, Mayr's deployment of "ultimate causation" was ambiguous, simultaneously seeking to encapsulate both the "function" of a character and its "evolutionary history" (Laland, Odling-Smee, Hoppitt, & Uller, 2012). In contrast, Tinbergen's formulation has the advantage of clearly distinguishing between the present and the past (see Table 6.1).

Unlike Mayr's scheme, Tinbergen's framework has attracted little criticism, and has stood the test of time (P. Bateson & Laland, 2013). The general point about the distinctions made by Tinbergen and repeated in almost every modern textbook about animal behavior is the valuable clarifications they brought to discussions among both biologists and psychologists. Biological function and current process were often confused and often still are. Consequently, when one scientist had been considering the current utility of a characteristic another might have thought the discussion was about the current processes that underlie that characteristic. Such misunderstandings can be avoided by appreciating that, unsurprisingly, different perspectives raise different questions. Indeed, the four questions apply broadly to any feature of living (and even some nonliving) systems. For instance, traffic lights could be thought of in terms of how they worked, how they were assembled, how their design evolved over time, and how their use increases the chances of survival of road users (Martin & Bateson, 2007).

TABLE 6.1 The Four Questions of Behavioral Biology and Psychology

	Current	Historical
Proximate	How does it work?	How did it develop?
Ultimate	What is it for?	How did it evolve?

Tinbergen (1963) posed four distinct questions that may be addressed when examining a biological or psychological phenomenon. Questions about current process and biological function deal with the present. Questions about evolution and development deal with the past. The mechanistic and developmental questions are sometimes called proximate and those about function and evolution are sometimes called ultimate.

Source: From *Measuring Behaviour: An Introductory Guide* (3rd ed.), by P. Martin and P. Bateson, 2007, Cambridge, England: Cambridge University Press.

Although Tinbergen's inclusion of development in his list of problems was important, he was not much interested in this aspect of ethology. Others were, however. Developmental ethologists, psychiatrists and psychobiologists formed strong links, leading to productive investigations of topics such as constraints on learning (Hinde & Stevenson-Hinde, 1973) and attachment of young to their parents (P. Bateson & Hinde, 1976; Bowlby, 1969). The interdisciplinary character of the work is apparent in two volumes of essays published in the early 1980s. They demonstrated that the problems of development have to be expressed very differently from the ways in which the ethologists had originally thought about them (P. Bateson & Klopfer, 1982; Immelmann, Barlow, Petrinovich, & Main, 1981). The book edited by Immelmann et al. emerged from a year-long meeting held in Bielefeld in Germany. The first editor and organizer of the meeting, Immelmann was trained as an ethologist, but the contributors to the book included theoreticians and child developmental psychologists.

The book edited by myself and Klopfer also included authors from a wide variety of disciplines, embracing the experimental analysis of behavior and theories of life history. It was already becoming obvious that highly beneficial interactions were developing between different disciplines, particularly between ethology and developmental psychobiology (Michel & Moore, 1995). The relevance of these interdisciplinary efforts to studies of human development has often been emphasized (Gottlieb, Wahlsten, & Lickliter, 2006).

BIOLOGICAL FUNCTION

Despite the broadening out of ethology, many research workers on animal behavior retained a strong interest in the adaptive value of behavior. Indeed this became the dominant focus of the behavioral ecologists. Even though the distinction between "what is it for?" and "how did it develop?" is a logical one, benefits flow from asking them simultaneously are often apparent. A growing number of examples have been found in both plants and animals of how the organisms characteristics are radically influenced by ecological conditions (Badyaev, 2009; Gilbert & Epel, 2009; West-Eberhard, 2003). These cases raise the question: Do plastic developmental responses represent adaptations to the environments in which they are found?

An example of the functional approach to development is provided by the changes that occur as a child develops.

Many aspects of body and behavior obviously change, sometimes relatively suddenly, during the course of an individual's development. Sudden discontinuous change is most obvious during the first two decades of a human life—for example, at birth and puberty. Such discontinuities are not mysteries. Many physical and biological systems are capable of changing in an abrupt, discontinuous way. Steadily increasing the pressure on a light switch does not produce a steady increase in the brightness of the bulb it controls. The switch has a point of instability, so that one moment the bulb is dark and the next moment it is fully lit. Similarly, a relatively small internal or external change can quickly transform a developing organism's characteristics to something that looks quite different. For instance, the fertilized egg of a mammal rapidly divides becoming a ball of cells, the blastula. The cells continue to divide, but do so at slightly different rates. The steady change is such that the blastula suddenly seems to collapse on one side like a deflated rubber ball and a two-layered structure called the *gastrula* is formed. The embryo has changed its appearance dramatically as a result of a process of continuous growth.

Adaptations to Early Life

Sudden shifts in behavior during an individual's development may have biological function, reflecting the changing ecology and needs of the individuals as they get older. Despite parental care, most individuals have to support themselves in at least some respects long before they are fully mature. Furthermore, they are emphatically not miniature adults. Given that the young have to survive in an environment that is radically different from that of the adult, it follows that they are likely to have specialized features for the conditions in which they live. The adaptations of larval forms with totally different phenotypes from those of adults provide the most striking examples. The caterpillar is specialized for eating and has none of the reproductive roles exhibited by the butterfly or moth that it will subsequently become. These changes over the course of the life history are found in invertebrates and in amphibia such as frogs. Mammals also have their juvenile adaptations. In rats the control system involved in suckling is distinct from that involved in adult eating (Hall & Williams, 1983). The suckling system cannot be satiated easily and time since the last meal does not affect the readiness of the pup to take a nipple and suck. Presumably the more milk the offspring can get, the better off it is. The end of a bout of feeding is provided by the mother's limitations in providing milk. Within a few days of birth and long before the weaning process starts, the pup can be induced to lap milk like an adult. When it feeds in this way, time since the last meal *does* affect its responsiveness. In other words, both juvenile and adult feeding systems are independent, work differently and are fully developed at the same time. Normally the rat's adult feeding system does not come into operation until at least 2 weeks after the juvenile one. The same point that suckling is a special form of feeding adapted for early life has been made in relation to human babies (Alberts & Pickler, 2012).

Behavior in Development as Scaffolding

Does a given behavior pattern function as part of the assembly process, falling away like scaffolding round a building when the animal matures? The biological function of some of the behavioral processes found in many developing animals seems to be the gathering of information. For instance, precocial birds such as chicks and ducklings actively work to present themselves with a form of input that will start off the process of behavioral imprinting (P. Bateson & Reese, 1969). Another plausible example is mammalian play. The duration and frequency of play categories have been found first to increase with age and then to decline (P. Bateson & Martin, 2013). Adults may not give up playing altogether, but unquestionably they do less of it than juveniles.

Play may enhance skills involved later on in life and have an impact on the child's creativity (P. Bateson & Martin, 2013). In such cases play has delayed benefits and is a preparation for the challenges of adult life. This being so, play does, indeed, function as scaffolding that has little use once the edifice of skills have been assembled. Some of the benefits of play may, however, be immediate and in such cases play should be thought of as partly a juvenile specialization. In short, many of the things that the young do are not incompetent or incomplete versions of adult behavior. The growing awareness of such facts has been an important benefit of adopting a functional approach to development that focuses on the usefulness to the individual in terms of its survival and reproductive success.

Adaptations Leading to Individual Differences

The variation in behavior found in most if not all species commonly arises because individuals have the capacity to respond in more than one way according to the state of the local environment or their own body. Individuals have many latent capacities that are expressed only under certain conditions. The developmental processes of *plasticity* that are elicited by those conditions normally provide useful adaptations to the environment. The implication of many of the examples of developmental plasticity is that environmental induction provides a forecast about the conditions of the world that the individual will subsequently inhabit. In mammals the best route for such a forecast may be via the mother. Vole pups born in the autumn have much thicker coats than those born in spring; the cue to produce a thicker coat is provided by the mother before birth (Lee & Zucker, 1988). The value of preparing in this way for colder weather is obvious. The individual may be likened to a jukebox, capable of playing many tunes but, in the course of its life, possibly playing only one of a set. The particular suite of adaptations that is expressed is elicited by the conditions in which it grows up or even by the conditions to which the individual's parents and grandparents were exposed.

Maternal forecasting by induction is now thought to be important in human biology and has important implications for adult health when, because of large changes in economic conditions, the maternal forecast is wrong (P. Bateson et al., 2004; Gluckman & Hanson, 2006). Generally such systems of developmental plasticity work well, but in a changing environment they generate poorly adapted phenotypes because the environmental forecast proved to be incorrect. The triggering of normally appropriate modes of response provides a fresh way of thinking about individual differences.

The functional argument is that the pregnant woman, living on a relatively low plane of nutrition, unwittingly signals to her unborn baby that the environment her child is about to enter is likely to be harsh. This weather forecast from the mother's body results in her baby being born with adaptations, such as a small body and a modified metabolism, thereby helping the child to cope with a shortage of food if the forecast is correct. These individuals, having small bodies and specialized metabolisms adapted to cope with meager diets, run into problems if, instead, they end up growing up in an affluent industrialized society to which they are poorly adapted. Among a group of individuals, who were born at term and breastfed as babies, those who had the lowest weights at birth had the highest death rate from cardiovascular disease (Barker, 1995). The argument is that mothers on a low level of nutrition signaled to their unborn child that the environment outside would be harsh. As a result, the babies were born with the suite of adaptations that would have suited them well to diets low in carbohydrates and fat. However, they were poorly adapted to the affluent environment in which they subsequently grew up. A great many other studies from around the world have supported this conclusion and shown that many conditions such as type 2 diabetes are exhibited by people born small but subsequently reared on rich diets. The opposite side of the coin is that people who grow up in plentiful environments may be at greater risk during periods of prolonged famine than those who were born as low-birth-weight babies. Children born to affluent parents are more likely to suffer adverse effects if they are starved in adulthood. In concentration camps and the worst prisoner-of-war camps, anecdotal evidence suggests that the physically large individuals died first whereas at least some of the small individuals survived. In a famine-exposed Ethiopian population, higher birth weight was associated with a ninefold higher risk of rickets (Chali, Enquselassie, & Gesese, 1998). This might have been caused by the children with large bodies having higher needs for calcium and vitamin D than those with smaller bodies, but the point is that these children were at greater risk and had a lower chance of reproducing successfully than the smaller children. Many other forms of plasticity exist each depending on environmental contingencies and each generating further differences between individuals (P. Bateson & Gluckman, 2011).

MEANINGS OF INNATENESS AND INSTINCT

Despite the healthy links that have been formed between different disciplines, the debate about development has been confused because the term *instinct* means remarkably different things to different people. To some, instinct means a distinctly organized system of behavior patterns, such as that involved in searching for and consuming food (Tinbergen, 1951). For others, an instinct is simply behavior that is not learned (Lorenz, 1965). Instinct has also been used as a label for behavior that is present at birth (the strict meaning of *innate*) or, like sexual behavior, patterns that develop in fully expressed form at a particular stage in the life cycle. Another connotation of instinct is that once such behavior has developed, it does not change. Instinct has also been portrayed as behavior that develops before it serves any biological function, like some aspects of sexual behavior (Hogan, 1988). Instinct is often seen as the product of Darwinian evolution so that, over many generations, the behavior was adapted for its present use (Lorenz 1965). Instinctive behavior is supposedly shared by all members of the species (or at least by members of the same sex and age) (Berridge, 1994). It has also been used to refer to a behavioral difference between individuals

TABLE 6.2 The Different Meanings of Innateness and Instinct

Present at birth or particular stage of development
Not learned
Genetic—highly heritable
Adapted during evolution
Develops before function is established
Shared by all members of species/sex/age group
A functional behavioral system
Controlled by a specialized neural module
Developmentally robust—well-canalized

Evidence for one of these meanings does not necessarily imply evidence for another.
Source: From "Developmental Approaches to Behavioural Biology," by P. Bateson and J. C. Curley, 2013, *Nova Acta Leopoldina*, *111*, 89–110.

caused by a genetic difference (Hinde, 1969). Confusions arise, therefore, because instincts are seen both universal and part of individual differences (see Table 6.2).

The overall effect of the multiple meanings and multiple origins is, to say the least, muddling (P. Bateson & Curley 2013; P. Bateson & Mameli, 2007; Blumberg, 2005; Mameli & Bateson, 2006, 2011). The conflation of different meanings appeared to justify the view that a single coherent and unitary notion of instinct is needed. If one defining characteristic of instinct has been found, then the rest will also be found. In practice, many behavior patterns have some, but not all, of the defining characteristics of instinct, and the unitary concept starts to break down under closer scrutiny. The various theoretical connotations of instinct—namely that it is not learned, caused by a genetic difference, adapted over the course of evolution, unchanged throughout the life span, shared by all members of the species, and so on, are not merely different ways of describing the same thing. Even if a behavior pattern is found to have one diagnostic feature of instinct, it is certainly not safe to assume that it will have all the other features as well.

In addition, many of the theoretical implications of the classical concept of instinct are difficult to test in practice. If instinct is defined as behavior that does not involve learning in its development, experiments to exclude all opportunities for learning are harder to conduct than might at first appear. One formidable obstacle to proving that a behavior pattern is not learned is the capacity that individuals have to acquire the necessary experience in more than one way. When an individual is isolated from one particular form of experience that is thought necessary for development, the behavior pattern may nonetheless develop by an alternative route (Martin & Caro, 1985). It is difficult to draw a clear distinction between experiences that have specific effects on the detailed characteristics of a fully developed behavior pattern and environmental influences that have more general effects on the organism, such as nutrition or stress. Experiences vary in the specificity of their effects (P. Bateson, 1976). Even if all obvious opportunities for learning a particular behavior pattern are excluded, a major problem remains. This problem is that individuals can readily generalize from the effects of one type of experience to another. It is therefore difficult to know whether an individual has transferred the effects of one kind of experience to what superficially looks like a quite different aspect of their behavior. For example, if somebody draws a letter of the alphabet on your hand while your eyes are shut, you should still be able to visualize the letter, even though you have not seen it. In doing this you will have demonstrated a phenomenon called cross-modal matching (Proops & McComb, 2012).

Another pitfall in the quest for instinct is that developing individuals cannot be isolated from themselves, and some of their own actions may provide crucial experience that shapes its subsequent behavior (Gottlieb, 1971, 1991). Finally, in human babies preference for the mother's distinctive voice at birth depends on experience that occurred before birth (DeCasper & Fifer, 1980). The use of different developmental routes to the same endpoint, cross-modal matching, the impact of self-stimulation, and experience at times that had not seemed likely to affect behavior all sound notes of warning. It is not as easy as it might seem to demonstrate that a behavior pattern has not been shaped by some form of experience that has a particular influence on the behavior.

In summary, then, the clutter of ideas associated with the uses of innateness and instinct has not served well the study of behavioral development. If innate behavior is defined as that which is not learned, what is it to be called if it is subsequently modified by learning? *Innateness* conflates different properties that ought to be kept separate according to the best biological and psychological knowledge. As these issues are clarified, many nativists and antinativists who thought they disagreed with each other will find that they do not (Mameli & Bateson, 2011).

Evolutionary Psychology

Despite all the difficulties, the idea that instinct is in some sense "genetic" was deeply embedded in conventional thinking and survives to this day particularly in the writings of some evolutionary psychologists and cognitive psychologists (e.g., Belsky, 2012; Ellis, Schlomer, Tilley, & Butler, 2012; Pinker, 2002; Tooby & Cosmides, 1992). Central to their thinking has been that adaptations to an earlier phase of human history continue to be inherited and the mode of transmission is genetic. When a pattern of behavior is referred to as being "genetically encoded," the metaphor of coding implies a one-to-one relation and seems warranted when talking about the way DNA sequences are related to some of their immediate molecular products, such as polypeptide chains. However, the idea that DNA codes for behavior is highly implausible given what is known about the dynamics of development. A genetic difference between two individuals may give rise to a behavioral difference, but that does not imply that in either individual a gene codes for that individual's distinctive behavior (e.g., P. Bateson & Martin, 1999; Charney, 2012; Johnston & Edwards, 2002; Keller, 2010; Lickliter & Honeycutt, 2010, Chapter 5, this *Handbook*, this volume; Oyama, 1985; Slavich & Cole, 2013).

If it is argued that a characteristic is genetically determined if and only if genes and nothing but genes are involved in its development, the notion of genetic determination relates to no phenotypic characteristic other than proteins. Moreover, if it is argued that the development of a characteristic involves gene expression, the notion of genetic involvement applies to virtually all of an individual's characteristics (Mameli & Bateson, 2006). Those who concern themselves with developmental processes mostly agree that, except for the immediate molecular products of DNA processing, all adult characteristics are the result of causal processes that involve both genetic and nongenetic factors (P. Bateson & Gluckman, 2011; Oyama et al., 2001; Sterelny & Griffiths, 1999). The much more holistic approach to development among behavioral biologists complemented what had been happening in other fields (Lerner, 1984; Lerner & Overton, 2008; Overton, 2013, Chapter 2, this *Handbook*, this volume; Overton & Lerner, 2012).

As a result of changes in thinking about development, much criticism has been directed at the arguments of the evolutionary psychologists (Rose & Rose, 2000). But some the critics have treated evolutionary arguments as though they were alternatives to developmental ones. As clearly recognized the "How did it evolve?" question should not be confused with the "How did it develop?" question. They are complementary. Even developmental analyses of forms of behavior that involve great plasticity leaves open the issue of how it might have evolved. To take a striking example from the modern literature, humans are much more likely to behave ethically if they are unconsciously aware of a pair of eyes watching them. M. Bateson and colleagues found that when members of their laboratory were asked to pay for the coffee and milk on a weekly basis, they contributed 3 times as much when the request was accompanied by a picture of eyes instead of a picture of flowers (M. Bateson, Nettle, & Roberts, 2006). Remarkably, the milk and coffee consumers were unaware that they had been manipulated in this way. In a subsequent experiment pictures of eyes in a bicycle shed significantly reduced the number of thefts of bicycles in the shed (Nettle, Nott, & Bateson, 2012). These findings invite the question, how did such an effect of eyes on human behavior evolve and, quite independently, how did it develop in each individual.

One of the difficulties in this field has been how explanations for one type of evidence in this field immediately evoke seemingly contrary explanations and even disbelief in the evidence that was being explained in the first place. Such academic disputes are not new. Oppenheim (1982), in an extensive and scholarly review of the back and forth debates about development, showed how people who espoused a nuanced view were often accused of being more extreme and more radical than in fact had been the case.

HERITABILITY

The concept of heritability is often mentioned in connection with the confused concept of innateness, particularly when it is used in the sense of behavior that is inherited. Given that behavioral development depends on both genes and the environment, many scientists have sought to partition the influences of the two classes of influence (Bouchard, Lykken, McGue, Degal, & Tellegen, 1990; Downes & Machery, 2013; Loehlin, Willerman, & Horn, 1988). The connection between the idea that a characteristic is innate and the idea that the same characteristic is hereditary seems obvious to many people even though the implication is incorrect. Some clarification is needed. In fact, heritability is not a single concept but a family of concepts. Broad heritability is defined as the ratio of the variance of the phenotype due to genetic variation to the total variance of the phenotype in the population. That is, a characteristic has high broad heritability in a population to the extent that the existing variation for that characteristic in the population is due to genetic variation. Narrow heritability gives the extent that the existing variation for the phenotype is due to variation in genes considered independently of their interactions with other genes at the same or at different loci. Selectional heritability, used by evolutionary biologists, measures the phenotype's response to Darwinian natural selection relative to the intensity of the pressure for change. Covariational heritability measures the strength of the correlation between close relatives for the phenotype in the population under study; this concept is most closely related to colloquial ideas about inheritance. Many textbooks (e.g., Futuyma, 1997; Ridley, 2003) claim that narrow heritability, selectional heritability, and covariational heritability are effectively equivalent. This is an oversimplification that can lead to the ignoring of important biological and psychological phenomena and the dynamics of development (Falconer & Mackay, 1996; Lynch & Walsh, 1997).

The focus now is on broad heritability because this is the concept most commonly used in discussions of human development. It has seemed, to those who use it, to be a helpful way of side-stepping the age-old nature-nurture conflict. Heritability is a *statistical concept* that applies to the variation in a given phenotype existing in a population at a given time. The question is how much of the variation found within a population in a given characteristic is due to differences in their genes, and how much is due to differences in their environments. Within a single individual this question cannot be answered, but it can be posed for a population of individuals (P. Bateson & Gluckman, 2011; P. Bateson & Martin, 1999; Keller, 2010; Lewontin, 1974).

The concept of broad heritability is best illustrated with an uncontroversial characteristic such as human height, which clearly is influenced by both the individual's lineage (genetic influences) and nutrition (environmental influences). The variation between individuals in height that is attributable to variation in their genes may be expressed as a proportion of the total variation within the population sampled. This index is known as the heritability ratio. If people differed in height solely because they differed genetically, the heritability of height would be 1.0; if, on the other hand, variation in height arose entirely from individual differences in environmental factors such as nutrition, then the heritability would be 0.

Calculating a single number to describe the relative contributions of genes and environment has obvious attractions. Estimates of heritability are of undoubted value to animal breeders, for example. Given a standard set of environmental conditions, the genetic strain to which a pig belongs will predict its adult body size better than other variables such as the number of piglets in a sow's litter. If the animal in question is a cow and the breeder is interested in maximizing its milk yield, then knowing that milk yield is highly heritable in a particular strain of cows under standard raising conditions is important.

Behind the deceptively plausible ratios lurk some fundamental problems (P. Bateson & Martin, 1999; Lewontin, 1974). For a start, the heritability of any given characteristic is not a fixed and absolute quantity—tempted though many scientists have been to believe otherwise. Its value depends on a number of variable factors, such as the particular population of individuals that has been sampled. For instance, if heights are measured only among people from affluent backgrounds, then the total variation in height will be much smaller than if the sample also includes people who are small because they have been undernourished. The heritability of height will consequently be larger in a population of exclusively well-nourished people than it would be among people drawn from a wider range of environments. Conversely, if the heritability of height is based on a population with relatively similar genes—say, native Icelanders—then the figure will be lower than if the population is genetically more heterogeneous; for example, if it includes both Icelanders and African Pygmies. Attempts to measure the relative contributions of genes and environment to a particular characteristic are highly dependent on who is measured and under what conditions.

What Does Heritability Explain?

The heritability ratio says nothing about the ways in which genes and environment contribute to the biological and psychological processes involved in an individual's development. This point becomes obvious when considering the heritability of a characteristic such as "walking on two legs." Humans walk on less than two legs only as a result of environmental influences such as war wounds, car accidents, disease, or exposure to toxins before birth. In other words, all the variation within the human population results from environmental influences, and consequently the heritability of walking on two legs is zero. And yet walking on two legs is clearly a fundamental property of being human, and is one of the more obvious biological differences between humans and other great apes such as chimpanzees or gorillas. It obviously depends heavily on genes, despite having a heritability of zero. A low heritability clearly does not mean that development is unaffected by genes. If a population of individuals is sampled and the results show that one behavioral pattern has a higher heritability than another, this merely indicates that the two behavioral patterns have developed in different ways. It does not mean that genes play a more important role in the development of the behavioral pattern with the higher heritability. Important environmental influences might have been relatively constant at the stage in development when the more heritable pattern would have been most strongly affected by experience.

The most serious shortcoming of heritability estimates is that they rest on the implausible assumption that genetic and environmental influences are independent of one another and do not interact. The calculation of heritability assumes that the genetic and environmental contributions can simply be added together to obtain the total variation. In many cases this assumption is clearly wrong. This type of interaction between the organism and its environment is fundamental to understanding behavioral development. In the postgenomic era, the simplistic notions that lie behind heritability estimates are increasingly criticized (e.g., Charney, 2012; Gottlieb et al., 2006; Greenberg, 2011; Joseph, 2010; Keller, 2010; Overton, 2013, Chapter 2, this *Handbook*, this volume; Partridge, 2005; Wahlsten, 2012).

Importance of Person ←→ Environment Coactions

It is only fair to say that nobody who studies the effects of genetic variation denies that nonlinear statistical interactions between genetic and environmental sources of variation can occur. Nonetheless, those with a strong commitment to using heritability estimates will go to great lengths to eliminate multiplicative interactions by rescaling their data. Unfortunately, independent grounds for validating a particular method of rescaling are rarely available. As a consequence, eliminating statistical interactions becomes the sole justification for transforming the data. Take for instance the advice given by Mather and Jinks (1971) in the standard work on biometrical genetics:

> The scale should preferably be one on which the analysis is as simple as possible, which means one on which interactions among the genes and between genotype and environment are absent, or at any rate as small as they can reasonably be made. (p. 64)

The trouble with following this recommended procedure is that awkward evidence is removed from sight. A superficial glance at the literature would suggest that the assumption of additivity had been justified (e.g., Broadhurst, 1979). The practice also meant that heritability estimates were given a much greater dignity than they ever deserved. Worst of all, the rescaling practice encouraged the view that the influences on the outcome of development act directly and straightforwardly, adding together but rarely coacting in combinatorial or reciprocal, bidirectional (←→) fashion. The widespread habit of using powerful statistical tools such as Analysis of Variance has also led to a confusion of statistical interaction with the coactions of actual process. It is all too frequently supposed that absence of statistical interaction means no interplay. The misconceptions and false inferences that can arise are many (Rutter, 1983).

In studies of children who have been adopted, it is sometimes possible to compare their performances on a given scale of measurement with those of their adopting parents and their true parents. In such studies it commonly seems to be the case that no statistical interaction is found between the scores of the two types of parents (see Plomin, DeFries, & Loehlin, 1977). The effects of the genes, provided by the true parents, and the effects of the environment, provided by the adopting parents, seem to add together in simple linear fashion. However, the quality of the environment provided by the adopting parents might not merely depend on their own IQs but also on the difference between their characteristics and those of the child. Disappointed adopting parents might provide a much less supportive environment for a dull child than those whose expectations were fully satisfied by the responsiveness of a bright child. It is highly likely that the expression of a child's potential depends on an interplay between her and the conditions in which she had been reared. A potentially bright child adopted by dull people might be much less challenged and much more frustrated than if she had been adopted by bright people. Here again the difference between the child and her adopting parents matters, but this time in the reverse direction. To test this idea properly it would be necessary to measure the child's abilities throughout development. However, if a true parent's IQ is taken as an indirect measure of a child's ability as it starts to influence and be influenced by her adopting parents, then the dynamics can be tested by examining the effect on the child of the absolute difference between the birth mother's IQ and the adopting mother's IQ.

When the appropriate analysis was carried out on data from Colorado provided by Plomin, the correlations between the children's Stanford-Binet IQ and the absolute difference between the true and adopting mothers' IQs were negative (−0.12 at 3 years of age and −0.23 at 4 years of age) (see P. Bateson, 1987). Though these negative correlations are far from being random associations, they are low. However, it would be surprising if, in the real world, the only sources of variation in IQ were the influences coming from the true and adopting mothers and the mismatch in IQ between them. An interesting feature is that the negative correlation was larger in the older children, suggesting that the dynamic approach would be profitable in such studies. In a subsequent simulation, Analysis of Variance failed to pick up the interaction between birth mother's IQ and the adopting mother's when the difference between them was great even though the dependent variable was affected by the difference between the independent variables (P. Bateson, 1989).

Much used analytical methods that look for statistical interaction can completely miss substantial interplay between the major factors that generate the measured outcome. This point has been made many times, but perhaps most amusingly by Levins and Lewontin (1985) in their spoof statistical analysis of data testing Newton's Laws of Motion. Additive models of development may make it easier to use the available statistical packages, but they are liable to be highly misleading in studies where nonlinear relations between variables are known to occur. What is worse, results that are inconvenient to the additive interpretation are all too easily swept out of sight.

The computer and its statistical packages do not magically generate the dynamics for the research worker. These are points that are well-known to the most influential people working on the genetics of human abilities, emphasizing the reciprocal bidirectional (←→) actions on each other of genes and environment (Plomin, Loehlin, & DeFries, 1985). Their arguments certainly raise issues about the nature of developmental process. Similarly, Scarr and McCartney (1983) have recommended that research workers look at the way individuals with particular genotypes actively select the environments into which they fit best. Even though it is highly unlikely that a person's genotype expresses itself in the same way irrespective of conditions, Scarr and McCartney's (1983) suggestion would encourage the investigation of what happens to individuals during development.

On grounds of biological and psychological plausibility alone, the notion of genetic and environmental factors adding together to produce their effects should be treated with the utmost skepticism. On the positive side, scientists ought, at the very least, to think about the nature of the developmental processes and, in so doing, ask more interesting questions of the available data. Better still, they should actually study the processes in action. When this analysis is done, an important conclusion is that the way an individual develops usually depends on conditions, but the conditions also often depend on the individual's mutually influential relations with his or her context, that is, on individual ←→ environment relations.

ROBUSTNESS OF DEVELOPMENT

When Linnaeus developed his classification of living organisms in the 18th century, he was probably clear in his own mind just what constituted a species. Each one was clearly distinct physically and could be recognized as such. It was God-given. Even when the development of evolutionary theory took off with the publication of Charles Darwin's *On the Origin of Species*, biologists continued to use the familiar Linnean binomial of genus and species for each organism. This was because species recognition was assumed by many to be straightforward and because of the presumed continuity over time from distinct ancestor to distinct descendant. Such views were challenged at the time, most notably by the French biologist Jean-Baptiste Lamarck, and in modern times the definition of a species is a source of much controversy among biological theorists. Nevertheless, the readily recognized features of a given species are generally familiar to anyone who has used one of the innumerable field guides or botanical keys. Something about a sparrow ensures that no member of its species becomes a crow. Gross atypical morphologies occur, but they are usually dysfunctional and in the past were termed *monsters*. Many structural attributes of an organism, such as the number of limbs or digits, are invariant and the molecular basis of this consistency of developmental pattern is increasingly understood (Carroll, 2005).

The resistance of bodies to deviation from the form or forms that are typical for the species is also expressed in behavior. The views of the founders of modern ethology, Lorenz and Tinbergen, on instinct were based on many compelling observations of animals' behavior in both captive and natural conditions (Burkhardt, 2005). These have been added to by a great wealth of evidence in subsequent years, and many examples of courtship, defensive behavior, specialized feeding methods, communication, and much else have become familiar to a wide audience through remarkable television films. Some behavior patterns are highly stereotyped in their form and are stable across a wide range of environmental conditions.

Insensitivity to Changes in the Environment

Beyond species-level consistency, the constancy of an individual's characteristics is maintained in the face of both environmental and genetic variation. The developmental biologist Nijhout has proposed a formal approach to *robustness* in which he suggested that the developing organism is robust if it is unable to detect changes in the environment or is resistant to them (Nijhout, 2002). If a developing organism cannot detect an environmental change, then it cannot respond to it. The organism may not have the sensory equipment that is sensitive to change, or a barrier may exist between itself and the change. For example, the dependence of the bird embryo on its yolk sac for nutrition means that it is insensitive to changes in the nutritional environment of the mother after the yolk sac has been formed. In that respect the bird embryo differs from the mammalian fetus, which is sensitive to some aspects of the nutritional environment of its mother throughout gestation.

A multicellular organism cannot maintain infinite plasticity in all its attributes. Stability of organization requires a series of irreversible steps; for example, the differentiation of embryonic stem cells into particular cell types is a fundamental aspect of development. Once committed to differentiation, cell lineages do not normally dedifferentiate. Rapidly dividing cancer cells were thought to be an exception to this rule, but most cancers arise from latent stem cells rather than dedifferentiation of specialized cells (Rosen & Jordan, 2009). In most sexually reproducing species, sexual differentiation is irreversible and sets a constraint on what can subsequently occur; some fish such as the wrasse being notable exceptions.

As a result, some changes in form and state may simply not be possible. Some constraints are imposed temporally by what has happened earlier in development and the architecture of the underlying molecular networks (Arthur, 1997). The analogy to a building is obvious: Just as it is impossible to redesign the foundations once a skyscraper is almost complete, once the basic organization of an organism is established, it cannot be revisited. Even when the organism changes its form through metamorphosis, the basic generalized body plan is maintained.

Other constraints are imposed by the provision of limiting factors such as nutrients. For example, the mammalian fetus is constrained in its growth by placental function and, in particular, nutrient and oxygen delivery. As a result of these processes, the mammalian fetus generally does not grow at a maximal rate; rather, fetal growth is coordinated with maternal size. Maternal constraint can be demonstrated by embryo transfer experiments. If an embryo is transplanted into a larger uterus, the fetus will grow larger, demonstrating the importance of nutrient supply in determining birth size. The classic demonstration of this principle was the work of Walton and Hammond (1938) studying the outcome of crossbreeding between small Shetland ponies and large Shire horses. The fetus of a crossbreed grew proportionately to the size of the dam. The fetus of a Shire mother crossed with Shetland father grew much larger than the fetus of the reciprocal Shetland mother/Shire father even though the genetics of each cross were similar. Since the 1990s the nongenetic nature of this phenomenon has been well established in embryo transplant experiments, so that in human pregnancies conceived using donor eggs, birth size is more closely related to the recipient mother's size than to the donor mother's size (Brooks, Johnson, Steer, Pawson, & Abdalla, 1995).

Constancy Resulting From Elasticity and Intrinsic Stability

Elasticity is a term that originally came from the analysis of inanimate materials and was used in contrast to plasticity. It was used to define a structure that can be deformed by a physical force, but once the force is removed, the structure would regain its previous form. For example, a rubber band can be stretched but will then revert to its original size. Some of the resilience or robustness seen in organisms after an initial response to a change in the environment might be explained in similar terms, although other aspects of such resilience, such as wound repair or catch-up growth after starvation or disease, probably involve active regulation.

Another proposal for robustness comes from dynamical systems theory (see Witherington, Chapter 3, this *Handbook*, this volume). Certain states are more stable than others, so that in dynamic systems they will be favored over time, thus acting as attractors. For example, a swinging pendulum will invariably come to rest in the same position—perpendicular to the ground—regardless of the position from which it was released. In biological terms, the characteristics of a system are stabilized by its attractor, and in that sense the system is robust. Attractors draw to themselves phenotypic characteristics that might have ended up in a variety of different places depending on local conditions (Huang, 2009). When formalized mathematically, an attractor can be a point, a curve, or a complicated set known as a "strange attractor." The way in which the phenotypic characteristics of an organism are drawn to an attractor does not have to satisfy any special constraints. The process might involve straightforward physical principles, as Newman (2007) has argued with respect to the formation of segments in the embryo.

Different Routes to the Same Endpoint

Usually the explanation for robustness based on attractor theory does not propose a particular process, but simply states that attractors are a fundamental feature of complex systems. However, feedback loops and dynamical interactions may limit the number of end states that are possible (Nijhout, 2002). Such explanations offer another way of thinking about how a specific end state can be achieved in many different ways—that is, the phenomenon of *equifinality* that interested the first systems theorists (von Bertalanffy, 1974). To take a biological example, cats can acquire and improve their adult predatory skills via a number of different developmental routes: by playing with their siblings, by playing at catching prey when young, by watching their mother catch live prey, by practicing catching live prey when young, or by practicing when an adult. Hence a kitten deprived of opportunities for play may still develop into a competent adult predator, but by a different developmental route (Martin & Caro, 1985). The general point is that organisms may reach the same endpoint via many different pathways.

In complex machines designed by humans, such as an airplane, back-up systems are commonly provided so that if one fails another can be brought into operation. Human lives depend on them. Such redundancy is also found in organisms. The provision of alternative systems protects against failure, and from time to time animals will inevitably be faced with the situation where no amount of tactical maneuvering will enable one of their developing systems to proceed along a particular route. Such an animal is in a position similar to a human arriving at a railway station only to find that the trains have been canceled. The traveler can still reach his or her destination but only by choosing a different method of getting there. The idea of *equifinality* is essentially an hypothesis about the existence of redundant processes, without specifying how they work.

One of the most unexpected aspects of studies in functional genomics has been the number of cases where the removal of a gene by way of recombinant technology, leading to the "knockout" of a gene in a mouse or other model organism, had no obvious effect on the phenotype. For example, mice lacking the *Hox C* gene cluster, which is known to be involved in body pattern formation, still possess the correct overall body plan (Suemori & Noguchi, 2000). Redundancy is common at the molecular level. Many genes are duplicated, particularly in vertebrate evolution. Gene duplication is a common phenomenon in molecular evolution, and up to 5% of the human genome consists of duplicated segments (Eichler, 2001).

Many organ systems are capable of a degree of robustness through repair, which manifests as hypertrophy (e.g., heart muscle), hyperplasia (e.g., skin, bone) or activation of stem cells (e.g., bone marrow). In vertebrates, one of the most dramatic examples is that of limb regeneration in the salamander. Uniquely, these animals can fully rebuild a lost limb even in adulthood. In contrast, other amphibians such as frogs may be able to do so in the larval form but not in the mature form. Some evidence suggests regenerative capacity even in the mammalian embryo (Stocum, 2006).

Regulation

The well-regulated body has been a hallmark of physiology since Claude Bernard's writing about the maintenance of *le milieu intérieur* in the 19th century and Cannon's elegant exposition of *homeostasis* in the first part of the 20th century. Stability is an inherent feature of feedback loops and many physiological systems involve direct or indirect feedback, creating a relatively robust state. The set point of a physiological feedback loop is central to the concept of homeostasis and provides one form of robustness. These set points may change across the life course in a process known as *homeorhesis* in a developmental context (Waddington, 1957), or as *rheostasis* for all cases where the physiological set point can change (Mrosovsky, 1990).

External feedback may also involve other individuals. If a goat has twins, the mother will lick the stronger of the twins, pushing it away from her teats and so promoting the weaker one's development. As the initially weaker kid receives more milk and outpaces its sibling's growth, the mother will now lick it more intensively to allow the now less vital sibling to have more milk; this reciprocal feedback between mother and her two kids continues until the kids have viable independence (Klopfer & Klopfer, 1977).

In the development of an individual, the maturation pattern of organs and behavior is well-regulated. In presenting his image of developmental canalization, Waddington (1957) offered a visual aid to those who have difficulty in grasping the abstractions of a purely mathematical model. He represented the development of a particular part of an embryo from a fertilized egg as a ball rolling down a tilted plane which is increasingly furrowed by valleys (see Figure 6.1).

He called the surface down which the ball rolls the *epigenetic landscape*. The mounting constraints on the way in which the phenotypic character can develop are depicted by the increasing restriction on the sideways movement of the ball as it rolls toward the front lower edge of the landscape. The landscape therefore represents the processes that regulate development. Waddington's model is attractive to

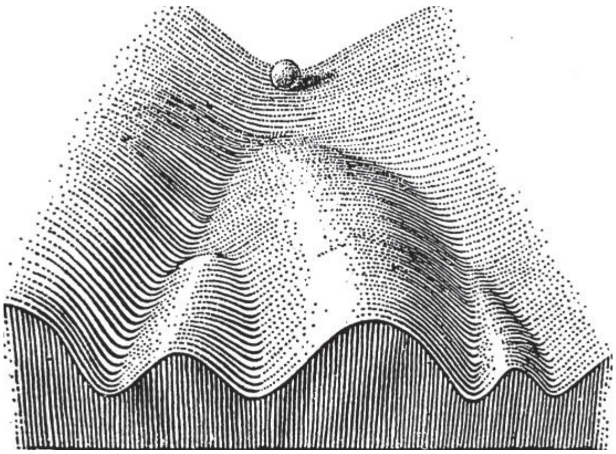

Figure 6.1 The epigenetic landscape as envisaged by Waddington (1957). The ball at the back of the drawing represents an undifferentiated cell. As the ball rolls down one of the valleys, its fate is increasingly determined and constrained as it reaches each choice point in the landscape. Study of the factors that determine the choices and the character of the differentiated cell are all part of the subject that Waddington called epigenetics.

the visually minded because it provides a way of thinking about developmental pathways and the astonishing capacity of the developing system to right itself after a perturbation and return to its former track. The phenotypic character is developmentally *canalized*. He regarded canalization as the capacity of development to produce a particular definite end-result in spite of a certain variability both in the initial situation from which development starts and in the conditions met during its course (Waddington, 1957).

I once tried to illustrate Waddington's landscape to students by stretching a sheet of elastic across a wooden framework and then, as in another of Waddington's famous illustrations in his 1957 book, tying strings from the undersurface of the elastic to pegs representing genes. Try as I might, it proved impossible to create more than one valley by varying the length of the strings. To create the multiply furrowed landscape I had to have strings attached to hooks above the elastic surface. I thought that this made a nice didactic point about the multiple factors, some internal and some external, influencing development. However, an even more interesting issue emerged when I experimented with cutting the strings from above or below. Sometimes nothing changed and the surface still retained its original shape. Cutting others of the strings had a dramatic effect and the shape of the surface was radically altered (see P. Bateson, 2013). Sometimes the course of development is unaffected by changes in the environment or the genome, but sometimes it can be massively altered.

Many Processes Leading to Robustness

Overlapping with the concepts of redundancy and regulation in providing ways of generating robustness is that of *developmental selection*. Throughout the process of forming the body and the brain, and hence behavior, the characteristics that develop are the ones that work best as an integrated whole. According to this view, integration of the whole body involves differential survival of particular functional systems and their subcomponents. A normal component of brain growth involves the formation of many more neurons than are required. Only those neurons that are attracted to others, and that form connections appropriately and establish functional networks are maintained. Cell death and neuronal pruning are well under way from before birth in species such as the human. Use modifies the rate and pattern of loss and confers a robustness of function.

Robustness is not necessarily an all-or-nothing phenomenon, need not affect all systems or organs of the organism in the same way, and has multiple dimensions. Many different processes, working in different ways, can ensure that members of the same species end up looking alike. These processes can operate at many different levels, ranging from the molecular to the behavioral.

PLASTICITY IN DEVELOPMENT

The term *plasticity* refers to the changeable character of matter. It is used in physics for inanimate materials and there it is contrasted with *elasticity*. If a coiled spring is pulled beyond the limits of elasticity, it will be permanently elongated. Provided that the spring does not break, the change is plastic. In the 19th century, the term was introduced into medicine to refer to the renewal of injured tissue and into popular literature to refer to impressionable minds. Plasticity was a dominant theme of James Mark Baldwin's (1902) book. It has returned in many other works about behavior and the nervous system (e.g., Gollin, 1981; Horn et al., 1973; Lerner, 1984; Rauschecker & Marler, 1987). It has been the subject of several symposia (Foster & Sih, 2013; Kappeler, Barrett, Blumstein, & Clutton-Brock, 2013).

Nowadays, plasticity, defined broadly in terms of malleability (see Pigliucci, 2001), is applied across a broad range of biological phenomena, and this extensive usage can cause confusion if the particular use is not well-defined. Muscles that are not used diminish in size and those that are exercised become larger. These are reversible phenomena. Many other cases occurring early in development usually are not. When one kidney fails to form, the other kidney undergoes compensatory hypertrophy and the outcome is stable. The behavioral repertoire of an individual can be changed by one of the many different types of learning, and at the molecular level the immune system responds to infection by developing a long-lasting reaction to the specific virus or parasite that caused the infection. In social insects, the particular way in which the larvae are nourished establishes whether the individual devotes her life to reproduction or to caring for the colonial nest. Such induced qualitative differences (that is, discontinuities in the range of phenotypes induced) that are found between members of the same species are sometimes referred to as *polyphenisms* (Mayr, 1963) or *morphs*. Alternatively the plastic response may induce quantitative differences across a continuous range and these are referred to as *reaction norms* (Stearns, 1992).

Examples of plasticity include coping with disruption of normal development, different phenotypic outcomes generated by different cues early in development, learning, and the plasticity found in the nervous and the immune systems. The key question is whether these vastly heterogeneous phenomena have anything in common with each other. Whether they are necessarily or even plausibly related, however, they are all of great biological and psychological significance.

Accommodating to Disruption of Normal Development

An individual whose body has been damaged in an accident or who is burdened with a mutation that renders his or her body radically different from other individuals may be able to accommodate to such abnormality (West-Eberhard, 1983). In doing so the individual may develop novel structures and behavior not seen in other individuals of the same species. Such accommodation can be particularly marked when it occurs early in development. An oft-cited example is that of a goat born without forelimbs that walked about on its hind legs and developed a peculiar musculature and skeleton (Slijper, 1942). The coping ability shown by the bipedal goat and the resulting effects on its behavior and skeleton illustrate one form of plasticity that is termed *phenotypic accommodation*. The organism has coped with an abnormality by accommodating to it. Similarly, humans born with limb abnormalities as a result of exposure to a teratogen such as thalidomide develop strategies to cope, for example by handling objects using their feet or teeth in ways for which others might use their hands (von Moltke & Olbing, 1989).

The ability of adult humans to deal with serious injury through accommodation can be remarkable. One case was that of Jesse Sullivan, who worked on high-voltage electricity lines as a technician for a power company. When in his 50s, he was badly electrocuted. Both his arms were terribly damaged and had to be amputated. In due course he had prosthetic arms fitted. One of these, the left arm, was a marvel of mechanical and electrical engineering. Electrodes from the artificial arm were attached to his chest muscles and within 6 months he was able to control the movements of the artificial left hand (McGrath, 2007). Such was his ability to accommodate that he was able to do something quite new and different with muscles that had never been required for such tasks during human evolution.

Another form of coping, found especially during early development, arises when the organism must make immediate responses to survive a challenge but, in contrast to accommodation responses, the normal developmental sequence is not disrupted. Although these responses may involve either structural or temporal changes in the course of development, in contrast to phenotypic accommodation they do not entail a fundamental change in the normal pattern of development. Thus the phenotypic consequences are not as dramatic as those that involve accommodation, but may have a cost and become disadvantageous to the individual later in life (Gluckman, Hanson, Spencer, & Bateson, 2005).

If the mother is undernourished or if the placenta is not delivering optimal nutrition, the offspring may be born smaller than usual, with the consequences of greater infant mortality and lower fitness in later life resulting from persistent growth failure (Gluckman et al., 2005). In polygynous species, such as red deer, the fitness costs may be severe because a small male is less able to compete with larger males for mates and, as a consequence, has a much lower chance of fathering offspring. Nevertheless, survival means that the small male does have some possibilities for mating unobtrusively when larger males are not looking (Kruuk, Clutton-Brock, Rose, & Guinness, 1999). In humans, growth retardation following placental insufficiency may be associated with reduced muscle mass, bone density, adult size, and cognitive and attentive function. These neurological effects may be related to a trade-off between investing for the long term in neural capacity and the need to expend the limited energetic supply for immediate survival (Gluckman & Hanson, 2006).

Adaptations to Local Conditions

In some plastic responses induced in early life may have delayed benefits, so that their primary or only adaptation is expressed at a much later stage in the life cycle. Such anticipatory responses rely on the cue in early life predicting some characteristic of the future environment. Many animals and plants develop defensive structures if they are exposed to cues associated with predators early in life, thus conferring potential advantages. A well-studied example is the small freshwater crustacean, *Daphnia*, which develops a defensive helmet and tail spike only if its mother has come into contact with water containing the body fluids of other *Daphnia* that had been eaten by a predatory midge (Laforsch, Beccara, & Tollrian, 2006). Many other induced defensive responses to predation are seen in much more complex animals (Gilbert & Epel, 2009). The crucian carp found in lakes containing predatory pike have much deeper bodies than those found in lakes without pike, and are consequently more resistant to attack. Experiments showed that this morphological difference was induced by the presence of pike (Brönmark, Pettersson, & Nilson, 1999). The migratory locust can be found as one of two common morphs, with some intermediate forms. If the population density is high, the locust will develop into the migratory morph with large wings, gregarious behavior, and an omnivorous diet. In contrast, when the population density is low, the locust develops into a solitary morph with small wings, reclusive behavior, and a selective diet (Applebaum & Heifetz, 1999). At the larval stage of development, when the trajectory that will determine the adult form is induced by environmental cues, neither form confers a particular advantage under the local conditions. The advantage comes later when, depending on conditions, it pays either to migrate or to stay put.

Handling Rats

The study of the impact of early experience on the stress response of the rat has a long history. Levine (1957) reported that handling rat pups caused them to develop in quite different ways from nonhandled pups. He subsequently found that when humans came through the animal house, the rats that had been handled in early life were at the front of their cages and the nonhandled rats, apparently more frightened, were at the back of their cages (Levine, 1969). The effects of the early experience were referred to as *programming* of the rats (Whimbey & Denenberg, 1967), foreshadowing the use of this slightly unfortunate term in the literature on the developmental origins of health and disease (DOHaD).

For many years the nonhandled rats were regarded as the control group. However, in a laboratory animal house where food is available all the time, and temperature, humidity and so forth are constant, rat mothers do not care for their pups as much as they would in natural conditions. The deprivation of maternal contact has a major effect on the offspring's behavioral temperament (Thoman & Levine, 1970). The adverse long-term effects can be prevented if the pups are handled by humans while they are still with their mother. The presumption is that the handled pups emitted ultrasonic distress calls that stimulated the mother to behave more as she would have done in the natural environment. Rats handled in early development, or born to mothers that exhibit high levels of grooming, subsequently have lower levels of adrenocorticotropic hormone than the nonhandled rats, indicating a major influence of the early experience on the hypothalamic–pituitary–adrenal axis as well as on behavior. The handled rats in the early studies were probably more like those found in natural conditions than the nonhandled rats were.

Subsequently, the role of the mother rat in stimulating development of her pups has been studied extensively by Meaney (2001) and his collaborators. A mother that licks her pups a lot has offspring which, when adult, lick their offspring a lot. Conversely mothers who are low groomers have offspring who grow up to be low groomers. In this way, a characteristic style of maternal behavior is transmitted from one generation to the next. Cross-fostering a pup born to a low-grooming mother to a naturally high-grooming mother switched the adult pattern of the pup to that of the foster mother (Champagne, Francis, Mar, & Meaney, 2003), showing that this is not a genetically transmitted characteristic but an acquired one. The mother's behavior toward her unweaned young can induce a behavior in the offspring that is likely to be appropriate for them if the environment remains threatening when they are adults.

When pregnant mother rats are given restricted diets, their offspring are smaller when they are born, but if these offspring are then given plentiful food they become much more obese than the offspring of mothers given an unrestricted diet (Jones & Friedman, 1982). This early observation has been followed by further extensive work on rats in many laboratories. Offspring born to undernourished rats develop increased appetites (Vickers, Breier, Cutfield, Hofman, & Gluckman, 2000), and show accelerated sexual maturation (Sloboda, Howie, Pleasants, Gluckman, &

Vickers, 2009). Even though the undernourished rats are more sedentary when kept in standard laboratory cages (Vickers, Breier, McCarthy, & Gluckman, 2003), their behavior differs in another striking way from the control animals. When given a choice between pressing a lever to obtain food and running in a wheel, they are significantly more likely to run in the wheel (Miles et al., 2009). Whatever the explanation, the behavioral differences between rats that were undernourished during fetal life and those that were well-nourished are remarkable.

Relevance to Humans

The work on rodents is now being related to striking discoveries that have been made about human biology that have already been discussed. Epidemiologists found that the smaller a baby at birth, the higher its risk of diabetes mellitus type 2 and cardiovascular disease later in life (Barker, 1995). An extensive field of enquiry then emerged, focusing on the relevance of early developmental plasticity in humans to the individual's subsequent health and risk of disease. This domain of research is often termed *developmental origins of health and disease* (DOHaD) (Gluckman & Hanson, 2006). Those individuals whose mothers had been on a lower plane of nutrition had a greater propensity in later life to lay down fat and to develop insulin resistance and high blood pressure in an affluent environment; consequently, vascular and metabolic pathology was more likely to develop. Subsequent studies showed that such effects were not limited to those of small birth size and, indeed, birth size is now considered as simply a crude index of the fetal experience (Gluckman, Hanson, & Buklijas, 2010). This is because maternal experiences such as nutritional intakes can affect the offspring's biology independent of birth weight effects. Alterations in infant feeding also have effects later in life (Plagemann et al., 2009).

Neural Plasticity

In humans who are subject to neurological injury, considerable neural plasticity may occur, particularly if the injury occurs early in life. Some children with brain injury *in utero* or at birth may be functionally relatively normal as a result of co-option of other neural elements. In adults who have strokes that lead to the death of neurons, over time the impact of the injury may lessen as new neural connections are formed and other neurons are co-opted to serve the lost functions. The remarkable reorganization that can take place is shown by brain scans of some people who had hydrocephalus early in development. The cerebral cortex is extremely thin, yet the person may be behaviorally normal (Feuillet, Dufour, & Pelletier, 2007). In this case, neural plasticity generated robustness of behavioral function.

The lack of use by one sensory modality may involve the takeover of part of the brain by another modality. In individuals who have been blind from an early age, tactile cues stimulate parts of the primary visual cortex. The change in brain organization was revealed by an experiment in which strong magnetic fields were used to disrupt the function of different cortical areas in people who had been blind from an early age (Cohen et al., 1997). Disruption of the visual cortex disrupted their ability to read Braille or embossed letters. In contrast, transient disruption of the visual cortex in sighted people had no effect on their ability to perform tactile tasks. Evidently the brains of the blind people had been reorganized in response to their particular experience of the outside world.

Learning

Clearly the developing organism has a particular capacity to demonstrate plasticity, and for many systems the capacity to be plastic later in life is much more limited both by functional considerations and because it may be energetically inefficient to maintain plasticity into later life. Nevertheless, some aspects of the phenotype, such as muscle or fat volume, are plastic throughout life. The most common form of plasticity in adults is seen in their behavior. Learning is the most obvious way in which individuals after birth interact with, and are changed by, their environment. Learning is entwined in the processes of behavioral development, adapting individuals' behavior to local conditions, enabling them to copy the behavior of more experienced individuals, and fine-tuning preferences and actions that were inherited from previous generations. Snell-Rood (2013) distinguishes between developmental plasticity occurring in early life and what she calls *activational plasticity* by which an individual can change its characteristics throughout life.

William Homan (Thorpe, 1956) brought together the insights of European ethology and holistic psychology with the vast corpus of work on the various processes of learning from American and Russian laboratories, as well as those from psychology departments worldwide. Thorpe classified learning into five categories: habituation, classical conditioning, instrumental conditioning, latent learning, and insight learning. Some forms of learning such as behavioral imprinting, which Thorpe discussed in his chapter on insight learning, and the acquisition of song in birds may be restricted to early development, but most can take place throughout life.

One of the most primitive changes in behavior in response to experience is nonspecific. Sensitization usually results from exposure to an alarming stimulus (such as a blow-up toy snake suddenly becoming inflated), which elicits a variety of defensive or aversive reactions from the animal. Subsequently, many other potentially aversive stimuli (such as loud sounds) will have the same effect even though this would not have been the case had the animal not been previously sensitized.

Habituation is defined as a decrease in response occurring as the result of prolonged stimulation, which cannot be attributed to fatigue or sensory adaptation. The phenomenon has been described widely, from single-celled organisms to humans. In some cases, the underlying process is simple and in other cases experiments suggest that the subject establishes a specific representation of the stimulus in its nervous system. So if the animal has been habituated to a sound of a specific duration and then tested with a sound that is shorter in duration, a nonhabituated response is elicited when the end of the shorter sound is reached. When a sound of longer duration is used, a nonhabituated response is elicited at the end of the habituated sound (Sokolov, 1963).

Establishing a neural representation is key to the form of learning that leads to a categorization of the sensory world. Here again such perceptual learning is found widely across the animal kingdom. In humans, it leads to the recognition of faces and places. The ability to distinguish between the vast array of objects, people, and scenes experienced in a lifetime is of inestimable value and happens simply as a result of exposure. The memory's capacity is extraordinary. In one experiment, human subjects were shown up to 10,000 different slides projected onto a screen in quick succession. Days later they were able to recognize thousands of those images. Some of the images, such as a dog smoking a pipe or a crashed airplane, were particularly striking. In these cases the recall was even better and the subjects seemed to have a virtually limitless capacity to store them (Standing, 1973).

The best-known type of *associative learning* process was made famous by Ivan Petrovich Pavlov a century ago. Pavlovian (or classical) conditioning allows the individual to predict what will be of real significance in the confusing world of sights, sounds, and smells. Pavlov's famous experiment was to teach a dog to expect food by repeatedly alerting it with a buzzer before the food was presented. Pavlov measured how much saliva the dog produced. As the dog was conditioned by the predictable association between the buzzer and the food, it came to produce saliva in response to the sound of the buzzer alone.

A different form of associative learning acts to control the environment. If a rat presses a bar and its action is swiftly followed by the delivery of food, it will repeat the action and will do so with increasing frequency if each time the action elicits the reward. As the action is strengthened, it may be repeated many times even in the absence of the reward (or *reinforcer*). As learning proceeds, the conditions in which the action generates a reward become in themselves rewarding. Subsequently, the individual may perform a quite different act to achieve the conditions that are associated with getting the primary reward. By degrees a whole chain of different behavior patterns can be established—a fact that is made use of by circus trainers.

In an idiosyncratic but highly original review, Moore (2004) identified 97 different processes of learning, some of which are highly complex, including abstract concept formation and cross-modal imitation. He may well have exaggerated but his survey serves to emphasize the heterogeneity of all those processes that are lumped under the general heading of *learning*.

Complex Processes

At one time psychologists were encouraged to interpret the behavior of animals in the simplest possible way until they had good reason to consider otherwise (a precept also known as Lloyd Morgan's canon). Many people—for a variety of reasons—have rejected this advice, focusing on those aspects of animals that resemble the conscious behavior of humans. This might seem questionable, given that much of human behavior is unconscious and that humans differ from other animals in some respects, such as size and complexity of the nervous system. Nevertheless, the so-called cognitive revolution in the study of behavior has undoubtedly greatly enriched the toolbox for understanding learning processes (Shettleworth, 2010). What Thorpe (1956) called *insight learning* related to, among other things, the experiments of Wolfgang Köhler (1925) on chimpanzees in the early part of the 20th century. Among many other experiments, Köhler provided the animals with interlocking sticks. The chimps learned to assemble longer sticks which then enabled them to reach bananas suspended high above them and otherwise beyond their reach.

Modern examples include food caching by blue jays. If they have been observed while caching food by other birds they move the food, but not otherwise (De Kort, Tebbich, Dally, Emery, & Clayton, 2006). Rooks are able to reach initially inaccessible food floating on the top of water in a plastic tube by dropping stones into the water and thereby raising its level in the tube (Bird & Emery, 2009). Parrots have been found to develop abstract concepts of color, shape, or material content (Pepperberg, 2008). Ways in which one individual learns from another range from the simple examples of social facilitation of behavior already established as a capacity in the individual, and enhancement of local cues, to cases where actions are observed and then copied (Laland & Galef, 2009). The study of complex cognition in animals, involving the plastic processes of learning, has expanded greatly and is very well summarized by Shettleworth (2010). The most complex forms of learning clearly involve plasticity of considerable elaboration and it is not surprising, therefore, that a growing body of evidence links these capacities to the relative brain size of the species concerned (Reader & Laland, 2002). These complexities have to develop and may often be derived from playful experiences earlier in life (P. Bateson & Martin, 2013).

The Immune Response

In the immune system of humans and vertebrate animals, molecular plasticity takes the form of generating new antibodies to foreign proteins that hitherto have not been encountered by the individual. Antibodies are immunoglobulins used by the immune system to identify and neutralize foreign pathogens such as bacteria and viruses, preventing them from causing disease. A small region at the tip of the critical immunoglobulin is extremely variable in amino acid sequence, permitting the existence of millions of antibodies with slightly different tip structures. Each of these variants can bind to a different protein (or antigen). The diversity of antibodies allows the immune system to recognize an equally wide array of antigens (Male, Brostoff, Roth, & Roitt, 2006). Recognition and binding of an antigen by an antibody provides a marker that enables it to be attacked by other cells of the immune system.

The hugely diverse population of antibodies is generated by random combinations of a set of gene segments that encode different antigen binding sites, followed by random mutations in this area of the antibody gene, which create yet further diversity. Each form of antibody is made by a different clone of B-lymphocytes. The antibody is specific to the part of the antigen recognized by the immune system. Once a particular clone is stimulated by contact with an antigen, it undergoes massive proliferation to produce more antibodies and long-lasting immunity.

On the face of it, the foreign protein might have instructed the process that generated the antibody in the sense that unique information carried by the protein provides the template on which the antibody is synthesized. However, the plasticity of the immune system involves selection rather than instruction since, by extremely rapid mutation and recombination within the histocompatibility complex, the immune system finds a match for the foreign antigen and this then sets in train rapid synthesis of the antibody from the mutated gene that provided the match (Neuberger, 2008). The gene has been selected by the challenge from outside the host's body.

Many Processes Involved in Plasticity

The plastic phenomena are without question biologically important, but do they have anything in common? Plasticity operating at different levels of organization often represents different descriptions of the same process. Underlying behavioral plasticity is neural plasticity, and underlying that is the molecular plasticity. Edelman (1987) suggested that the immune system provides a model for understanding the processes that underlie learning. The plasticity of the immune system relies on a selective process. In contrast, at the level of the whole organism, the processes of learning that change behavior seem to involve instruction. Whether the same selective process could be involved in any or all of the myriad examples of learning is, however, much more controversial. In the case of associative learning, for example, a cue from the environment instructs the individual about the causal nature of its environment, providing a link between something that is biologically significant and something that had hitherto been neutral. As yet, the underlying processes involving changes in neural connectivity is not readily attributable to a process that involves selection.

The image of selection might fit better with the examples of *polyphenisms* and *reaction norms*, whereby the genome is capable of giving rise to a variety of phenotypes depending on the individual's experience. In many cases of developmental plasticity that abound across the animal and plant kingdoms, the individual starts its life with the capacity to develop in a number of distinctly different ways. Like a jukebox, the individual has the potential to play a number of developmental tunes. The particular developmental tune played by the individual is triggered by a feature of the environment in which it has grown up—whether it is the odor of its predators, the available quality of food, or the presence of other males. Furthermore, the particular tune emanating from the developmental jukebox is adapted to the conditions in which it is played (P. Bateson, 1987; P. Bateson & Martin, 1999). The jukebox analogy has its drawbacks because it implies that the tune is preformed somehow (Oyama et al., 2001); but, like everything else, the predispositions have to develop. However, the image does draw attention to what may be a useful distinction between forms of plasticity that involve selection and those involving instruction.

Plasticity can be viewed in many ways and along many different dimensions. The temporal dimension, the dimension of different organizational levels, the dimension of whether plasticity involves selection or instruction, and the functional and evolutionary issues are all part of the picture. A multidimensional view is essential if the ways in which the organism responds to environmental cues and challenges are to be understood. However, the understanding needs to be broadened to take account of the ways in which plasticity is constrained and regulated.

INTEGRATION OF ROBUSTNESS AND PLASTICITY

The developmental processes of robustness and plasticity that give rise to an individual's characteristics are not polar opposites, nor are they independent of each other; instead they stand in a relational context to each other (Overton, 2013, Chapter 2, this *Handbook*, this volume). Indeed, plasticity is often regulated by robust processes and robustness is often generated by plasticity. In the case of sensitive periods in development, in which experience can have a particular impact on the phenotypic characteristics of an organism. The environmental cues are often highly specific and are often referred to as predispositions. Learning is the archetype of plasticity. Yet learning processes are highly regulated by robust rules.

Robustness at one stage of development does not necessarily imply robustness at another. A characteristic that is robust up to one stage may not continue to be robust thereafter, and vice versa. Developmental malleability may be followed by nonmalleability, as in many examples of alternative phenotypes found throughout the animal kingdom, including humans (Gilbert & Epel, 2009). Conversely, developmental nonmalleability may be followed by considerable malleability, as in the case of the human smile, which reliably appears in infants during the fifth or sixth week after birth and is subsequently greatly modified by social interactions and cultural influences (P. Bateson & Martin, 1999).

One of the public health triumphs of genetics was the discovery that the expression of an inherited disease, phenylketonuria, could be prevented by providing the patient with an appropriate diet from an early age. The affected people have a mutated gene that meant that an enzyme, phenylalanine hydroxylase, was deficient; therefore, the amino acid phenylalanine could not be converted to tyrosine and instead was converted to toxic phenylpyruvate. The poison caused brain damage, resulting in great loss of cognitive ability, seizures, and other behavioral disorders. These dire consequences could be prevented by genetically testing neonates at birth and feeding children with the mutation a special diet that did not contain phenylalanine (Centerwall & Centerwall, 2000).

Another example of how the phenotypic consequences of a genetic change can be prevented by a change in the environment involved a knocked-out gene that normally codes for an important neurotransmitter (Rampon et al., 2000). When mice with the missing gene were kept in standard bare laboratory cages they developed a profound loss of the ability to recognize objects, loss of olfactory discrimination, and absence of memories of noxious events. However, when the mice were exposed daily to cages containing toys, running wheels and tunnels, and other forms of environmental enrichment, all these behavioral deficits were lost. The behavioral effects of the enrichment were accompanied by an increase in the synaptic density in a particular region of the hippocampus.

The examples of the interplay between genetic background and experience of the environment might seem to justify the phrase *gene–environment interaction*. In the popular domain, Shenk (2010) has described how each individual interacts with his or her environment in such a way that potentialities may be revealed or suppressed by circumstances. The message is optimistic and has major implications for public policy. Shenk's perspective was presented as an interaction between genes and environment; an image which he drew from the scientific literature (Meaney, 2010). The interaction is often abbreviated as $G \times E$. Some problems arise from this formulation because it conflates ideas about sources of variation in populations with those about an individual's development. It is the person who interacts with the environment, not his or her genes (Lehrman, 1953). Although genes are definitely activated or repressed by some environmental conditions, individuals can change their environments without necessarily producing changes in the expression of its genes. This has been termed *niche construction* (Odling-Smee, Laland, & Feldman, 2003). Furthermore individuals can choose to inhabit environments that match their characteristics, referred to as *niche picking* (Scarr & McCartney, 1983). For all these reasons it is more satisfactory to refer to organism ←→ environment coactions when considering the integration of plasticity and processes that generate robust outcomes.

Sensitive Periods

Charles Stockard (1921), a leading embryologist of his time, observed that the embryos of many species could resist oxygen deprivation at some stages of their development, but that at times of rapid embryonic growth, oxygen deprivation could induce gross malformations such as two heads. Tissues are particularly vulnerable to disruption at times of rapid growth. In humans, much organ formation occurs during the first 8 weeks after conception. The science of teratology is replete with examples of how toxins exert their effect at a specific stage of development, the impact of the drug thalidomide on limb development being one of the most famous.

By way of contrast to the examples described earlier, many sensitive periods in development exist within which the organism acquires information from its environment in order to develop normally or in a way that is appropriate to that environment. This information can play a crucial role in determining which of several alternative developmental courses the individual will adopt. For example, on the basis of the nutrition they receive in early life, female social insects are either capable of reproduction or adopt one or more sterile forms that perform specialized jobs in the service of the colony (Wilson, 1971). The sisters differ enormously in subsequent phenotype due to this one environmental exposure within a sensitive period in development (Maleszka, 2008).

Unlike other vertebrates, sex is not determined by chromosomes in some reptiles, such as the turtles and crocodiles. Instead the temperature of the sand in which the egg is buried is crucial. Each individual starts life with the capacity to become either a male or a female. If the egg from which it hatches is buried in sand at a temperature below 30°C, the young greenback turtle becomes a male. If, however, the egg is incubated at above 30°C, it becomes a female. Temperatures below 30°C activate genes responsible for the production of male sex hormones and male sex hormone receptors; incubation temperatures above 30°C activate a different set of genes, producing female hormones and receptors instead. It so happens that in alligators the sex determination works the other way round, such that eggs incubated at higher temperatures produce males. The outcome depends on environmental temperature during the middle third of embryonic development (Yntema & Mrosovsky, 1982).

The developmental processes involved in the start of a sensitive period correspond with changes in the ecology of the developing individual. These changes are linked to developmental processes of regulation and cellular replication. The processes that bring the sensitive period to an end may reflect the passage of normal growth and temporal constraints on development in other related processes. Hypothalamic maturation in mammals needs to be largely completed before weaning because the hypothalamus controls so many aspects of homeostasis, and maintaining plasticity in some pathways might constrain fixation of others. Sometimes the terminating processes are related to the gathering of crucial information and, except in extreme circumstances, do not shut down until that information has been gathered. In these cases the ending of the sensitive period reflects the variable opportunities for gathering such domain-specific information in the real world. For example, in cold weather, ducks brood their hatched young for longer than in warm weather, and the ducklings delay the process of learning the characteristics of their mother (P. Bateson & Martin, 1999). A limit must be set on such flexibility, however, because so much else has to be done in development. If the relevant information remains unavailable for too long, the individual may eventually have to "make the best of a bad job" and develop without acquiring that information.

Sensitive periods may be limited because of what has happened previously to the individual. For example, structures in the brain that have been altered by earlier experience may preempt the formation of new structures. The brain processes involved in visual development have been analyzed in cats and monkeys. The capacity of a cat's eye to activate neurons in the visual cortex depends on whether that eye had received visual input during the first 3 months after birth (Freeman, Sengpiel, & Blakemore, 1996). If one eye is visually deprived during this period it largely loses its capacity to excite cortical neurons. The other eye then becomes dominant and, once established, usually remains dominant for the rest of the individual's life. Once one set of neurons has established a connection, they exclude others from doing so thereafter. Specific neurobiological processes, involving noradrenergic receptors at the site of this plasticity, are required for such preemptive developmental changes to occur. Once a stable pattern of responding has developed normally, these processes fall away. If the brain is not stimulated in the normal way through the visual pathways, then the reduction in the number of these receptors is delayed until the necessary interconnections between neurons have been established (Liu, Jia, Gu, & Cynader, 1994).

In general, neural plasticity during sensitive periods is likely to involve a variety of different processes (Hensch, 2004). Moreover, many such sensitive periods are not infinitely flexible. At some point, other developmental processes within the brain constrain plasticity. If the lack of visual experience goes on long enough, the period of sensitivity will terminate and the animal will end up with a brain that differs from the normal. In humans the development of binocular vision is seriously affected if a child has an uncorrected squint in the first few years of life. The child accommodates to the squint by becoming dependent on one eye and not using the other eye. The squint can be corrected by surgery, in which case the child usually develops normal binocular vision, but only if the surgery is performed sufficiently early in development. If it is left until much after the age of 3 years, surgery will do no good and the child will be left with permanently impaired vision in the affected eye (Campos, 1995).

The nature of such sensitive periods shows that experience at a given stage in development can fundamentally shape the individual's subsequent development. In general, the organization that underlies the existence of such periods, such as in temperature-dependent sexual differentiation, is highly robust. In turn, after the plastic changes have been initiated during a sensitive period, the phenotypic outcome can be extremely robust, again as in the case of sex determination. The intertwining of developmental processes is complete.

Ethological Studies of Birds

Behavioral imprinting has been much studied by ethologists. It is the process by which a young animal rapidly learns the details of its mother's individual appearance and forms a social attachment to her (P. Bateson, 1966; Bolhuis, 1991; Lorenz, 1935). Some young animals, such as goslings and cygnets, learn to recognize their father as well, but this is less common because, particularly in mammals, fathers rarely play a substantial role in caring for their offspring. A distinction is drawn between filial imprinting and sexual imprinting whereby the animal's experience later in life affects its sexual preferences. These sexual preferences are for partners that are slightly different from those individuals (usually close kin in natural conditions) with which the animal is already familiar (P. Bateson, 1983). Behavioral imprinting of both kinds provides a good example of a process that starts within a sensitive period. It also demonstrates nicely how learning is guided by certain robust predispositions.

Birds respond to a pattern of stimulation, and characterization of the most effective stimulus must be cast in terms of clusters of features. Some features of the jungle fowl, the ancestral form of the domestic fowl, are particularly attractive to chicks. The head and neck is the crucial characteristic, but the head and neck of a small mammal is as effective as that of a jungle fowl (Horn, 1985). Plasticity is initiated by robustly developing predispositions, and that once strong attachments are formed, they may remain stable for the rest of the animal's life.

Another striking example of the ways in which predispositions influence learning is given by the acquisition of songs by birds. The process starts early in life. The typical pattern is for the young male bird to listen to and store sounds made by his father and other males during the first few months after he has hatched (Marler & Slabberkoorn, 2004). The following spring he produces a range of sounds and, by degrees, settles on songs he has heard before. When he is mature, he uses his songs to defend his territory and attract females. The range of songs acquired by each male is transmitted within the neighborhood from one generation to the next, in much the same way as language, customs, and ideas are transmitted across the generations in humans. Under laboratory conditions, hand-raised birds will learn sounds played back from tape recorders. Typically, however, they are much more likely to acquire songs made by their own species than songs made by other species, even when the songs are mixed up in the recordings (Marler & Peters, 1977). Marler (2004) referred to the readiness of birds to learn about particular features of their acoustic environment when developing their songs as an *instinct to learn*. Despite the unfortunate ambiguity of the term *instinct*, the concept of a hunger to learn about certain things is important when considering the interplay between plasticity and robust features of the animal.

Rules for Learning

As any dog-owner knows, a hungry dog will do many other things once it detects cues that predict the arrival of food: It will go to the food bowl, whine, wag its tail, jump up, and show all the familiar signs of expectation. When learning about the relevant cue that predicts the arrival of food, the sequence in which the events occur is crucial. If the cue comes *after* the presentation of food to a dog that has not yet been conditioned, it will not salivate or show any other expectant signs when the cue is subsequently presented. The link in time between the action and the outcome is crucial.

The interplay between the rules for learning and robust features of the animal's behavior can sometimes lead to amusing outcomes. Keller and Marian Breland (1966) were experimental psychologists who later became professional animal trainers. On one occasion they tried to train pigs to take a wooden coin from a pile and drop it into a piggy bank in return for a food reward. Initially the pigs learned the task well, but as they came to associate the pile of coins with food, the sequence broke down because the pigs started rooting in the pile of coins! Robust features of their behavior came to dominate the initial effects of learning.

Storing information about visual experiences requires a different set of rules from those involved in the prediction and control of the environment. Animate and inanimate objects in the real world are rarely flat and their appearance depends on how they are viewed. Friends or relatives are easily recognized from the front or the back, whether they are in the distance or close up. But they may not be so readily recognized if the photograph is taken from an odd angle such as from their feet. The recognizable features of a familiar person are fused together by the brain into a single category when these different views are seen in quick succession (P. Bateson, 2000). Time plays a different role in such perceptual learning than is usually the case in Pavlovian conditioning. The order in which different events are experienced is important when one event causes the other, but unimportant when the experiences are of different views of the same object. In the case of perceptual learning, just as in conditioning, profoundly important plastic processes are dependent on robust rules.

The Need to Understand the Processes

Modern understanding of an individual's development goes well beyond accepting that bidirectional relations between the organism and its environment are crucial. The conditional character of an individual's development emphasizes the need to understand the processes of development that underlie these coactions. This is what Waddington (1957) called the study of *epigenetics*. He distinguished epigenetics from the 18th-century term *epigenesis*, which had been used to oppose the notion that all the characteristics of the adult were preformed in the embryo. *Epigenetics* has become defined as the molecular processes by which traits defined by a given profile of gene expression can persist across mitotic cell division, but which do not involve changes in the nucleotide sequence of the DNA (Carey, 2012). This area of research is one of the most rapidly expanding components of molecular biology and has considerable implications for how the actions of genes are treated (Charney, 2012; Slavich & Cole, 2013). The term has come to describe those molecular processes through which both dynamic and stable changes in gene expression are achieved, and ultimately how variations in environmental experiences can modify this regulation of DNA (Gilbert & Epel, 2009; Gissis & Jablonka, 2011; Jablonka & Lamb, 2005). Robust processes of development and those that generate plasticity are closely intertwined by such interplay.

Variation in the context-specific expression of genes, rather than in the sequence of genes, is critical in shaping individual differences in phenotype (P. Bateson & Curley, 2013). This is not to say that differences in the sequences of particular genes between individuals do not contribute to phenotypic differences, but rather that individuals carrying identical genotypes can diverge in phenotype if they experience separate environmental experiences that differentially and permanently alter gene expression (Spector, 2012).

The molecular processes involved in phenotypic development were initially worked out for the regulation of cellular differentiation and proliferation. All cells within the body contain the same genetic sequence information, yet each lineage has undergone specializations to become a skin cell, hair cell, heart cell, and so forth. These phenotypic differences are inherited from mother cells to daughter cells. The process of differentiation involves the expression of particular genes for each cell type in response to cues from neighboring cells and the extracellular environment, and the suppression of others. Genes that have been silenced at an earlier stage remain silent after each cell division. Such gene silencing provides each cell lineage with its characteristic pattern of gene expression. Because these epigenetic marks are faithfully duplicated across cell division, stable cell differentiation results. These processes also have many other roles in development, including mediating many aspects of developmental plasticity.

Epigenetic research does raise questions about the ways in which data obtained from populations are interpreted. For example, in both medical and psychological research, attempts have been made to separate genetic from nongenetic effects by the comparison of identical and nonidentical twins. The correlation between a characteristic in “identical” monozygotic twins, who share all their genes in common, is compared with that in “nonidentical” dizygotic twins, who do not. The difference in correlation between the identical twins and that between the nonidentical twins is used to calculate the likely contribution of genes to that characteristic. The likelihood was, however, that identical twins shared a placenta and therefore had a more similar uterine environment than did nonidentical twins.

Some authors such as Jablonka and Lamb (2010) and most developmentally inclined ethologists like myself (P. Bateson, 2012; P. Bateson & Curley, 2013) continue to use Waddington’s broader definition of epigenetics to describe all the developmental processes that bear on the character of the organism. Critical issues arise over what an animal inherits at the beginning of its lifetime. Major understanding of extragenetic inheritance processes such as cytoplasmic effects, parental effects, including maternal and paternal genomic imprinting and other epigenetic impacts on gene expression, ecological legacies, behavioral traditions, and cultural inheritance (Danchin et al., 2011; Gilbert & Epel, 2009; Gissis & Jablonka, 2011; Jablonka & Lamb, 2005; Mousseau & Fox, 1998; Odling-Smee et al., 2003). These legacies mean that the processes shaping the character of an individual will often start before conception.

Many of the factors that influence individual development, be they social or ecological, have been amassed by the activities of multiple individuals over multiple generations (cultural knowledge, ecological legacies). Some of these influences on development may stretch back a long way. The presence of animal burrows, mounds, and dams—or, on a larger scale, changed atmospheric states, soil states, substrate states, or sea states (Erwin, 2008; Meysman, Middelburg, & Help, 2006)—persist or accumulate in environments, and can be crucial for normal development. Tracing backward in time to the origins of all these factors would probably be regarded as irrelevant to a modern study of development, except in that subset of cases where those legacies function to elicit epigenetic changes in the development of descendants (Badyaev, 2009). The spirit of the developmental question does push back the historical account of how the character developed to before conception, but, for practical purposes, probably not *too* far back. However, acknowledging the variety of factors that are inherited, and the manner in which parents construct developmental environments, is important for developmental studies.

EVOLUTION AND DEVELOPMENT

For many years the debate about the role of an individual’s development and its impact on its descendants was sharply polarized. The impact was seen as substantial by some and as nonexistent by others. Some evolutionary biologists (e.g., Ridley, 2003; Wallace, 1986) still hold to the view that genetics, and hence evolution, could be understood without understanding development. Briefly put, their opinion is that genes influence the characteristics of the individual; if individuals differ because of differences in their genes, some may be better able to survive and reproduce than others and, as a consequence, their genes are perpetuated. The extreme alternative is a caricature of Lamarck’s views about biological evolution and inheritance. If a blacksmith develops strong arms as a result of his work, so the argument went, his children will have stronger arms than would have been the case if their father had been an office worker. This view has been ridiculed by essentially all contemporary biologists. Nevertheless, as so often happens in polarized debates, the excluded middle ground concerning the evolutionary significance of development and plasticity has turned out to be much more interesting and potentially productive than either of the extreme alternatives. The way in which an organism’s plasticity could influence evolution has intrigued many authors (Avital & Jablonka, 2000; P. Bateson, 1988; Gottlieb, 1992; Hardy, 1965; Pfennig et al., 2010; Tierney, 1986; Wcislo, 1989). West-Eberhard (2003) has been a prominent advocate of the view that an individual’s plasticity plays an important role in evolution and she has been supported by other influential writers (e.g., Gilbert & Epel, 2009; Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume; Pigliucci & Müller, 2010). A central role was given to development in evolutionary processes and has prompted researchers to wonder whether, and how, developmental systems fashion evolutionary outcomes (Badyaev, 2009; Moczek et al., 2011; Müller, 2007; Pfennig et al., 2010; Verzijden et al., 2012).

From Passive to Active

Organisms and proto-organisms were doubtless passive in the initial stages of biological evolution. However, as they evolved, they would soon have become active. This is the key conceptual point in understanding how plasticity and behavior can drive evolutionary change. Development depends on the constancy of many genetic and environmental conditions. If any of these change, as can happen to environmental conditions when organisms are mobile, the characteristics of the organism can also change. High mobility by animals, such as that involved in active exploration or migration, would have frequently placed them in conditions that revealed heritable variation not previously apparent in the population. By their mobility, in the case of animals, or facility to disperse in the case of plants (Donohue, 2005), organisms would have exposed themselves to new conditions that might reveal heritable variability, thereby opening up possibilities for evolutionary changes that would not otherwise have taken place.

A striking example of what can happen when an animal is mobile has been provided by the work on the three-spined stickleback (Foster & Wund, 2011). This fish moved from a marine environment to freshwater and thence from living near the surface in streams to much deeper water in lakes. As it moved from one environment to the next its morphological and behavioral characteristics changed.

When discussing his results of experiments on what he called *genetic assimilation* (Waddington, 1953), suggested that the heat shock, applied to the larvae of fruit flies, led to the expression of genes that were carried in only a part of the population. Waddington bred from the flies that had developed a particular character (lack of a cross-vein in the wings) as a result of their larval experience. He continued to apply heat shock in each generation and to breed selectively from the flies with cross-veinless wings. After many generations of heat shock and selective breeding, cross-veinless wings developed spontaneously in the absence of the external triggering condition of heat shock.

Waddington's finding involved expression of a novel character in a new environment, but the character was not an adaptation to the triggering condition. Because of artificial selection, however, it did confer some advantage on its possessor. Cross-veinless wings do not bear any functional relation to the environment, which supplied a heat-shock when the flies were larvae. Nor need such a relation exist under natural conditions. All that is required initially is that the environmental conditions trigger the expression of a phenotype that can be repeated generation after generation so long as the environmental conditions persist.

Waddington's fruit fly experiment is just one illustration of innumerable possible scenarios. The developmental breakout may provide radically new opportunities for those individuals equipped with the new phenotype (West-Eberhard, 2003). For that reason, behavior, along with other forms of dispersion, was likely to be important in initiating evolutionary change. In addition, behavioral adaptability of the animals would have helped buffer them against extinction in new conditions. West-Eberhard argues that after developmental disruption, the reorganization of the genome might have a much broader effect than that envisaged by Waddington. She suggests that major changes might evolve as the character in question became more variable; in other words it became developmentally less robust or less canalized. The umbrella term that she uses for all the heritable changes that might occur in the genetic regulation of development in response to environmental influences is *genetic accommodation*.

Choice

Charles Darwin (1871) argued that choice of a mate could drive evolution. He called the evolutionary process *sexual selection*. For nearly a century most biologists did not take sexual selection seriously. Subsequently, however, many experiments have supported Darwin's thinking. A famous study by Andersson (1994) involved artificially lengthening the tail of male long-tailed widow birds. He found that the males with extra-long tails attracted more mates. The reason why longer tails are not found in nature is probably because it carries a big cost for the male so that in rainy weather, a bird with an extra-long tail cannot drag the great encumbrance off the ground when attacked by a predator. The growth of interest in the subject has been rapid (Cornwallis & Uller, 2010). A total of 762 papers on sexual selection were published in the year 2000 alone. In 2010, an astonishing 1,427 papers on sexual selection were published and the numbers continue to rise year on year. In sexual selection, differential survival of individuals is not at issue; rather the process depends on differential reproductive success.

Another example of active choice is that involved in predators' choice of prey. When gazelle see a predator, they jump into the air, a behavior pattern called *stotting*. A suggested evolutionary process is that first some gazelle jump after noticing cheetah (Fitzgibbon & Fanshawe, 1988). Cheetah learned not to chase jumping gazelle because such effort would be a waste of time. The next step is that all gazelle jump after noticing cheetah. Some gazelle gain advantage by giving an exaggerated jump—a stott—after noticing cheetah. This is because cheetah learn not to chase stotting gazelle. Cresswell (1994) found that when skylarks were attacked by a merlin, those that sang most were least likely to be killed by the bird of prey, suggesting once again that the predator learned not to waste effort attacking the strongest individuals. Cresswell argued, therefore, that the predators' choices had driven the evolution of the antipredator responses of their prey.

Control of the Environment

The environment does not simply set a problem to which the organism has to find a solution. The organism can do a great deal to create an environment to which it is best suited. This should give pause if evolution is considered purely in terms of selection by external forces (Lewontin, 1983). By leaving an impact on their physical and social environment, organisms may affect the evolution of their own descendants, quite apart from changing the conditions for themselves. Some of the impact is subtle, such as when a plant sheds its leaves that fall to the ground and change the characteristics of the soil in which its own roots and those of its descendants grow. These ideas have been developed extensively and are now referred to as *niche construction* (Odling-Smee et al., 2003). One example is provided by beavers that change their environment by building dams and creating lakes for themselves. This activity sets up conditions that affected the subsequent evolution of the ancestral beavers' descendants. The artificially created aquatic environment led the beavers to evolve adaptations such as webbed feet that facilitated swimming.

The effect of behavioral control on evolutionary change could be especially great when a major component of the environmental conditions with which animals have to cope is provided by their social environment. A similar type of positive feedback to that flowing from the effects of mate choice could operate in such circumstances (Jolly, 1966). If individuals compete with each other within a social group and the outcome of the competition depends in part on each individual's capacity to predict what the other will do, the evolutionary outcome might easily acquire a runaway property. In discussing the social function of intelligence, Humphrey (1976) suggested that an evolutionary *ratchet* was set up, acting to increase the general intellectual standing of the species. As he noted, such an explanation makes sense of the astonishing rate of increase in the cranial capacity of humans, if it is assumed (reasonably) that cranial capacity and intellectual ability are correlated. Here again the ideas have been developed extensively (Byrne, 2000).

A growing body of evidence suggests that the cultural environment of humans has affected the human genome (Laland, Odling-Smee, & Myles, 2010). A much-cited example is the way in which herding cattle and drinking their milk influenced the evolution of the gene that is required for the synthesis in adult life of lactase, the enzyme required for digesting milk. In human populations that are not descended from cattle owners, such as the Chinese, the gene is not expressed in adulthood and these people are unable to digest cow's milk (Gerbault et al., 2011).

The Adaptability Driver

The adaptability of the organism is likely to have played an important role in initiating evolutionary change. This hypothetical effect is often called the *Baldwin Effect* after Baldwin (1896). Two others published the same idea in the same year, namely Lloyd Morgan (1896) and Osborn (1896). At the time, the proposed evolutionary process was called *organic selection* and was thought to be original to the three authors. However, 23 years before, Spalding (1873) had published the same hypothesis in *Macmillan's Magazine*. This was not an obscure publication—it was the predecessor of *Nature*, which continues to be published by Macmillan. Spalding's driver of evolution comprised a sequence of learning followed by differential survival of those individuals that expressed the phenotype more efficiently without learning. Given Spalding's precedence and the simultaneous appearance in 1896 of the ideas about organic selection, it seems inappropriate to term the evolutionary process the *Baldwin effect*. The trouble is that calling the proposed process the *Spalding effect* is not descriptive of what initiates the hypothetical evolutionary process; hence the term used here, the *Adaptability Driver* (P. Bateson, 2005).

Lloyd Morgan's account of the hypothetical adaptability driver process was particularly clear. He suggested that if a group of organisms respond adaptively to a change in environmental conditions, the modification will recur generation after generation in the changed conditions, but the modification will not be inherited. However, any variation in the ease of expression of the modified character that is due to genetic differences is liable to act in favor of those individuals that express the character most readily. As a consequence, an inherited predisposition to express the modifications in question will tend to evolve. The longer the evolutionary process continues, the more marked will be such a predisposition. Plastic modification within individuals might lead the process and a change in genes that influence the character would follow; one paves the way for the other.

As a possible example of the adaptability driver, the Galapagos woodpecker finch pokes sharp cactus spines into holes thereby obtaining insect larvae as food. Suppose it does so without much learning but that an ancestor did so by trial and error. In the first stage of the evolutionary process, a naive variant of the ancestral finch, when in foraging mode, might, for example, have been more inclined to pick up cactus spines than other birds. This habit spread in the population by Darwinian evolution because those behaving in this fashion obtained food more quickly. At this stage the birds still learned the second part of the sequence. The second step would have been that a naive new variant, when in foraging mode, was more inclined to poke cactus spines into holes. Again this second habit spread in the population by Darwinian evolution. The end result is a finch that uses a tool without having to learn how to do so. Simultaneous mutations increasing the probability of two quite distinct acts (taking cactus spines and poking them into holes in the case of the woodpecker finch) would be very unlikely. Learning makes it possible for them to occur at different times and in any order. Without learning processes, having one act but not the other has no value. As a matter of interest, it seems to be the case that the behavior of the woodpecker finch is halfway down the evolutionary road from fully learned to fully spontaneous because naïve birds readily pick up small sticks but then have to learn how to use them (Tebbich, Sterelny, & Teschke, 2010).

An early example of how the adaptability driver process might work was provided by the famous child psychologist and genetic epistemologist Jean Piaget, who began his career as a biologist and was much influenced by Baldwin (Piaget, 1979). He studied the freshwater snail *Limnaea* and found that in still ponds the coiled shell of the form known as *stagnalis* was elongated. In lakes where wave action could render such a shell disadvantageous, the shell of the form known as *lacustris* was much shorter and the snail could cling onto the substrate much more firmly. When the *lacustris* form was raised in a still aquarium, half of the snails developed the shell of the *stagnalis* form, whereas the other half developed the more compact *lacustris* form without needing to be exposed to the wave action of a lake. One interpretation of this result is that the population of snails living in the lakes was midway through an evolutionary change. On this view the *stagnalis* form was evolutionarily more primitive, and in the lakes with wave action, some snails developed the *lacustris* adaptation as a result of developmental plasticity, but the evolutionarily more advanced snails no longer required such plasticity to develop their advantageous shell shape. Although Piaget carried out this work early in his career, it did not come out in book form until the end of his life. In the terms used by Lloyd Morgan, the initial change could involve adaptability by the individual snail; the adaptability is won at some cost so that descendants expressing the character more efficiently would be more likely to survive.

An important empirical demonstration of adaptability driving evolutionary change is that of the house finch. In the mid-20th century, the finch was introduced to eastern regions of the United States far from where it was originally found on the west coast. It was able to adapt to the new and extremely different climate and spread up into Canada. The finch also extended its western range north into Montana, where it has been extensively studied. After a period involving great deal of plasticity, the house finch populations spontaneously expressed the physiological characteristics that best fitted them to their new habitats without the need for developmental plasticity (Badyaev, 2009). Initially the adaptive onset of incubation and the sex bias in the order of ovulation were affected by ambient temperature in the more northerly climes, but as evolution in the population occurred these behavioral and physiological effects were no longer dependent on the external cues for their expression. After initially using their adaptability to respond to the new environmental conditions, the house finch populations spontaneously expressed the physiological characteristics that best fitted them to their new habitats.

Generating Complexity

Paenke, Kawecki, and Sendhoff (2009) proposed a general framework that explained cases in which adaptability would increase behavioral complexity as well as those in which it would not. Spontaneously expressing a behavior that had been learned in previous generations could be costly if it meant that the animal lost all of its ability to learn. Some evidence from fruit flies suggests that this might well be the case, at least in simpler organisms (Kawecki, 2010). The benefit of expressing a behavior spontaneously was found to be outweighed by the cost of losing the capacity to learn about other things. The argument is much less cogent when applied to big-brained animals like birds and mammals with multiple parallel pathways involved in learning. In these animals, the loss of capacity to learn in one way has no effect on the capacity to learn other ways (P. Bateson, 2004).

The effect of plasticity on evolution is likely to have become increasingly powerful as animals, in particular, become more complex. When such complexity entailed a greater ability to discriminate between different features of the environment or a greater ability to manipulate the environment, the organism would benefit and would be more likely to survive and reproduce in the face of multiple challenges during its lifetime. Plasticity would promote much more rapid genetic evolution of complex sets of adaptive systems than can be accomplished by mutation alone. Theoretical studies have indicated how crucial plasticity could be in such an evolutionary process (e.g., Beltman, Haccou, & ten Cate, 2004; Dukas, 2013).

In general, an ability to cope with complex environmental challenges by means of plasticity opens up ecological niches previously unavailable to the organism. This would inevitably lead to the subsequent evolution of morphological, physiological, and biochemical adaptations to those niches and the likelihood of speciation (Pfennig et al., 2010; Pfennig & McGee, 2010). Where an environmental challenge involved greater processing capacity by the brain this organ, too, would be expected to evolve with greater rapidity. On the assumption that the larger brain relative to body size ensures greater learning capacity, the rate of evolution should correlate positively with the relative brain size. This expectation is given some support by the study suggesting that taxonomic groups evolving most rapidly have the biggest brains relative to body size (Wyles, Kunkel, & Wilson, 1983). The expectation is also supported by the correlation between behavioral innovation and brain size reported for birds (Sol, Lefebvre, & Rodríguez-Teijeiro, 2005) and primates (Reader & Laland, 2002).

Some theorists have argued that plasticity could dampen down the rate of evolution (e.g., Price, Qvarnström, & Irwin, 2003; Robinson & Dukas, 1999). Their idea was that, with every individual in the population coping plastically with an environmental challenge, natural selection would have had no variation on which to act. In some cases this might well have been true in the short run. However, if operating plastic processes involved time and energy costs, then individuals that expressed the adaptation spontaneously would readily invade the population and the dampening effect would be lost.

In summary, the organism's mobility, its choices, its construction of a niche for itself, and its adaptability, have all played important roles in biological evolution. All these activities should be contrasted with the essentially passive role often attributed to the organism by some evolutionary biologists (e.g., Ridley, 2003) and is implicit in Darwin's metaphor of *Natural Selection*.

Evo-Devo and Epigenetics

The view that development was irrelevant to an understanding of evolution was repeatedly challenged by Gould (1977, 2002), who referred to the *unity of type* as in the shared forelimb structure of all mammals from whales to bats. His views have been strengthened the growth of the evo-devo movement, which has shown how developmental toolkits can profoundly influence the course of evolution (Carroll, 2005). Knowledge of the constraints on an animal at all stages of its life cycle is important (Arthur, 2004; Brakefield, 2011; Danchin et al., 2011). Further support for the importance of development in evolution is provided by the rapidly expanding field of epigenetics and the variety of legacies, from gut bacteria to ecological habitat, that an individual can inherit (P. Bateson, 2012; Gilbert & Epel, 2009). Acquired characteristics can be passed to progeny without changing DNA sequences and such characteristics can be inherited for a period in the *absence* of the initial environmental trigger (Bonduriansky, 2012; Bossdorf, Richards, & Pigliucci, 2008; Gissis & Jablonka, 2011; Jablonka & Raz, 2009). In itself, this evidence does not relate to the thinking about biological evolution because the transgenerational epigenetic effects could wash out if the conditions that triggered them in the first place did not persist.

DNA silencing can be stable across generations. For example, in the plant *Linaria* the epigenetically induced phenotype does not change from one generation to the next (Cubas, Vincent, & Coen, 1999). Usually, inherited epigenetic changes are less stable than genomic variations. Even so, such heritable epigenetic effects might play an important role in evolutionary processes. The central question is whether the transmitted epigenetic markers could facilitate genomic change (Johnson & Tricker, 2010). The answer is that, in principle, they could if (a) they were transmitted from one generation to the next, (b) they increased the fitness of the individual carrying the markers, and (c) genomic reorganization enabled some individuals to develop the same phenotype at lower cost. Epigenetic inheritance would serve to protect the well-adapted phenotypes within the population until spontaneous fixation occurred. That much is exactly the same as has been proposed for the operation of the adaptability driver. However, another process could be at work. Evidence suggests that DNA sequences where epigenetic modifications have occurred are more likely to mutate than other sites (P. Bateson & Gluckman, 2011). The consequent mutations could then give rise to a range of phenotypes on which

Darwinian evolution could act. If epigenetic change could affect and bias mutation rates, such nonrandom mutation would facilitate fixation at the genomic level.

CONCLUSIONS

This chapter has provided an overview of how developmental processes are integrated from the standpoint of an ethologist, surveying some of the contributions that ethology has made to an understanding of human development and evolution and how these contributions are being integrated with modern studies of epigenetics. Although much coming together of different disciplines has occurred, ethologists are still distinctive in the way that they focus on biological function. The static view that divided behavior into the innate and the acquired has been replaced by a much more dynamic view of the underlying processes (P. Bateson & Gluckman, 2011). At the same time, the massive growth of epigenetics has provided understanding of how the molecular processes of development work.

Simplifications are necessary as aids to discovery, but the notion that the organism's characteristics are based on two sources of instruction: one from within and one from without is far too simplistic. Metaphors such as the supposed "hard-wiring" of the brain or the "blueprint" for development are equally unhelpful. The conventional opposition of nature and nurture relates to two different domains and should not be contrasted directly; indeed one is a state and the other a process. Nature properly refers to the fully developed characteristics of the child and these will depend on circumstances, and nurture should refer to the ways in which those characteristics were derived through development. What is required is understanding of the biological and psychological processes that build a unique adult from a fertilized egg.

When the phenomena of robustness and plasticity are examined in greater detail, they are both found to comprise bundles of distinct processes. Many different ways of generating robust outcomes have been found and equally many different forms of plasticity can be recognized. All these processes can operate at many different levels, ranging from the molecular to the behavioral. And different combinations of developmental processes can be involved in the emergence of different characteristics of the child.

As attention is focused on the development of behavior, more and more is being learned about the underlying processes. Many of the regularities found in development are amenable to analysis. Knowing something of the underlying regularities in development does bring an understanding of what happens to the child as it grows up. The ways in which learning is structured, for instance, affect how the child makes use of environmental contingencies and how the child classifies perceptual experience. It does not follow that as these regularities are uncovered, the outcome of development necessarily becomes more predictable. To understand why, consider a rule-governed game like chess. It is impossible to predict the course of a particular chess game from knowledge of the game's rules. Chess players are constrained by the rules and the positions of the pieces, but they are also instrumental in generating the positions to which they must subsequently respond. The range of possible games is enormous. The rules may be simple but the outcomes can be extremely complex. In the course of development the rules influence the course of a life, but they do not determine it. Like chess players, children are active agents. They influence their environment and are affected by what they have done. Furthermore, children's responses to new conditions will, like chess players' responses, be refined or embellished as they gather experience. Sometimes the normal development of a particular ability requires input from the environment at a particular time; what happens next or even much later in the life course depends on the character of that input. The upshot is that, despite their underlying regularities, developmental processes seldom proceed in straight lines. Big changes in the environment may have no effect whatsoever, whereas some small changes can have big effects even if not immediately manifest. The only way to unravel this path dependency is to understand the regulatory processes and their interplay with the processes that generate change.

Individuals play an active role in their own development. Moreover, their activities can have an impact on their descendants and how they involve. This awareness, which was fostered by ethologists, has led to a profound change in the way that biological evolution is considered. The advances in molecular understanding are also feeding into an understanding that links studies of development to those of evolution. A central question in considering evolutionary change driven by the environment is whether transmitted epigenetic changes induced by developmental exposures in one generation could facilitate genomic change in later generations. In principle they could if they increased the fitness of the individual carrying the markers and genomic reorganization enabled some individuals to develop the same phenotype at lower cost in fitness terms. Increasing empirical evidence exists for both male and female mediated epigenetic inheritance. It seems plausible that such epigenetic inheritance may serve to protect the well-adapted phenotypes within the population until spontaneous mutation leading to phenotypic fixation occurs.

By bringing together evidence from different levels of analysis, ranging from the molecular to the social, a much more powerful theoretical perspective can be formulated. Its impact is not only on scientific approaches to development and evolution, but also on how humans think about themselves and how they design public health measures when mismatches between themselves and their environment occur.

The brain is an immensely complex organ: One estimate puts the number of neurons in the adult human brain at about 100 billion (Pakkenberg & Gundersen, 1997), with perhaps 100 trillion synapses or connections between neurons. Despite this enormous complexity, the past decades have seen advances in theory and method that are leading to a greater understanding of brain function and the ways in which neuroscience relates to psychological science (Berntson & Cacioppo, 2009). However, neuroscience is clearly a large discipline and an umbrella term for a variety of subdisciplines that intersect with the field of psychology in various ways, and understanding these relations is not a straightforward endeavor (Rosvall & Bergstrom, 2010).

Advances in cellular, molecular, and electrophysiological methods have facilitated the rise of what has become known as *behavioral neuroscience* and have led to significant increases in knowledge concerning the neurobiology of learning, memory, and motivation, with a focus on animal models. In human work, various related subdisciplines have emerged such as *cognitive neuroscience* (Gazzaniga, 1995), *affective neuroscience* (Davidson & Sutton, 1995), *social neuroscience* (Cacioppo et al., 2007; Ochsner & Lieberman, 2001), and *social-cognitive neuroscience* (Adolphs, 2003; Frith & Frith, 2003). There has also been increasing interest in the development of the brain and nervous system in relation to cognitive, emotional, and social development (de Haan, Chapter 18, this *Handbook*, this volume; Nelson & Luciana, 2008; Zelazo, Chandler, & Crone, 2010).

The various areas of neuroscience have also attracted the attention of funding agencies, in light on the presumed importance of investigating what could be termed the *neural mechanisms* or *neural processes* involved in psychopathology, including developmental aspects. One salient example comes from the emphasis at the National Institute of Mental Health that the first step in the classification of mental disorders is not the clinical description of symptoms but rather "to inventory the fundamental . . . behavioral functions that the brain has evolved to carry out, and to specify the neural systems that are primarily responsible for implementing these functions" (Cuthbert & Insel, 2013, p. 4). From this perspective, psychopathology is then considered "in terms of dysfunction of various kinds and degrees in particular systems" (p. 4).

The increase in the status and visibility of neuroscience has significantly altered the landscape of psychology, and has stimulated a discussion concerning the present and future relations between the disciplines of psychology and neuroscience (Decety & Cacioppo, 2010). One prediction is that "harder" areas of neuroscience (i.e., the areas focusing primarily on cellular and molecular aspects) will split from psychology, which would then primarily be left as a social science of behavior and experience (Kagan, 2006). Arguably, the signs of such a split are already visible in the way that graduate training programs in many psychology departments separate the more cellular and molecular areas of neuroscience not only from other traditional areas of specialization such as cognitive, developmental, or social psychology (Spear, 2007), but also from the more psychologically oriented area of cognitive neuroscience.

The relations between psychology and neuroscience have also been the subject of a good deal of attention in the philosophy of mind, in which views can be broadly characterized as lying at or between two extreme positions. One position espouses the status of psychology as an autonomous discipline, with little or no meaningful connection to neuroscience (Cummins, 1983; Fodor, 1974, 1997). This view has encountered many difficulties, some of which will be considered in this chapter. The opposing position is that psychological constructs will ultimately be reduced to and replaced by descriptions of neurobiological processes (e.g., Bickle, 2003; Churchland, 1981, 2013). In turn, this reductionist view has also found little support from neuroscientists, psychologists and philosophers. Neuroscience and psychology address different subject matter, which precludes reduction (Chemero, 2007), but which also leaves open difficult questions about the relations between the disciplines.

So, how to proceed? The opposing scenarios of "brainless" autonomy and "only-brain" elimination do not appear to present palatable options for the future of psychological or developmental science. Between the extremes, a moderate position invokes a conceptualization of psychology and neuroscience as separate but complementary levels of analysis (e.g., Miller & Keller, 2000). From this perspective, addressing questions on each level has more explanatory power than dealing with one level alone. However, one central premise of this chapter is that as a field, psychology has failed to give sufficient consideration to how to approach the concept of *different levels of analysis* as well as the relations among such levels. One argument is that these issues are not well understood within the psychological literature because the trajectory of this discipline over the past decades has prevented the emergence of a more integrative view (Marshall, 2009). One aim of this chapter is to show how more integrative accounts are coming to the fore, with new perspectives in developmental science adding an indispensable dimension (Greenberg & Partridge, 2010; Marshall, 2013).

OVERVIEW

This chapter takes a wide-angle look at developmental features of the relation between psychology and neuroscience, and is not meant to provide a basic description of brain development (see instead Nelson, de Haan, & Thomas, 2006; Paus, 2009; Stiles, Brown, Haist, & Jernigan, Chapter 2, this *Handbook*, Volume 2; Zelazo & Lee, 2010). The chapter begins with a broad introduction to the concept of neuroscience as a different level of analysis, initially working from an account of how classical cognitivism resulted in a neglect of neuroscience in psychology, and how the growing field of cognitive neuroscience has attempted to address this omission. The emergence of developmental cognitive neuroscience is then considered, with a focus on central questions of plasticity and how early experience relates to the development of brain and behavior. Current theoretical perspectives in developmental cognitive neuroscience are also outlined, including the neuroconstructivist approach.

One feature of neuroconstructivism is an appreciation of the embodied nature of development, which is considered here to be an essential part of any theory of developmental cognitive neuroscience. Indeed, a key argument outlined in the second part of the chapter is that embodiment has the potential to reframe the ways in which neuroscience data are viewed and analyzed in relation to other kinds of data. This potential can be realized through a reconceptualization of what cognitive scientists have termed the *level of implementation*. However, key developmental features of this reconceptualization are currently underspecified, and in the final part of the chapter it is suggested that a relational developmental systems perspective provides a way forward. The implications of this approach for forging a new biologically inspired direction for developmental science are profound, and are discussed in more detail toward the end of the chapter.

NEUROSCIENCE AND LEVELS OF ANALYSIS

Conceptualizing the relations between psychology and neuroscience remains the subject of extensive debate and discussion (Miller, 2010). The question at the heart of this debate is what kind of explanation can be provided by neuroscience data. This question is the starting point for the discussion here, with an initial focus on the concept of neuroscience data as occupying one of several levels of analysis. This focus reflects a current trend in certain areas of psychology to emphasize the utility of studying a phenomenon across multiple levels of analysis, an emphasis that is particularly strong in certain areas of developmental science (see, e.g., Cicchetti, 2008). Within developmental work, this emphasis has roots in theory-predicated research in classic comparative psychology studies involving levels of integration in behavioral development (Schneirla, 1957, 1959; Tobach & Greenberg, 1984; Tobach & Schneirla, 1968).

The position that neuroscience data occupy one of several levels of analysis is a common one across psychology more broadly. For example, in an influential discussion of the emerging subdiscipline of social-cognitive neuroscience, Ochsner and Lieberman (2001) proposed three such levels of analysis: A motivational level, a cognitive level, and a "neural level, which is concerned with the brain mechanisms that instantiate cognitive-level processes" (p. 717). Similar distinctions are common, and are usually accompanied by an emphasis on the deeper understanding that results from studying phenomena at different levels (e.g., Ozonoff, Pennington, & Solomon, 2006). From such a perspective, the study of different levels and their interactions is considered to be a productive and worthwhile enterprise (Cacioppo, 2002; Machamer & Sytsma, 2007).

Although the notion of multiple levels appears at first sight to present a potentially integrative picture, what is specifically meant by different levels of analysis—and how to conceptualize the relations among levels—is often left unsaid. This remains problematic, because issues about levels and the relations among them are at the heart of fundamental questions about the enterprise of explanation across the entire field of psychology. However, addressing these questions has a long history of difficulties, and the vexing nature of many of the associated issues is well known. As framed by Dennett (2000), "it has been widely recognized that many of the false starts in cognitive science have been due to failures to find the proper level of analysis for the topic. The bold claim might be defended that all the really tough problems . . . reside in the murky and embattled zones where the relations between these levels must be clarified" (pp. xi–xii).

Developmental science does, in fact, have a history of tackling the difficult issues concerning the integration of different levels—as seen, for example, in the work of developmentally oriented comparative psychologists working in the mid-20th century (see, e.g., Aronson, Tobach, Rosenblatt, & Lehrman, 1972). However, the emerging discipline of cognitive science also taking shape over that time period did not reflect this move toward integration, but instead it encouraged separation. As discussed by Floridi (2008), the notion of separate levels of analysis became popular among cognitive scientists in the 1970s, in part through an increase in attention to computational methods. Early supporters of levels-based approaches were Dennett (1971), Simon (1969), and Wimsatt (1976), although perhaps the best-known framework came via the theorizing of the vision scientist David Marr (1982). Despite the relative neglect of neuroscience in his own work, Marr's three-level approach has provided a useful conceptual framework for a number of past and present discussions concerning the relations between psychological constructs and neuroscience (e.g., Clark, 2000; Gold & Stoljar, 1999; Kitcher, 1988; Mitchell, 2006; Poeppel, 2012; van Eck, de Jong, & Schouten, 2006).

Specifically, Marr's account concerns "the three levels at which any machine carrying out an information processing task must be understood" (Marr, 1982, p. 25). In brief, these three levels are:

1. A *computational* level that refers to a general analysis of the requirements of the task and the formulation of an overall strategy toward fulfilling those requirements.
2. A level of *representation and algorithm* consisting of the description of a series of mechanical steps that would solve the problems outlined at the first level, including the specification of the representational format to be used.
3. A level of *implementation* that consists of a description of the physical hardware needed to carry out the sequence of steps that was specified at the second level.

Although he was primarily concerned with problems in visual perception, the information processing emphasis in Marr's account is consistent with how cognitive psychology was approached at the time that he was writing—with mental processes being framed primarily in computational terms. As an example, in line with this emphasis Marr illustrated how his three-level framework could be applied to an everyday machine—a cash register. At the first computational level, the question is a broad one: What is the general nature of the task or problem at hand? In the example of the cash register, the computational problem refers to addition—what a cash register needs to do. However, at this level nothing is said about how to *do* addition. This is the question at the second level of representation and algorithm, which can also be considered a level of *mechanism*.

For the example of the cash register, an account at the second level should provide an answer to the question of *how* addition is done. In Marr's account, a description at this level would specify what kind of representation might be used, given the problem stated at the first level. For the cash register, one might adopt Arabic numerals as the representational format. One would then specify the rules or procedures that would be applied to these representations, such as adding the least significant digits first and carrying if the sum exceeds 9. At the third level of implementation, the question concerns how the symbols and processes specified at the second level might be physically implemented. Implementation then becomes a problem of engineering a machine in which the chosen mechanism could be instantiated. In the example of the cash register, this could be done as binary coded decimal numbers in the electrical states of digital logic circuitry, or it could be done on a notched metal wheel (McClamrock, 1995).

Although the machine example of Marr may seem out of place in a contemporary discussion of developmental science, emphasizing the similarities between mind and machine has been a dominant theme in psychology over the past 50 years. The *mechanistic* focus of the level of representation and algorithm closely aligns with a key objective of cognitive science, which is quite literally to try to understand *how* the mind works. In this sense, most of the work in cognitive psychology has taken place at what corresponds to Marr's second level of representation and algorithm—the level of problem solving in terms of what symbols are needed for a solution, and the rules under which those symbols can be manipulated. Indeed, the premise of mainstream cognitive psychology for decades was that the real work was in solving problems at the algorithmic level, with the physical means that might be used to instantiate the solution to the problem being viewed as "mere implementation" (see Smolensky, 1988, p. 7). This lopsided approach was a key aspect of the *cognitivist framework* that underwrote one interpretation of the so-called cognitive revolution in psychology (Miller, 2003; see Bruner, 1990, and text below for an alternative interpretation). Although developmental aspects remained on the sidelines, it is worth further exploring the implications of these broader issues about cognitivism here, because they are closely related to the primary questions concerning levels—and the relations among them—that are central to this chapter.

Cognitivism and the Neglect of Neuroscience

Although the *neopositivism* of the early 20th century aimed to purge psychology of its metaphysical overtones (Overton, 2006), the original objective of the cognitive revolution was to return the study of mental life and meaning to the field of psychology after decades of behaviorism. According to Bruner's (1990) interpretation, the foundational emphasis of the cognitive revolution was "to discover and to describe formally the meanings that human beings created out of their encounters with the world, and then to propose hypotheses about what meaning-making processes were implicated" (p. 2). However, the cognitivist understanding of the nature of mind that emerged from the cognitive revolution did not reflect this emphasis. Instead, the predominant conceptualization of the mind became influenced by the idea that cognition consists of formal computational reasoning processes acting on the syntactic, but not the semantic, aspects of symbolic representations (Fodor, 1975).

The adoption of the cognitivist framework within psychology was also associated with an alignment with the emerging discipline of artificial intelligence, which further contributed to the dominance of an information processing view of the mind. From this perspective, cognitive operations could be seen as manipulations of subpersonal representations to which meaning had been preassigned (see Allen & Bickhard, 2013, for a critique of this position). One rationale for the growth of this view was the sentiment that if computers could be used to model the ways that representations are manipulated, mental processes could be made more transparent (Newell, Shaw, & Simon, 1958). This rationale was an important aspect of the turn toward computational approaches because it provided one way of moving beyond the behaviorist paradigm that had dominated psychology for the preceding decades. However, it has been argued in various places that the move toward the cognitivist view of the mind was fundamentally a wrong turn in that it prevented the emergence of more integrative accounts (e.g., see Rowlands, 2010; Smythe, 1992; Thompson, 2007). In the context of the current project, a related argument is that the turn toward cognitivism encouraged a neglect of neuroscience among cognitive psychologists (see Edelman, 1992).

In encouraging a computational view of the mind, the cognitivist approach put an unduly strong emphasis on the level of representation and algorithm (i.e., Marr's second level), with little or no regard for how these information processing mechanisms might be realized in living systems. As such, perhaps it is not surprising that mainstream cognitive psychology became disconnected from the study of neuroscience: If mental processes could be modeled using symbol-manipulating algorithms implemented on a computer, the actual makeup of the human brain was not particularly relevant. Indeed, Marr's own theorizing put an emphasis on the relation between the computational and the representational/algorithmic levels. The origins of this emphasis lie in the background assumption that the optimum level of explanation involves translating task requirements into an algorithmic solution using an appropriate representational format. If this assumption is accepted, the actual hardware that could be used to manipulate the representations and to implement the algorithmic solution can be seen as less important than the method by which the problem was solved. Within the philosophy of mind, this emphasis on Marr's algorithmic level remained a dominant force in cognitive psychology in the decades following the cognitive revolution. As such, this approach became the conventional way that psychological explanations are understood—as functional explanations that are distinct (and separable) from other kinds of explanation (such as neuroscientific explanation, see Piccinini & Craver, 2011).

At the time of his writing in the late 1970s, the neglect of the implementational level in Marr's own work was partly a response to the sheer complexity of understanding the physiology of the visual system, which was his specific area of study. However, in other circles a similar outlook was further propelled by a particular philosophical perspective—in vogue at the time—that further discouraged a serious consideration of the implementational level. This discouragement concerning the value of neuroscience was based on the argument of *multiple realization*: That the same problem could potentially be solved using processes that were implemented on different *hardware*, be it a human brain, a machine, or even an extraterrestrial being with a physiological makeup completely different to any biological system on earth (Fodor, 1975). The invocation of this argument buttressed the isolation of the computational mind in the cognitivist approach, and placed a further barrier to the integration of psychology and neuroscience (see also Putnam, 1975; Pylyshyn, 1984).

From the perspective that is developed over the course of this chapter, the failure to maintain a focus on the necessary constitutive character of all of Marr's levels represents a distinct problem. Given this fundamental shortcoming of the cognitivist emphasis, more integrative approaches are needed that would incorporate all three of the levels in a unitary framework. However, formulating specific relations between levels has been a notoriously difficult endeavor. Much work in the philosophy of science has attempted to map how interlevel relations could be conceptualized, although as noted by Houng (2012), the concept of level "has been used in philosophical communities in a vague and confusing way" (p. 324).

One attempt to sidestep some of this confusion comes from the suggestion that Marr's levels are *levels of realization* (for discussion see Craver, 2005, 2007). From this viewpoint, the computational level is realized by the algorithmic level, which is realized by the implementational level. Levels of realization can, therefore, be understood as different ways of looking at the same thing, with no level having particular explanatory priority. This may appear at first to be an attractive option because it seems to avoid problematic issues of *reductionism*, either in the traditional sense that one level can be derived (and thus reduced to) another level, or in a more contemporary view that lower level processes might have a stronger explanatory privilege (for discussion see Piccinini & Craver, 2011). Indeed, Miller (2010) has argued that the neutral approach of levels of realization is preferable to one of causal reductionism (see also Miller & Keller, 2000). However, the concept of levels of realization may also give the misleading impression that the different levels of analysis can be considered in relative isolation: One could pay lip service to the importance of levels, while, in fact, neglecting a serious consideration of the relations among them (Marshall, 2009).

Given these difficulties, how can a more integrative account of the development of body, brain, and mind be formulated? The two intertwined central premises of this chapter are that a *relational developmental systems* framework (see Overton, Chapter 2, this *Handbook*, this volume), in which the relational ties among levels can be articulated within the context of *embodiment,* can provide a way forward. To move toward an elaboration of this premise, the field of cognitive neuroscience is first considered, because it has been a testing ground for many of the key questions involving the relations among levels.

The Emergence of Cognitive Neuroscience

The past 30 years have seen advances in neuroscience methods that have driven the emergence of the discipline of cognitive neuroscience (Kosslyn & Koenig, 1992; Posner & DiGirolamo, 2000; Posner & Raichle, 1994). Building on an established tradition of brain research in neuropsychology, newer neuroimaging technologies such as functional magnetic resonance imaging (fMRI) joined existing methods such as electroencephalography (EEG) to allow cognitive neuroscientists to probe brain function in ways that simply had not been possible before (see de Haan, Chapter 18, this *Handbook*, this volume). Furthermore, cognitive neuroscience potentially allows these methodological advances to be used to address questions about implementation alongside questions of mechanism. In other words, the promise of cognitive neuroscience has been that explanations framed at Marr's first two levels can potentially be connected with explanations at the third level of implementation.

Although some have argued otherwise (e.g., Bennett & Hacker, 2003), most cognitive neuroscientists do not view their approach as a reductionistic one nor as a replacement for psychological concepts. Instead, they intend the use of functional neuroimaging and related techniques as a means of decomposing cognitive processes into component activities in much the same way that earlier cognitive scientists used chronometric behavioral measures such as reaction time (Posner, 1978). Related to this aim, the principal goals of cognitive neuroscience have been summarized by Bechtel (2002) as follows: "that an explanation of a cognitive performance involves both decomposing an overall task into component information processing activities and determining what brain area performs each" (p. 49, see also Bechtel, 2008). Each of these two aspects will be considered separately here.

The use of neuroimaging data to investigate the cognitive processes involved in task performance relies on what has been called a strategy of *forward inference* (Henson, 2006). In its most basic form, this method is meant to indicate whether carrying out two related tasks might involve similar cognitive processes. If regional or temporal differences in brain activation are observed during the performance of two seemingly related tasks, the hypothesis that the tasks utilize identical cognitive processes can be rejected. In this approach, neuroscience data can help distinguish between competing psychological hypotheses that were formulated using behavioral data (Schall, 2004). When used in this manner, neuroscience data do not have a privileged status, but instead represent another dependent variable for testing competing hypotheses about unseen mental processes. In this sense, the use of forward inference is consistent with the suggestion that cognitive theories should be the starting point for the application of neuroscience data (Cooper & Shallice, 2010; Hatfield, 2000), although it has also been suggested that this relation operates in the opposite fashion (i.e., from data to theory, see Forstmann, Wagenmakers, Eichele, Brown, & Serences, 2011).

Inferences about which brain regions are associated with the cognitive functions involved in the performance of a task (Bechtel, 2002, 2008) are often made through a different strategy, called *reverse inference* (Poldrack, 2006). Poeppel (2012) refers to this endeavor as *making maps*, with activation of a specific brain region during performance of a task being taken as indicative of the engagement of a particular cognitive process. However, such inferences about the activation of a specific cognitive process have to be made on the basis of evidence from prior studies linking this cognitive process to this particular pattern of brain activation. As noted by Poldrack (2006), this sequence involves the logical fallacy of affirming the consequent, and as such is not particularly helpful (see also Levin & Aharon, 2011). However, it has been suggested that the understanding of relations between activation of certain brain regions and cognitive functions can be strengthened in a number of ways. These include employing neuropsychological data involving transient deactivation or the effects of chronic damage to specific brain regions, and the use of Bayesian inference and meta-analytic approaches that draw on large numbers of datasets and which include parametric manipulations of the supposed cognitive process (see Decety & Cacioppo, 2010; Zacks, 2008).

Although cognitive neuroscience has maintained a high profile, some scientists working within the discipline have voiced concern that the original objective of informing the study of cognitive processes has been pushed aside by a flurry of technological advances. Cooper and Shallice (2010) argue that much of contemporary neuroscience neglects what they see as Marr's most critical level—the information-processing level of representation or algorithm—and that if cognitive neuroscience focuses too much on neuroscience, the cognitive aspect is at risk. Similarly, Poeppel (2012) cautions that the trend toward finer and finer localization methods can only do so much:

> [While] the spatial organization of information-processing systems can be a useful, and even necessary, intermediate

> step in explaining a system ... even fantastic localization of function, incorporating the newest techniques ... does not constitute an explanation. The cartographic imperative does not suffice. It is the mechanistic understanding of the function that we seek, and that is not going to be tractable by localization of function and spatial topographic mapping alone. (p. 38)

In emphasizing the continuing value of Marr's levels as "distinct but tightly yoked levels of description," Poeppel (2012) suggests that although cognitive neuroscientists have been preoccupied with making *maps*, questions about making *mappings* between the structure and units of cognitive psychology and those of the neurosciences have been neglected (see also Poldrack, 2010). Cooper and Shallice (2010) further argue that these kinds of problems lend support to critiques of localization studies in cognitive neuroscience (e.g., Coltheart, 2006, 2013; Hardcastle, 2007; Harley, 2004), and that the response of cognitive neuroscientists to such critiques have been insufficient to adequately counter them.

From the perspective of the current chapter, one suggestion that strongly points toward a break in this impasse comes from the need to consider *developmental* aspects of the mappings problem. Indeed, Poeppel (2012) emphasizes that developmental data—in the context of theory building—can play a key role in providing answers to many of the fundamental problems in cognitive neuroscience. However, the mainstream discussions that have occurred among cognitive neuroscientists about the utility of neuroimaging data in cognitive psychology have not generally recognized a fundamentally important role for development (see, e.g., Shimamura, 2010). This lack of recognition is illustrated by the fact that a recent textbook on cognitive neuroscience by two prominent neuropsychologists (Shallice & Cooper, 2011) contains virtually no mention of developmental processes.

Developmental Cognitive Neuroscience

Despite the adult-centric nature of mainstream cognitive neuroscience, developmental features of neuropsychology have had advocates who have consistently emphasized that studying only the adult state places fundamental limits on the understanding of brain and cognition (e.g., Karmiloff-Smith, 1998, 2013). Building on this advocacy, a subfield explicitly called *developmental cognitive neuroscience* (DCN) has emerged, with the appearance of a handbook (Nelson & Luciana, 2001, 2008), an eponymous journal (Blakemore, Dahl, Frith, & Pine, 2011) and a textbook (Johnson, 2011a).

According to Johnson (2011a), DCN is concerned with the origin of the organized biological structure of the brain and how this structure comes to play its key role in mental life. Relevant background emphases include the notion that "biological structure emerges through complex and variable interactions between genes and their environments" (p. 2) and that "there is no simple sense in which information either exclusively in the genes or in the environment can specify the end product" (p. 5). At a certain level, DCN is therefore a *systems* approach, with implicit connections to the notion of *probabilistic*—rather than predetermined—*epigenesis*, as put forward by the developmental systems theorist Gilbert Gottlieb (1970, 1998; see also Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume). In turn, these connections link further back, to the influence of a lineage of comparative perspectives on the development and integration of behavior (Schneirla, 1959).

In emphasizing "complex *self-organizing* interactive processes" (Johnson, 2011a, p. 225, italics added), the DCN approach is broadly aligned with a *constructivist* approach to the development of human knowledge. One attempt to further expound a constructivist manifesto for DCN comes from the work of Mareschal et al. (2007), who give three reasons why they are committed to considering neural processes in the study of cognitive development:

1. Ontogeny is understood as involving "the construction of increasingly complex levels of biological organization, including the brain and the cognitive processes it supports" (p. 7). Within this context, Mareschal et al. (2007) also argue that higher-level cognitive functions are established through organizational processes operating at lower levels (e.g., cellular interactions).
2. They argue that developmental neuroscience data can be helpful in understanding the origins of developmental disorders and, hence has important clinical implications.
3. They maintain that considerations of brain structure and function place important constraints on theories of cognitive development such that "a proper consideration of brain mechanisms is likely to result in a more adequate model of cognition in general and cognitive development in particular" (p. 8). More specifically, Mareschal et al. (2007) argue that explanations of what they term *representational change* should be consistent across the cognitive and neural levels of explanation.

One other emphasis of DCN has been on the utility of computational modeling in the study of cognitive development (see also Marcovitch & Zelazo, 2012). Indeed, the approach of Mareschal et al. (2007) is essentially an information-processing account, with a key role for the manipulation or transformation of representations by computational mechanisms. At first sight, this emphasis might suggest a continuation of traditional *connectionist* approaches to development such as that of Elman, Bates, Johnson, and Karmiloff-Smith (1996). However, Mareschal et al. (2007) suggest that connectionism has tended to view the child as a passive experiencer without an active or agentive role in his or her own learning. In contrast, they propose that their flavor of developmental theory—*neuroconstructivism*—allows for a stronger role for activity and bodily context in brain and cognitive development.

In line with this emphasis, Mareschal et al. (2007) define a representation as "an information state within the brain of the organism that contributes to adaptive behavior within a given environment" (p. 4). In this view, a consideration of neuroscience means that "representational states must be expressed through patterns of neural activity that reflect (to some extent) states in the world" and that "these representations may interact with, exploit, be constrained and enhanced by physical components outside the brain" (p. 5). This assumption is further reflected in the emphasis of neuroconstructivism on *partial representations*, a term that encompasses both the idea that information is not "stored" in one particular brain region and also that internal representations cannot be central, detailed copies of the world but instead allow the organism to utilize aspects of its environment to accomplish salient goals. The emergence of representations is, therefore, constrained by context dependence, which in turn operates through general processes of cooperation and competition between components and a temporal ordering of the emergence of functional units. From the neuroconstructivist perspective, the context dependence of partial representations stands in contrast to the more limited cognitivist notion of symbolic, acontextual representations (although Lickliter, 2008, raises the question of whether neuroconstructivism can really account for the problem of meaning).

Neuroconstructivism stands as an example of an approach that has taken a computational or information-processing perspective while at the same time engaging with the literature from developmental neuroscience. It is worth noting that the application of computational models remains a theme in other recent high-profile theoretical work on early cognitive development, although the specific connections to neuroscience are less clear. One example comes from prominent developmental approaches involving probabilistic models (Tenenbaum, Kemp, Griffiths, & Goodman, 2011). In employing hierarchical Bayesian multilevel models to model cognitive development, Tenenbaum et al. (2011) note that they "target a view between the computational and algorithmic levels: cognition as approximately optimal inference in probabilistic models defined over a learner's subjective and dynamically growing mental representations of the world's structure, rather than some objective and fixed world statistics" (p. 1284).

Probabilistic approaches such as that of Tenenbaum et al. (2011) have become highly visible in the literature on cognitive development, although key issues remain. Related questions arise about developmental proposals of a *rational unconscious* (Gopnik & Wellman, 2012) and the *rational constructivist* account (Xu & Kushnir, 2013), both of which are firmly grounded in probabilistic models. Echoing the issues faced by theories of cognitive development involving perceptual primitives (e.g., Mandler, 2004), these questions include how and whether the implicit representations of probabilistic approaches connect with experience at the level of the person or with symbolic representations at higher levels of consciousness (Müller & Overton, 1998). Another question about the emerging computational, probabilistic models of cognitive development concerns the nature of their connections with neuroscience, which as noted by Tenenbaum et al. (2011) remains a key challenge for future analyses. In investigations with adults, one line of research has attempted to reconcile features of brain function with probabilistic mechanisms (Friston, 2012), although developmental implications of these linkages have not yet been well explored.

Elaborating the scope and implications of Bayesian approaches has become a very active area of research in cognitive science (see Clark, 2013). However, from the perspective of this chapter, a further problematic omission concerns the role of the active, agentive organism in relation to processes of thought and reasoning. In the Bayesian account, the brain processes information, but on the embodied account that is developed in this chapter, information processing as well as meaning making cannot be fully encapsulated in the brain, but rather they are a function of the actions of the fully embodied organism. Thus, the organism as active agent in this embodied model both acts, which constitutes a prediction, and modifies its actions, which operates to reduce an error of prediction. This is closely akin to the Piagetian notion of the organism's assimilatory action, which predicts, and accommodatory action, which modifies the assimilatory structure, hence reducing the error of prediction. Although elements of this framework are visible in some contemporary probabilistic accounts (Friston, Mattout, & Kilner, 2011), a constructivist embodied developmental perspective might significantly inform such accounts.

Brain Development: Networks and Plasticity

Part of the emerging field of DCN is aimed at understanding the ontogeny of the brain, with a particular focus on the development of the cortex. Although it has a consistent basic structure, the mammalian cortical sheet is not uniform; rather it is characterized by areas that differ in terms of their cellular organization and their connectivity to other parts of the brain (Mountcastle, 1998). Key questions about cortical development include how the laminar (layered) structure of the human neocortex arises as well as how the cortical sheet becomes differentiated into cytoarchitecturally and functionally distinct areas (see Stiles et al., Chapter 2, this *Handbook*, Volume 2). Concerning the first issue, early work in developmental neuropsychology suggested that the development of the laminar structure of the cortex as well as the initial differentiation of cortical neurons do not appear to depend on sensory input to be established (Rakic, 1988). Johnson (2011a) suggests that one view of these processes would be to see them as occurring through processes of *intrinsic* cellular and molecular interactions, but not as the unfolding of a genetically predetermined plan. In line with this emphasis, Stiles and Jernigan (2010) note that "nothing in neural development appears to be predetermined" (p. 345), with all aspects of brain development involving an intricate temporal and spatial web of events entailing the coactions of the genome, the epigenome (Meaney, 2010), and cellular environments.

How the various major regions of the cortex develop and differentiate has been the focus of a great deal of research in developmental biology, some of which is outlined by Stiles et al. (Chapter 2, this *Handbook*, Volume 2). Although primarily the domain of developmental biologists, questions in this area have also been of particular interest to developmental cognitive neuroscientists because they present an ideal opportunity to explore the coactions of genes, cellular environments, and neural activity in the ontogeny of the human brain (Stiles, 2009). One starting point for these questions comes from a consideration of constraints on cortical organization. A comparative examination of brains across mammalian species suggests commonalities in the specialization of major regions of the cortex, such as the presence and relative locations of primary sensory areas (Krubitzer & Kaas, 2005). Indeed, primary cortical areas involved in somatosensation (area S1), vision (V1), and audition (A1) and that are defined by a topographic representation of sensory organs have been identified in all mammalian species examined thus far. Although these areas are positioned similarly across species, their relative size is extremely variable depending on ecological niche (e.g., bats have a particularly large amount of primary auditory cortex). Although this suggests some evolutionary constraints (see also Finlay, 2005), it is also clear that there is a great deal of plasticity during cortical development, in large part due to a key role for activity-dependent processes. As detailed by Karlen, Hunt, and Krubitzer (2010), there is an abundance of data from developing mammals indicating that activity in peripheral sensory receptors plays an important role in influencing the functionality, internal organization, size, and connectivity of cortical fields.

Johnson (2011b) presents two contrasting possibilities for how the apparent functional specialization of major cortical regions arises (see also Mallamaci, 2011). One is that the function of each area of cortex mainly results from intrinsic cellular and molecular factors, such that a biologically specified protomap is generated in the absence of sensory or neural activity. This model of development is sometimes termed the *mosaic* model of development as exemplified by the roundworm *C. Elegans*, which has various cell lineages that develop independently of each other. If such a deterministic model was applied to cortical development, the expression of particular genes in specific regions would allow new functions to emerge, with a resultant mapping between brain regions and particular cognitive functions, and specific abilities coming online as cortical areas mature.

The second possibility for the origin of cortical regions is much less deterministic than the mosaic model. According to this alternative, functionally different areas of cortex arise from a relatively equipotential sheet of protocortex that differentiates based on patterns of neural activity and sensory input. With respect to evidence for either model, the data suggest a middle viewpoint, such that graded patterns of gene expression create large-scale regions, which are then shaped by finer-grained interactions involving genes, epigenetic factors, cellular coactions, and thalamic input. For instance, the early development of cortical patterning is shaped by the coaction of differential gradients in various signaling molecules that lead to the initial differentiation of large-scale regions of the cortex (Sansom & Livesey, 2009). This initial patterning process in cortical development results in areas with properties best suited to certain broad functions (e.g., motor, somatosensory, visual). The specific functional characteristics of these regions then differentiate through activity-dependent processes, with the functions of these regions becoming more integrated over development (Krubitzer & Kaas, 2005).

This process of differentiation and integration is fundamental to Johnson's (2000) *interactive specialization* (IS) model of brain development in which cognitive functions are the product of emergent coactions among different brain regions. According to this view, changes in task performance are subserved through the developmental combination of cortical networks having different computational capacities. Although the result of this combination may give the appearance of specific brain areas as being specialized for processing specific kinds of stimuli, it hides a significantly more complex picture. This developmentally oriented realization provides an important rejoinder to much of contemporary cognitive neuroscience in adults (see Poeppel, 2012), and it has been strengthened by observations that a given brain region or neuroanatomical structure is often activated across multiple tasks and cognitive domains (Anderson, Kinnison, & Pessoa, 2013). As noted by Anderson, Richardson, and Chemero (2012), such findings also bring into question the related assumption in cognitive psychology that the mind can carved up into distinct, separable cognitive domains. Similarly profound notions have also been raised in the context of affective science, where problems with delineating discrete emotions and associated brain circuits have been noted (Lindquist & Barrett, 2012).

Within cognitive neuroscience, a shift away from the localization of cognitive functions in the brain has led to an emphasis on the complexities of brain networks (Sporns, 2011, 2014). As scientists working in this area, Bressler and Menon (2010) state:

> Much of our current knowledge of cognitive brain function has come from the modular paradigm, in which brain areas are postulated to act as independent processors for specific complex cognitive functions. Accumulating evidence suggests that this paradigm has serious limitations and might in fact, be misleading. Even the functions of primary sensory areas of the cerebral cortex, once thought to be pinnacles of modularity, are being redefined by recent evidence of cross-modal interactions. A new paradigm is emerging in cognitive neuroscience that moves beyond the simplistic mapping of cognitive constructs onto individual brain areas and emphasizes instead the conjoint function of brain areas working together as large-scale networks. (p. 277)

In many ways, the importance of brain networks as a *new paradigm* reveals the real promise of DCN, which is that developmental data can add an indispensable component to understanding the integrated functioning of these networks (Dekker & Karmiloff-Smith, 2011). Although much of the study of brain networks has focused on the adult brain, developmental considerations are clearly extremely important, and how networks emerge in the developing brain is currently the focus of increasing attention (Byrge, Sporns, & Smith, 2014; Collin & van den Heuvel, 2013; Hagmann, Grant, & Fair, 2012; Hwang, Hallquist, & Luna, 2013; Power, Fair, Schlaggar, & Petersen, 2010). In a related context, Johnson (2011b) has suggested that the IS framework is a useful way of viewing brain networks in the context of the development of behavior and cognition. According to this view, large-scale patterns of brain organization emerge through the activity of interregional interactions, and developmental processes involve changes in connectivity between brain regions, with network-level changes impacting the development of cortical areas on a smaller scale. Specific evidence for the IS model comes from a variety of findings about brain activity becoming more focal with increasing experience with particular kinds of stimuli (Johnson, 2011b).

This emphasis on the shaping of cortical networks through experience also implies a degree of *plasticity* in cortical tissue, such that a brain region could potentially develop different functions based on the coaction of cortical tissue and input rather than the location of the brain region per se. Relevant studies in this area have examined the sequelae of transplanting or rewiring certain cortical areas (usually primary sensory areas) in early development. In one well-known example, Sur and colleagues induced rewiring in juvenile ferret brains so that visual input was projected to typically auditory regions of the cortex (see Sur & Leamey, 2001). The relative immaturity of visual connections at birth in the ferret meant that the auditory nerve could be stopped from entering the thalamus, after which the optic nerve innervated both visual and auditory cortex. The result of this rewiring was *cross-modal plasticity*, as shown by the development—in what would typically be part of auditory cortex—of a pattern of organization and responsivity that usually characterizes neurons in the visual cortex. Sur's work is an example of what Hurley and Noë (2003) termed *cortical deference*, such that the function of cortical tissue can be shaped according to the type of input (e.g., the modality) received. This deference may be particularly strong in early life, but it should be noted that cross-modal pathways play an important role in the adult brain (Calvert, 2001). Although some of these pathways may be apparent in naturalistic activities and tasks, others can be "uncovered" in adults through experimental manipulations of the availability and patterning of information across different modalities (Merabet et al., 2007).

The findings above from the developmental neuroscience literature highlight the significance of neural activity in the differentiation of major cortical regions. A dependence on activity has also been demonstrated *within* cortical regions, as evidenced by classic animal work examining plasticity in emerging cortical maps of somatosensory space. One example comes from research in rodents on the development of whisker barrel fields, which receive input from individual whiskers and which form a cortical map of sensory space. If one whisker is removed in early development, the corresponding barrel field does not emerge, and neighboring fields will take over the space (Loos & Woolsey, 1973). Although this again suggests a role for early sensory experience, evidence has shown that within somatosensory cortex, the potential for reorganization also remains present across the life span. One well-known example of later-occurring reorganization comes from an examination of adult macaque monkeys following severing of afferent connections along the pathway from spinal cord to primary somatosensory cortex (Pons et al., 1991). This work demonstrated that areas of somatosensory cortex corresponding to a particular limb can begin to process input from adjacent cortical areas (e.g., corresponding to the face) following deafferentation of that limb.

In humans, research on phantom limbs has also demonstrated the plasticity of somatosensory cortex, and it has illuminated additional complexities related to changes in qualitative experience following the loss of limb function. Sensations of a missing limb sometimes remain even when the relevant area of somatosensory cortex has been innervated by neurons from adjacent areas (e.g., the face area). In such cases, stroking of the face can result in the experience of the phantom limb also being touched (Ramachandran & Rogers-Ramachandran, 2000). Hurley and Noë (2003) suggest that this finding is an instance of *cortical dominance* in which qualitative aspects of the prior characteristics of a cortical area are retained after the rewiring of cortical connections. Developmental data have added a fascinating layer of complexity to this area through investigations of aplasic individuals who were born without a particular limb (or without multiple limbs). There is evidence that at least some aplasics experience phantom limb sensations (see, e.g., Brugger et al., 2000), which has provided support for conjectures concerning the origin and development of what could be termed the *body schema* (Gallagher & Meltzoff, 1996). This construct refers to sensorimotor representations of the body that guide actions, or what Gallagher (2005) terms a "system of sensory-motor capacities that functions without awareness or the necessity of perceptual monitoring" (p. 24). As such, the body schema is distinct from the concept of the *body image* that refers to more conceptual, consciously accessible aspects of bodily awareness (for discussion, see de Vignemont, 2010).

Early Experience and Brain Development

As outlined above, one central question in early brain development concerns the balance of constraints on cortical development and a role for activity-dependent plasticity. With the field of DCN, this question relates to attempts at delineating the ways in which *experience* is a factor in the development of brain and behavior. For example, Johnson (2011a) distinguishes between three ways of considering the role of experience:

1. *Innate* (i.e., biological) factors refer to interactions that occur *within* the organism at the level of the internal cellular environment and that are relatively insensitive to the external environment.
2. *Primal* factors refer to interactions between the organism and aspects of the environment that are species-typical (i.e., reliably present) such as the presence of patterned light or gravity.
3. *Learning* refers to life-span interactions between the organism and unique aspects of its environment.

As noted later in this chapter, any discussion of the role of experience requires the recognition of *experience* as a wider concept that represents the coaction of the action of the organism and the action of the environment (e.g., environmental stimulation). In some contexts the focus will be on the organismic activity, while in others it will be on the external environment (Overton, 2010). In the following discussion the focus is on the action of the external environment.

One area of developmental science where related questions about early experience have been the focus of much discussion concerns the effect of early adversity on brain development. As part of this wider debate, recent decades have seen sustained interest in the relation of early adverse rearing experiences and later psychological outcomes, with a recent focus on whether the impact of such early experiences is mediated by changes in the development of particular neural structures or brain networks.

In the mid-20th century, the dominant view of early experience was skewed toward the primacy of early adversity in having long-lasting and often irreversible effects (for reviews see Brim & Kagan, 1980; Kagan, 1998). However, consistent with wider changes across psychology, the 1970s saw a move toward less deterministic approaches in the study of early experience and its impact on behavioral development. Viewpoints emerged that emphasized change and plasticity of behavior across the life span, in part based on more dialectical models of human development (Riegel, 1976; Sameroff, 1975; see also Kuczynski & De Mol, Chapter 9, this *Handbook*, this volume) as well as descriptions of individual recovery from early adverse conditions once those conditions had been remediated (e.g., Clarke & Clarke, 1976).

This questioning of persistent effects of early experience was modified in the 1980s and 1990s by increasing evidence relating early adversity to later psychopathology (for review, see Rutter, 1999). In contrast to earlier deterministic approaches, this body of work in the emerging discipline of developmental psychopathology showed an increasing awareness of the heterogeneity of the effects of early adverse experience, both within and between individuals (Cicchetti, 1990; Sroufe & Rutter, 1984). The work of life-span developmental psychologists also contributed to this awareness, particularly concerning the importance of intraindividual change (Baltes, Lindenberger, & Staudinger, 2006).

The past two decades have also seen increasing interest in the role of neuroscience data in studying the relations between early adversity and later outcomes (Cicchetti & Curtis, 2006; Cummings & Valentino, Chapter 15, this *Handbook*, this volume; Gunnar, 2003; Hostinar & Gunnar, 2013; Mirescu, Peters, & Gould, 2004; Nelson, 2000; Pollak, 2005). The origins of this interest are partly founded in work on the neural changes accompanying manipulations of early experience in various mammalian species (e.g., Rosenzweig & Bennett, 1996) including maternal separation (e.g., Levine, 2001; Polan & Hofer, 1999) and the effects of natural variation in maternal behavior (e.g., Meaney, 2001). This comparative literature has been particularly influential in shaping current research and theory on early experience and neuroscience in humans, particularly in the realm of social and emotional development. One illustration is the work of Greenough, Black, and Wallace (1987), whose constructs of experience-expectant and experience-dependent processes are based in the comparative literature and are closely related to contemporary discussions of early experience and brain development. Indeed, the levels of primal factors and learning outlined by Johnson (2011a) are quite similar to these two constructs.

Bearing a close resemblance to the concept of critical periods, experience-expectant models posit that appropriate stimulation within a specific period is required for species-typical development to proceed (Greenough et al., 1987). The expected experience is usually characterized as having features with survival value that would be common to all individuals in that species. For example, the brain “expects” to be exposed to patterned light, without which the visual system will not develop normally. Thus, the typical consideration of experience-expectant programming is that development is likely to be permanently and adversely affected when exposure during a critical period is outside the typical range of environmental variation, with subsequent exposure to typical environments having no effect. As with critical period models, individual differences in outcome are not expected or considered, because all individuals would be equally affected by the adverse experience.

Much of the work on experience-expectant models has been conducted with animal models, with effects resembling critical periods being documented for certain aspects of behavioral development in various species, including birdsong in oscine songbirds (e.g., Nottebohm, 2005) and auditory localization in the barn owl (e.g., Knudsen & Knudsen, 1990). Such investigations have often involved examination of the neurobiological systems involved, as in the classic work on critical periods for the development of ocular dominance columns in mammalian visual cortex by Wiesel and Hubel (1965). This work also showed that in contrast to partial deprivation that provided aberrant sensory input, behavioral and anatomical changes resulting from complete deprivation (i.e., the complete absence of any stimulation) were more readily modified by the later restoration of typical sensory input. This finding supports the expectancy aspect of experience-expectant plasticity, and suggests that if no relevant input is present, the offset of critical periods may be extended in time (see Hensch, 2004; Knudsen, 2005). This latter effect was originally demonstrated by Moltz and Stettner (1961) who in line with Schneirla (1959) rejected the simplistic notion of fixed, age-based critical periods.

In contrast to the focus on critical periods that is connected to the construct of experience-expectant processes, experience-dependent processes optimize “individual adaptation to specific and possibly unique aspects of the individual organism’s environment” (Black & Greenough, 1986, p. 14). For example, the brain does not “expect” the child to develop a specific vocabulary, which is dependent on observational experiences. Experience-dependent processes place an emphasis on continued plasticity and individual differences. Instead of stressing the need for particular experiences to be present in a specific time frame, experience-dependent processes involve sequential dependencies such that mastering one skill is dependent on the previous learning of other skills. In this sense, a focus on experience-dependent processes emphasizes the capacity for adaptation across the life span.

In addition to the constructs of experience-expectant and experience-dependent plasticity, a third construct that combines elements of both constructs has become increasingly visible in the literature on the biology of early experience (Marshall & Kenney, 2009). Founded in studies of the impact of the prenatal and early postnatal environment on later health outcomes (Barker, 1994), the concept of experience-adaptive plasticity has been proposed as another way in which early experience could exert persistent effects on brain and behavioral function (Rutter, 2002).

Models of experience-adaptive plasticity are closely related to the constructs of developmental programming or developmental plasticity, which emphasize individual adaptation to environmental signals present in early phases of development (Bateson, 2007). According to one prominent account of developmental plasticity, such signals influence the characteristics of various regulatory systems in the developing organism, with related implications for health and disease across the life span. This hypothesis has been explored quite extensively with regard to prenatal development (Coall, Callan, Dickins, & Chisholm, Chapter 3, this *Handbook*, Volume 3), particularly in terms of the consequences of fetal undernutrition. For instance, citing an association between low birth weight in term infants and a range of increased health risks throughout life, Barker (1994) proposed that the nutritional environment experienced by the fetus influences the homeostatic set points of various physiological systems. He further proposed that the prenatal environment may, under certain conditions, be mismatched with the postnatal environment such that these systems (which were established prenatally) cannot adjust. For example, consider an individual who experienced undernourishment in utero but then is exposed to a significant change in the nutritional environment (e.g., a large increase in caloric intake) postnatally. According to the developmental plasticity model, the programmed metabolic systems may be unable to adjust to this change, with an increased likelihood of later adverse health outcomes such as diabetes or cardiovascular disease (Barker, 1999).

Although the original focus of the developmental plasticity work was on the lasting effect of early prenatal nutritional deficiency, there is continued interest in the potential influence of other factors, such as prenatal maternal anxiety, on the development of brain systems related to stress regulation (e.g., Talge, Neal, & Glover, 2007; Weinstock, 2008). Related comparative work has focused on the lasting effects of the early postnatal caregiving environment in relation to the development and activity of the hypothalamic-pituitary-adrenal (HPA) axis (e.g., Meaney, Szyf, & Seckl, 2007; Seckl & Meaney, 2004). One line of studies in this area has shown that the pups of rat mothers who attend to them less tend to have deficits in various learning tasks in later development (Fenoglio et al., 2005; Liu, Diorio, Day, Francis, & Meaney, 2000). One posited physiological process linking the early experience of rat pups and later outcomes is the epigenetic modification of regulatory genes involved in the stress response (Cameron et al., 2008; Champagne & Curley, 2009; Meaney & Szyf, 2005). These effects have been framed as a form of experience-adaptive plasticity, with deficits in the early caregiving environment acting as a signal triggering epigenetic upregulation of the stress response system in the offspring (Weaver et al., 2004).

The relation between early experience and epigenetic regulation of the stress response has been a focal point of interest in discussions of early adversity and brain development, with particular interest in whether the rodent work can be translated to the human context (Kaffman & Meaney, 2007; Roth & Sweatt, 2011). Related human work has suggested that variation in factors such as maternal mood during pregnancy and the experience of abuse during childhood is associated with epigenetic alterations in the regulatory region of a glucocorticoid receptor gene associated with stress reactivity (McGowan et al., 2009; Oberlander et al., 2008). Further notable findings from humans suggest that epigenetic modifications accumulate over the lifetime (Fraga et al., 2005) and also that differences in DNA methylation are apparent in monozygotic twins at birth, most likely as a function of differences in the intrauterine environment experienced by each individual twin (Gordon et al., 2012). Such findings have contributed to a high level of sustained interest in the potential of epigenetics to inform the study of early experience and brain development. However, practical options for examining the epigenome in relation to human brain function are still limited (Champagne & Curley, 2009) although recent work in developmental psychopathology has suggested the utility of assessing epigenetic markers in blood samples (Wang et al., 2012).

In contrast to the highly controlled nature of the comparative work, testing hypotheses related to the role of early adverse experience in the development of brain function in humans presents a variety of methodological and conceptual problems (Repetti, Taylor, & Saxbe, 2007). One such obstacle, concerning inferences about the persistent impact of early adverse experience, is that outcomes for children living in environments high in psychosocial risk could be due to the cumulative effects of adversity, rather than any special effects of early experience per se (Schaffer, 2000). Early adverse experiences during infancy often tend to be followed by adverse experiences during childhood, such that the effects of the early experience cannot be teased apart from the cumulative effects of experience over the entire time span. A related but often overlooked problem is that it is also difficult to show that a particular experience has greater effects on later development when it occurs earlier in life as opposed to at a later age. In this respect it is challenging to definitively show that the early environment has specific effects, rather than exposures that occur for a similar duration but which begin later (Ames & Chisholm, 2001; Bruer, 2002).

There have been various attempts to overcome these issues in developmental studies on early psychosocial risk (Fox, Levitt, & Nelson, 2010; Fox & Rutter, 2010; Gunnar, 2003). One strategy has been to examine situations in which a large discontinuity in a child's environment arises, such as adoption or entry into long-term foster care, following early experience in an adverse environment (O'Connor, 2003). In the case of children coming from severely deprived backgrounds, such a life change provides an opportunity to examine whether early adverse experience has persisting effects once the caregiving environment improves. A growing number of related studies have examined the development of formerly institutionalized children who were either placed into family care through international adoption (Hellerstedt et al., 2008; Loman, Wiik, Frenn, Pollak, & Gunnar, 2009) or who entered into foster care within their home country (Nelson et al., 2007). Through documenting the relations between early adverse experience and the development of brain and behavior (Nelson, Fox, & Zeanah, 2014), studies in this area are also relevant to wider questions of early intervention and social policy (Bakermans-Kranenburg et al., 2011; Groark & McCall, 2011; Gunnar, Bruce, & Grotevant, 2000; Millum & Emanuel, 2007).

Although neuroscience data are assuming an important place in the study of early adverse experience, many questions remain about how best to frame the role of such data (Marshall & Kenney, 2009). One such question concerns the translational gap between comparative and human work (Gottlieb & Lickliter, 2004). As mentioned above, this gap arises in part through the multifaceted nature of early adversity in studies of human development (Boyce, Sokolowski, & Robinson, 2012). A further concern arises from the fact that as psychological agents, humans construct and reflect on their own experiences in a way that other animals may not. A related issue concerns a growing literature in biological psychiatry concerning the impact of early stress on brain functioning (e.g., Anda et al., 2006; Bremner & Vermetten, 2001; Kaufman, Plotsky, Nemeroff, & Charney, 2000). Although such work has become a significant force in the study of early experience, it could also be argued that it downplays fundamental questions about agency and plasticity in human development (Lerner, 2002; Lewis, 1997; Lillard & Erisir, 2011; Nelson, 2011).

One further key issue in the study of early experience concerns the construct of experience itself. As mentioned earlier, much of the literature concerning early experience and brain development tends to take a particular view of experience as a distinct external influence on the developing brain (e.g., Perry & Pollard, 1998). This partly reflects the historical focus of neuroscience on a reactive view of brain activity as mainly reflecting responses to external stimuli (for discussion see Abrahamsen & Bechtel, 2012). However, in their framing of experience-expectant plasticity in the context of human development, Greenough et al. (1987) note that "we suspect that some types of 'expected' experience may rely largely on the infant to produce them" (p. 545). Such a suspicion is well-founded and is illustrated by classic work showing the necessity of self-produced activity for typical development (Held & Hein, 1963), with this work being later extended to humans by Abravanel (1968) and Birch and Lefford (1963).

A deeper consideration of the active role of the organism works against a further tendency that is prevalent in work on early experience, which is to pit the individual and their internal properties against an external environment. As is emphasized later, this split or dichotomous approach is not supported by integrative approaches in developmental science, particularly the relational developmental systems perspective (Overton, 2013, Chapter 2, this *Handbook*, this volume). This perspective has implications for reframing the study of early experience and brain development through its emphasis on experience as embodied action (Overton, 2006). In this reframing, the conventional view of interaction between the individual organism and its environment would be replaced with the notion of reciprocal bidirectional coactions (←→) across all levels of analysis (Gottlieb, 2007). With this in mind, the focus of this chapter now turns to embodiment as a way of moving beyond the split notion of individual and environment and other problematic dichotomies that have historically impeded the emergence of a truly integrative developmental science. This endeavor entails a coherent account of the development of body, brain, and mind as a differentiated and unified system, operating within a broader sociocultural system.

EMBODIMENT AND THE INTEGRATION OF LEVELS

The constructs of embodiment and embodied cognition have become the focus of interest and debate across psychology and cognitive science (Foglia & Wilson, 2013; Menary, 2010; Shapiro, 2011). Part of this interest comes from studies showing how cognitive processing and decision making can be influenced by bodily states, although as detailed below, this is only one aspect of what embodiment can entail (Overton, 2008; Stapleton, 2013; Wilson & Golonka, 2013). At a more foundational level, embodiment is fundamentally a rejection of the isolated, computational mind of cognitivism (Edelman, 1992). By locating, in a constitutive fashion (Rowlands, 2010), the brain in the body of an active organism, embodiment threatens the traditional distinctions between perception, cognition, and action that are essential to the cognitivist account. Although they have deeper roots (see Beer, 2008), embodied approaches have gained a good deal of momentum in recent years (e.g., Barsalou, 2008; Clark, 1998; Damasio, 1994; Gibbs, 2006; Glenberg, 1997; Overton, Müller, & Newman, 2008; Rowlands, 2010; Semin & Smith, 2008; Thompson, 2007; Varela, Thompson, & Rosch, 1991; Wallace, Ross, Davies, & Anderson, 2007; Wheeler, 2005; Wilson, 2002).

Developmental features of embodiment are being increasingly considered (Lerner & Benson, 2013a, 2013b; Overton, Chapter 2, this *Handbook*, this volume; Overton et al., 2008), and an important component of this chapter concerns the exposition of those features as part of a move toward a more integrative developmental science that entails a coordination among psychological, developmental, and neuroscience concepts. Other discussions on embodied cognition and development appear to suggest that a role for embodiment may be particularly (or primarily) apparent in the study of infancy—echoing aspects of Piaget's theorizing about the sensorimotor stage of development (e.g., Daum, Sommerville, & Prinz, 2009). The premise of this argument is that as symbolic thought emerges, mental life becomes more "disembodied" or less dependent on aspects of bodily action. This premise is reflected in an emphasis on studies of physical and motor development in infancy as providing evidence for the importance of an embodied approach (Needham & Libertus, 2011). While this emphasis may serve an illustrative purpose (although see Longo, 2009), throughout this chapter the term *embodiment* refers to a much broader view. As Overton (2008) points out.

> Embodiment references not merely physical structures, but the body as a form of lived experience, actively engaged in and with the world of sociocultural and physical objects. The body as form references a biological [including a neural] standpoint, the body as lived experience actively engaged references a phenomenological or psychological person standpoint, and the body actively engaged in and with the world points to a contextual social, cultural, and environmental standpoint. (p. 3)

The Scope of Embodied Cognition

Within cognitive science there has been vigorous debate concerning the meaning and implications of an embodied approach to the study of cognition. In a useful summary, Kiverstein (2012) distinguishes between three current views: what he labels *body-conservatism*, *body-functionalism*, and *body-enactivism*. Although issues of development and neuroscience remain in the background, delineating the differences between these views is helpful for understanding the wider issues at stake in the area of embodied cognition.

For the *body-conservative*, the scope of embodiment is necessarily limited, because the body can only contribute to cognition by providing inputs to the brain and as the apparatus through which motor commands (from the brain) are executed. In many ways, such a position does not go far beyond the traditional cognitivist model in the sense that although it places the brain in a body, this brain is still a central processor and a clear divide between perception, action, and cognition is maintained. This divide is anathema to the *body-functionalist*, who sees embodied cognition as mounting a strong challenge to the cognitivist approach. For the body-functionalist, the body itself is understood "as playing a role in implementing the computational machinery that underpins our cognitive capacities" (Kiverstein, 2012, p. 740), with the proviso that this "computational machinery" does not need to be exclusively located in the brain but can be distributed across a wider brain-body-environment system. As suggested by this description, the account of cognition for the body-functionalist is still fundamentally a computational one; therein lies the contrast with the more radical position of *body-enactivism*, whose proponents tend to eschew a role for computational approaches in the study of mental life. The distinction between these two latter positions is an important one, and it is worth expanding on here in order to avoid potential confusion.

In defining the notion of computation as advocated by the body-functionalist, Kiverstein (2012) notes that: "Sometimes computation can be done through the recruitment and bodily manipulation of external artifacts; other times it can be done entirely within the head. This is a decision the brain makes on the fly, temporarily constructing short-lived coalitions of neural, bodily, and cultural artifacts when this is the most appropriate strategy for accomplishing a cognitive task" (p. 742). As noted by Silberstein and Chemero (2012), one early example of such a "wide" computational explanation came from Rumelhart and McClelland (1986) who discussed the act of solving math problems on a chalkboard: This act was seen as involving a cognitive system that went beyond the brain to include the chalkboard itself as well as the act of writing on the board. One contemporary advocate of wide computationalism is Clark (2008) who also put forward the thesis of the *extended mind* (Clark & Chalmers, 1998), which provides a prominent example of the body-functionalist perspective. According to Clark, cognition inherently involves computational processes, but the computational work of cognition is not always carried out solely in the head. Instead, this work can be spread across the wider brain-body-environment system through the recruitment of external objects and artifacts (see also Anderson, 2003; Hutchins, 1995; McClamrock, 1995; Rowlands, 2010; Rupert, 2010).

Although not as radical as enactive accounts of embodiment (see below), the views of the body-functionalist still present a distinct challenge to traditional notions of mental life and brain function. Indeed, the concept of the extended mind has not gone unchallenged within cognitive science, with reactions ranging from mild criticism about emphasis to complete rejection of the central premise. Along the lines of the former, Sterelny (2010) notes that the original view of the extended mind as put forward by Clark and Chalmers (1998) may understate the importance of broader cultural and environmental scaffolds for cognitive competence by emphasizing what he calls "highly trusted, individualized and entrenched, single-user resources" (p. 480). According to Sterelny, the extended mind construct occupies one corner of a much larger space in which "the most critical, mind-and-brain-shaping environmental supports for cognition are those cumulatively built, collectively provided tools for thinking" (p. 479). For the purposes of this chapter, this perspective allows a potentially important entry point for embodiment to be considered from a combination of cultural and developmental standpoints, which also remains an important area for future work.

A stronger challenge to the notion of wide computationalism comes from those who believe that cognitive processes are confined to the head (e.g., Adams & Aizawa, 2010; Fodor, 2009). On this reading, the challenge for embodied cognition is to show that processes going on outside the brain can be genuinely *constitutive* parts of cognition, rather than being inputs and outputs for the central processing taking place in the head. Fodor (2009) objects to wide computationalism on the basis of the argument that only internal mental states can have *underived*, intentional content—the so-called "mark of the mental"—that distinguishes them from any of Clark's examples, which according to Fodor can be seen as *derived* content. Although acknowledging that there is a slippery slope between underived and derived content, Fodor (2009) does not accept that the externalism of wide computationalism follows from the existence of this slope: In his view, internal representation will always be necessary to bridge "the gap between mind and world."

Although the criticisms of Fodor come from a cognitivist perspective that depends on a wholesale rejection of embodied cognition, a further challenge to the body-functionalist account has come from within the embodiment literature itself. This challenge comes from *body-enactivism* (or what is usually known as simply *enactivism* or *enaction*), which is the third view of embodiment outlined by Kiverstein (2012). Compared with body-functionalism, enactivism takes a more radical stance, which begins with the perceived inadequacy of any kind of computational account to provide a context of meaning for an organism. From the enactivist perspective, the body itself is a source of meaning, and this meaning can be experienced without a reliance on either traditional notions of internal representation or the more externalist (but still computational) leanings of body-functionalists such as Clark.

Meaning and Representation

As noted earlier, the problem of *making meaning* is one that has plagued computational approaches to mental life, and it is this precisely this problem that enactivists seek to solve. In framing cognition as a disembodied process occurring on an isolated computational device, cognitivism precluded any real consideration of meaning or meaning-making (Bruner, 1990). This omission echoes the central problem with 20th-century neopositivism, which required the meaning of a statement to depend on verification, even though any statement must already have some meaning in order to consider verifying it (Smythe, 1992). Cognitivism suffers from a similarly fundamental issue in the form of the *symbol grounding problem* (Harnad, 1990).

The symbol grounding problem refers to the issue of explaining how representational items come to have psychological meaning: As such, the formal properties of representations cannot be sufficient for their semantic properties. This problem is at the heart of arguments that were initially voiced by critics of the cognitivist focus of early work in artificial intelligence (Dreyfus, 1972; Searle, 1980). According to these critics, the disembodied nature of symbol-crunching computational approaches could not adequately address the question of how these symbols can be meaningful for the device on which their manipulation is being carried out. Early expectations for progress in artificial intelligence through a cognitivist framework were, therefore, misplaced because of the fundamental problem faced by an isolated computational system in "needing to impose a meaning on a meaningless Given" (Dreyfus, 2006, p. 45).

The enactive perspective attempts to solve the symbol grounding problem in a particular way. For many contemporary observers, enactivism became crystallized through the publication of *The Embodied Mind* by Varela, Thompson, and Rosch (1991). These authors drew on an eclectic mix of philosophy, biology, and psychology to propose a paradigm shift from the computational account of mind that had dominated cognitive science for the previous decades. One important influence on this way of thinking about embodiment came from phenomenology, particularly the work of Merleau-Ponty (1962), who drew on the notion that the body is not merely an object among other objects, but is instead the phenomenal body or "the situation from which our world and experience flows" (Johnson, 2008, p. 164). As such, the enactive approach frames the biological nature of what could be called *sensemaking*, such that the individual brings forth or enacts the world in which it exists, and sustains its identity as a self-organizing system (Thompson, 2007). This idea relates closely to the notion of *autopoiesis* as put forward by Maturana and Varela (1980) who framed living systems as being self-creating and self-organizing in a fundamentally different way to nonliving systems. From this perspective, living systems are not created or maintained according to externally imposed influences that assign meaning. Instead, living systems "construct themselves by generating the very boundary conditions necessary for the creation and maintenance of their self-organization" (Witherington, 2011, p. 79). From the enactive perspective, this stipulation not only allows living systems to be studied from the empirical viewpoint of self-creation, self-organization, and self-regulation, but it also enables the consideration of questions of agency, individuality, identity, and the construction of meaning.

At the center of the enactive approach is the recognition of the organism as an active agent that is tightly interconnected with its environment, such that the actions of the individual modify its relation to the environment, which in turn influences subsequent actions (←→). For enactivists, this concept of the *action feedback loop* is the basis of a dynamic system in which the boundaries between individual agent and environment cannot be definitively determined (Stewart, Gapenne, & Di Paolo, 2010). This assumption brings with it some strong suggestions. Advocates of what Chemero (2009) has termed *radical embodied cognitive science* propose that the dynamic coupling of organism and environment has two important implications for understanding cognition (see also Hutto & Myin, 2012). First, in contrast to the more constrained computational thesis of Clark and other body-functionalists, the radical tenets of enactivism necessitate that cognitive processes are distributed across the dynamic system that results from the nonlinear coupling of individual and environment. Second, according to these theorists, the formulation of the wider cognitive system as a dynamic system pushes against the need to invoke the concept of representation as an explanatory vehicle. As framed by Silberstein and Chemero (2012):

> Non-linearly coupled animal-environment systems are taken to form just one unified system. This removes the pressure to

> treat one portion of the system as representing other portions of the system—at least for many cognitive acts. That is, if the animal-environment system is just one system, the animal portion of the system need not represent the environment portion of the system to maintain its connection with it. There is no separation between animal and environment that must be bridged by representations. So extended cognition invites anti-representationalism. Of course, extended cognition does not entail anti-representationalism and many extended cognitive scientists are also representationalists. Nonetheless, anti-representationalism is made plausible by the non-linear connections between animal and environment one sees in extended cognitive systems. (p. 40)

For proponents of enactivism, it is these "nonlinear connections" that preclude a clear distinction between the organism and the environment, and which together constitute a wider system in a more fundamental sense than in the body-functionalism of Clark. In line with these suggestions, a good deal of empirical work from the enactivist perspective draws on *dynamical systems theory* (see Witherington, Chapter 3, this *Handbook*, this volume), which has its origins in the study of chaos and complexity from a mathematical perspective (see Molenaar & Nesselroade, Chapter 17, this *Handbook*, this volume) and which is increasingly visible in developmental science (Hollenstein, 2011; Molenaar, Lerner, & Newell, 2014). To proponents of enactivism, the attraction of dynamical systems methods partly comes from their ability to model the coupling of an agent's behavior over time with the changing state of the environment. Accounting for the coupling of organism and environment is inherent in the methodology of the state space and phase space models that have been the typical ways in which dynamical systems approaches have been applied (Partridge, 2011; see also Molenaar and Nesselroade, Chapter 17, this *Handbook*, this volume; Witherington, Chapter 3, this *Handbook*, this volume).

One key facet of dynamical systems models is that they do not rely on the manipulation of symbols or the need to invoke the concept of representation. Given this emphasis, it is perhaps no surprise that Chemero (2009) connects antirepresentationalism in radical embodied cognitive science to the work of Gibson (1979). Indeed, there are linkages between the Gibsonian perspective and certain threads of the enactivist perspective, such that the sensorimotor abilities of the organism are seen as the coupling between its nervous system and its ecological niche, or its network of available affordances, which are in turn altered by the activity of the organism. However, despite this association, it would not be accurate to equate an embodied approach with a Gibsonian perspective or with one particular flavor of dynamic systems models. As Witherington (2011; see also Witherington & Heying, 2013) argues, a complete understanding of self-organization entails seeing process (function) and organization (structure) as being complementary and indissociable. As further noted by Witherington (2011), this pushes against the Gibsonian notion of preexisting environmental structure that is apparent in certain flavors of dynamic systems theory, for instance that of Thelen and Smith (1994). According to Witherington and Margett (2011), enactivism could be more productively aligned with Piagetian constructivism, in that "meaning must be actively constructed and does not inhere in the world. . . . the world becomes meaningful . . . only in the context of an organism actively structuring it—assimilating it—and in turn actively accommodating to it" (p. 287). This sentiment would be endorsed by those dynamical systems practitioners who see constructivism as being fundamentally consistent with systems approaches to development (van Geert, 2012). As such, constructivism appears to be appropriate as a potentially productive emphasis for the application of embodiment to developmental science.

The Embodied Brain

Although there are clearly different strands of embodiment, to a greater or lesser extent they all challenge the notion that cognition can be neatly packaged into a level of information processing—or the level of mechanism in the framework of Marr (1982). As noted by Clark (2000), embodied cognition blurs the lines between Marr's levels, such that "our notions of what top-level task needs to be performed, and what kinds of algorithms are adequate to perform it, are deeply informed by reflection of details of bodily implementation, current needs, and action-taking potential" (p. 96). Embodiment is, therefore, particularly relevant to integrating neuroscience into the study of psychology, as a counter to the neglect of the brain that was a consequence of the information-processing interpretation of the cognitive revolution (see also van Dijk, Kerkhofs, van Rooij, & Haselager, 2008). Although cognitive neuroscience added a consideration of how cognitive processes might be implemented in the brain, embodied cognition can be seen as reframing the level of implementation beyond the brain, which then precludes the notion of a clear distinction between levels. As such, embodiment puts pressure on a tidy separation of levels, and understanding the relatedness or interconnections among levels becomes paramount.

As discussed by Marshall (2009), one of the key implications of embodiment for conceptualizing the relations among levels of analysis stems from its rejection of the assumption of a linear perception-cognition-action that is at the heart of the cognitivist framework. Relevant evidence from neuroscience comes from a growing body of work demonstrating that neural processing can be altered by varying the context in which stimuli are presented (Engel, 2010; Freeman, 2000). Contextual or top-down effects have long been discussed in psychology (e.g., in terms of expectancy effects) but are the importance of these effects for studying brain function can be clearly seen across the field of cognitive neuroscience. For instance, it has been found that parietal and premotor activity depends on action context (Graziano & Gross, 1998). In a related vein, there is a growing emphasis in cognitive neuroscience on the fundamental role of attention in modulating the activity of brain circuits involving in early sensory processing (Engel, Fries, & Singer, 2001; Reynolds & Chelazzi, 2004). This modulation even seems to apply in primary visual cortex (V1), which had previously been thought of being invulnerable to contextual influences (Kok, Jehee, & de Lange, 2012).

The sensitivity of early cortical processing to contextual factors provides further evidence against the cognitivist emphasis on the modular divisions between perception, cognition, and action. Evidence for this sensitivity is further buttressed by neuroanatomical findings that the visual system involves highly complex bidirectional pathways involving extensive back-projections from deep inside the brain to early sensory-processing centers (Felleman & van Essen, 1991). These back-projections in the visual system play a key role in attention to relevant events, as the person moves his/her eyes, head, and body to better characterize things in its environment that have been captured by low-level perceptual processes (Clark, 1998).

Considerations of attentional and contextual influences as well as of neuroanatomy lead to a very different model of the brain than would be suggested by the linear perception-cognition-action sequence described by classical cognitivism. In an embodied model of brain function, perception and action are naturally linked through the interconnectivity of the brain. Edelman (e.g., Edelman, 1992; Edelman & Tononi, 2000) has proposed that all brain networks have the dual properties of reentry (with complex bidirectional connections between outputs and inputs) and degeneracy (a lack of specialization of any individual neural pathway). The contrast between this account of brain function and the classical cognitivist account is related to alternative perspectives on the directional flow of causality. One perspective—associated with both stimulus-response psychology and cognitivism—understands causality as unidirectional, flowing from input to output. The second perspective—associated with embodiment—understands causality as relationally bidirectional (←→) and as entailing positive and negative feedback loops (Overton, 2013).

As an example, Engel (2010) describes an approach to the relations among context and patterns of brain activity that is particularly informed by considerations of embodiment. This approach emphasizes the dependency of neural activity on contextual factors, and the role of neural activity as supporting the organism's capacity for structuring situational contexts in a prescriptive manner. This emphasis leads to a novel view of the role of neuroscience data in the context of perception and action. Engel uses the term *directives* to refer to states of the wider cognitive system in its entirety, rather than the narrower focus that is associated with the concept of *representation*. From this perspective, objects in the environment are not understood as simply the represented targets of actions: Instead, environmental objects are part of the broader directive, or the state of the wider cognitive system. Importantly, neuroscience data can be readily accommodated in this framework, as patterns of neural activity can be understood as measurable traces that "support and partially implement directives as their functional roles" (Engel, 2010, p. 230).

The action-oriented nature of directives means that patterns of brain activity are closely tied with attention to relevant features of the environment, with a view to acting. Engel (2010) further suggested the value of developing a view of attention as a bias in sensory processing that is introduced by the selection of particular directives in the context of current or imminent action (see also Engel, Maye, Kurthen, & König, 2013). This turn toward action in cognitive neuroscience is a promising development, and one that has begun to be explored in more detail (Cisek & Kalaska, 2010). It should be further noted that such an action-oriented emphasis does not simply refer to action in the sense of overt movement or motor control, but is instead connected with the broader, constructivist notion of action in the sense of Piagetian operative intelligence.

Within Engel's model, the neural aspects of directives are highly complex, involving cell populations distributed across numerous brain regions that coact in a dynamic fashion. In the context of neural synchrony and binding, Engel further notes that "temporally coordinated signals from other regions can have a strong impact on assembly formation in sensory regions by modulating the local neural dynamics in a top-down manner" (Engel, 2010, p. 232). Attention then plays a key role in this modulation, with attentional and sensory processes being closely linked (Engel et al., 2001). Indeed, the neural signature of attention may be understood as increased activation of cortical networks related to the processing of task-relevant sensory information (Jones et al., 2010). Relevant studies with humans support the idea that attention modulates neural synchrony in the auditory, visual, and tactile system (Bauer, Oostenveld, Peeters, & Fries, 2006).

Embodiment and Social-Cognitive Neuroscience

As Overton (2008) points out, the unified study of embodiment entails at least three interwoven perspectives—the biological, the cognitive, and the sociocultural. Although much of the discussion above has focused on the cognitive perspective, the wide scope of embodiment clearly has repercussions for the study of the involvement of brain and body in social processes. This relates to what has become known as *social neuroscience* (Cacioppo et al., 2002) and the associated subdiscipline of *social-cognitive neuroscience* (Ochsner & Lieberman, 2001), which have become the focus of much research in recent years, including growing interest from developmental scientists (Marshall & Fox, 2006; Zelazo et al., 2010). Although a significant portion of this work has not directly explored the issues discussed above concerning embodiment, the literature is seeing a growing emphasis on embodied themes such as the *socially situated nervous system* (Coey, Varlet, & Richardson, 2012) or the *interactive brain* (Di Paolo & De Jaegher, 2012). From an enactivist perspective, Gallagher, Hutto, Slaby, and Cole (2013) argue that

> The explanatory unit of social interaction is not the brain . . . but a dynamic relation between organisms, which include brains, but also their own structural features that enable specific perception-action loops involving social and physical environments, which in turn affect statistical regularities that shape the structure of the nervous system. (p. 422)

Related work has included a call for the strengthening of a *second-person neuroscience* (Schilbach et al., 2013), although specifically how to proceed in this direction has been debated, with disagreements reflecting the various perspectives on embodiment and representation that were outlined above. In addition, Lewis and Stack (2013) note that the recent prescriptions by Schilbach et al. (2013) lack a thoroughly developmental perspective (for further discussion see also Moore & Paulus, 2013). However, this increasing focus on a neuroscience of social interaction promises to be an important area for developmental neuroscientists to explore in the coming years.

One area that has attracted a great deal of attention from those interested in the intersection of social interaction, neuroscience and embodiment relates to the discovery of *mirror neurons* in the ventral premotor cortex (F5) of macaque monkeys (di Pellegrino, Fadiga, Fogassi, Gallese, & Rizzolatti, 1992; Gallese, Fadiga, Fogassi, & Rizzolatti, 1996; Rizzolatti, Fadiga, Gallese, & Fogassi, 1996). Monitoring their activity using single-cell methods, it was shown that mirror neurons fired not only when the animal executed an action on an object (e.g., grasping a food item), but also when the monkey was observing the same action being carried out by another individual. Individual mirror neurons have not been shown to exist in the human brain; this may be, in part, because single-cell recording is not possible in healthy individuals (for a study in a patient population, see Mukamel, Ekstrom, Kaplan, Iacoboni, & Fried, 2010). However, a good deal of evidence has accumulated to support the notion of an overlap in the activation of certain brain systems between the production of action and the perception of others' actions (e.g., Hari & Kujala, 2009), with developmental considerations also being a key focus of interest (Decety & Sommerville, 2003; Marshall & Meltzoff, 2011, 2014).

In adults, evidence for overlaps in brain activation patterns between action observation and execution derives from a variety of neuroimaging techniques including functional magnetic resonance imaging (fMRI), magnetoencephalography (MEG), and electroencephalography (EEG), and the transient disruption of cortical tissue via transcranial magnetic stimulation (TMS). The basic contention from this work of an overlap in patterns of cortical activation between action perception and action production is fairly well established (Wilson & Knoblich, 2005). However, much debate has centered on the inferences that can be made about the function of this overlap (Gallese, Gernsbacher, Heyes, Hickok, & Iacoboni, 2011). Some have argued that it reflects the activity of a putative mirror neuron system (MNS) in humans, and that this activity plays an important role in the understanding of others' actions (Rizzolatti & Sinigaglia, 2010). On the opposite side of the debate, it has been argued that evidence for involvement of mirror neurons in action understanding is weak and that theoretical speculations have gone beyond the extant data (Hickok, 2009).

Among those who believe that mirror neurons may play some (direct or indirect) role in action understanding, the debate has concerned how and whether accounts involving mirror neurons can explain the attribution of mental states, which has traditionally been what theories of social cognition are aimed at explaining. As reviewed by Michael (2011), there are various models of MNS function, including the *direct matching* account of Gallese (2007), the *action reconstruction* approach of Csibra (2007) and the related account of Jacob (2008), the *interactionist* view of Gallagher (2007), and the *predictive* account of Kilner (e.g., Kilner, Friston, & Frith, 2007b). As an illustration of divergent views on the relation of mirror neurons to embodiment, the accounts of Gallese and Kilner are briefly outlined here.

Gallese (2007) views mirror neurons as contributing to a form of action understanding characterized by a form of prelinguistic, pretheoretical content originating in the relations between the organism and the world of objects that it inhabits. According to Rizzolatti and Sinigaglia (2010), this kind of attribution constitutes a form of action understanding, but not a mentalistic understanding as such. They suggest that "this understanding is completely devoid of any reflexive, conceptual, and/or linguistic mediation as it is based exclusively on the vocabulary of acts and the motor knowledge on which our capacity to act depends" (p. 125). As noted by a number of critics, a key challenge to this account is its ability (or inability) to handle the more conventional notion of intentionality (de Bruin & Kästner, 2012). According to other critics, the activation of mirror neurons during action observation could at best signal to the observer that the other person is acting purposefully, but cannot shed light on what the actor's intention is (Borg, 2007; Jacob, 2008). In turn, advocates of a role for mirror neurons in action understanding agree that mirror neurons cannot capture reasons, beliefs, desires, and intentions but still argue that a putative MNS could play a role in intentional attribution (Sinigaglia, 2008). However, according to others who generally favor a minimal, unconventional approach to social cognition, mirror neurons cannot be involved in action understanding, although a role in a nonmentalistic intersubjectivity may be granted (Hutto, 2013).

A contrasting view of mirror neuron system function comes from Kilner (e.g., Kilner et al., 2007b). In this account, motor system activity during action observation is part of the activation of a wider system that generates a prediction of the sensory consequences of the action that would be most likely to complete the inferred goal of the action. As noted by Friston, Mattout, and Kilner (2011), certain other accounts of a role for mirror neurons in action observation have emphasized a combination of forward and inverse models (e.g., Keysers & Perrett, 2004). In such accounts, mirror neurons are a product of associations between carrying out (including watching, hearing, and feeling) one's own actions and their sensory consequences, with these associations being established in the brain through a forward model. Via an inverse model, the observation of others' actions (i.e., sensory input from action observation) then activates the corresponding motor representations that had previously been paired with those actions through Hebbian processes. The activation of this inverse model can then be used to recognize the action and/or infer the goal of the actor (Keysers, Kaas, & Gazzola, 2010).

An associative account of mirror neuron function has also been espoused by Heyes (2010) who combined related ideas about forward and inverse models into a developmental model of *associative sequence learning*. However, the purely associationist accounts of Heyes (2010) and Keysers and Perrett (2004) differ from Kilner's account in which there are no inverse models that directly link sensory information about observed actions with the observer's motor representations. Instead, a different kind of mapping is accomplished through the suppression of *prediction error*. Building on the free energy principle outlined by Friston (2005), Kilner, Friston, and Frith (2007a, 2007b) have suggested that mirror neurons "emerge naturally in any agent that acts on its environment to avoid surprising events" (Friston et al., 2011). What takes this model beyond an associationist account is that it "depends on self-organizing, reciprocal exchange of signals among hierarchical levels of the brain's generative model" (Friston et al., 2011, p. 157). This account also has implications for theories of motor control, such that the need for an explicit motor control signal is removed—instead, movement is controlled by predictions (Adams, Shipp, & Friston, 2012).

The contrast between the viewpoints of Gallese and Kilner was presented here as an illustration of two of the various positions that have been advanced as explanatory frameworks for the functioning of a putative MNS in the human brain. The coming years will doubtless see continued exchanges and new ideas. Although much of the theoretical writings to date have only considered research with adults, there is increasing interest in developmental aspects. However, it is arguably the case that initial speculations about MNS development (Del Giudice, Manera, & Keysers, 2009; Gallese, Rochat, Cossu, &

Sinigaglia, 2009; Kilner & Blakemore, 2007; Lepage & Théoret, 2007) outstripped the available empirical evidence. Although more extant data are now available, many questions still remain about the existence and nature of neural overlaps between action perception and action production in early human development (Marshall & Meltzoff, 2011, 2014). These questions are wide ranging and include the need to go beyond simple associationist theories to recognize the more specialized nature of connections between action perception and action production (Boyer, Longo, & Bertenthal, 2012). Given that these connections likely originate very early in life, one key challenge for developmental neuroscientists has been to develop relevant techniques and protocols for use with infants. Because methods such as fMRI and TMS are precluded for use with these populations due to practical and ethical constraints, empirical research in this area has focused on the use of EEG methods, which are more amenable to use with infants and young children (see De Haan, Chapter 18, this *Handbook*, this volume).

Recent developmental research has focused interest on the *mu rhythm* in the infant EEG, which occurs in the alpha frequency range at central electrode sites overlying sensorimotor cortex. Mu rhythm desynchronization. (evidenced by a reduction in amplitude) is thought to reflect increased cortical activation through a decrease in synchrony in the underlying neuronal population (Pfurtscheller, 2003). Regional similarities in mu rhythm desynchronization have been used to infer an overlap in patterns of cortical activity during infants' execution of actions and their observation of similar actions (Marshall, Young, & Meltzoff, 2011; Southgate, Johnson, Osborne, & Csibra, 2009). Further work has begun to show the complexities of the mu rhythm response during action observation in relation to infants' action experience (Marshall, Saby, & Meltzoff, 2013; Saby, Marshall, & Meltzoff, 2012).

Of particular interest here are the theoretical challenges that arise from interpreting the data from EEG studies involving infants' observation and execution of actions. Although some of this infant EEG research has attempted to directly connect with the concept of mirror neurons and the associated debate about action understanding in adults (Nyström, Ljunghammar, Rosander, & von Hofsten, 2011), others working in this area have adopted different perspectives in order to address related developmental questions. For instance, Marshall and Meltzoff (2011) explore a series of issues related to how an extant behavioral literature—specifically on infant imitation—can inform the findings from developmental cognitive neuroscience (see also Marshall & Meltzoff, 2014; Saby, Meltzoff, & Marshall, 2013). These challenging issues relate to wider questions of placing findings from developmental neuroscience in the context of an existing knowledge base on social cognitive development (Meltzoff, Williamson, & Marshall, 2013).

In summary, the field of mirror neuron research stands as a particularly interesting example of the complexities of combining embodiment, development, and neuroscience. The relevance of this work for embodiment comes from the fact that by their definition, mirror neurons have been seen as a neural instantiation of linkages between perception and action, which are a key aspect of theories of embodiment. However, as can be seen from the discussion above, accounts of mirror neuron function have emphasized very different functional roles for these linkages, from the non-representational resonance of Gallese's account through to the radical Bayesian account of Kilner. Given the ongoing interest in questions related to the role of a putative neural mirroring system in human social cognition, the coming years will likely continue to see further elaboration of theories in this area—and it is hoped that developmental work will come to take center stage in this respect (Marshall & Meltzoff, 2014).

EMBODIMENT WITHIN A RELATIONAL DEVELOPMENTAL SYSTEMS PERSPECTIVE

Returning to the question of different levels of analysis, considerations of embodiment clearly complicate the convenient but simplistic notion from cognitivism that questions about neural functioning can be consigned to an inconsequential level of implementation. Yet although many would acknowledge that neuroscience should be integrated with psychology, how to conceptualize the role of neuroscience data continues to present a challenge. So how should the deep challenges of integration be met? Although the construct of embodiment (as outlined earlier) suggests one avenue, embodiment and related constructs such as that of the developmental system operate within the assumptions of a broader set of principles. In the following sections, these are discussed and elaborated as they participate in forming the integrative approach of *relational developmental systems*, which has been proposed as a scientific paradigm within which formulations of the interrelations among brain, body, and mind can be advanced (Overton, 2013, Chapter 2, this *Handbook*, this volume). The relational developmental systems approach is based on the integration of two metatheoretical streams: *Developmental systems* and *relationism*. What is broadly meant by each of these terms is now discussed, and the value of their integration is then emphasized as an important step toward a thoroughly integrative, developmental science that includes all levels of the organism's functioning—from the genetic through the neuroscientific to the psychological and sociocultural (see also Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume).

TOWARD AN INTEGRATIVE DEVELOPMENTAL SCIENCE

It is arguably the case that the emergence of a truly integrative, biologically informed developmental science of brain, body, and mind has been hampered by the inherent limitations of what Goldhaber (2012) labeled *the classic debate* concerning nature and nurture, which was manifested in various ways throughout the 20th century. This debate has deeper origins, but a rough sketch of the beginnings of its contemporary form—at least in North American psychology—serves to inform why more integrative views of biology, neuroscience, and mind have historically struggled to gain a foothold in mainstream developmental science. In terms of the project at hand, understanding the inherent limitations of the classic nature-nurture debate is relevant to building a developmental science that is fruitfully informed by biology more generally and neuroscience more specifically—and at the same time avoids the mistake of isolating neuroscience data on a "biological" or "nature" side of a false dichotomy.

Accounts of the origin of the contemporary nature-nurture or nativist-empiricist debate often begin with Francis Galton (Logan & Johnston, 2007). The influence of Galton and his associates such as Pearson and Fisher on early American nativism in the 20th century has been well documented. Combined with the translation of Binet's intelligence test, this influence set the stage for the political and social ramifications of eugenics. However, moving against this tide were empiricist voices such as the psychobiologist Zing-Yang Kuo (1939), who went on to be influential in the emergence of the developmental systems approach (see Honeycutt, 2011). It is notable that early attacks on nativism also came from embryologists such as Kuo and also Carmichael (1925), foreshadowing the influence of developmental biology on the emergence of more organismic, developmental systems perspectives.

From the start, the classic nature-nurture debate was characterized by split notions of additivity (Overton, 2006). The divide between biological and environmental explanations of behavior became particularly apparent in the 1930s through the advent of kinship studies and adoptive designs as well as intervention and deprivation studies. Across such studies, the same data could lead to quite different conclusions, depending on whether its interpretation was focused on consistency (as in the nativist emphasis on rank order correlations) or change (as in the empiricist focus on change on group means). Although these exchanges were inherently limited by the opposition of nature against nurture, sporadic critiques and calls for more sophisticated developmental approaches were made. Anastasi (1958) suggested that the wrong questions were being asked about behavioral development: Instead of asking "Which" type of factor was more important, or "How much" development was due to one factor versus another, Anastasi argued that the correct question to ask was simply "How?" That is, how do biological factors and how do environmental factors contribute to behavior and the development of behavior? At the time of her writing, Anastasi's call for a more nuanced, integrative consideration of process was, in fact, already being answered as part of the transatlantic exchanges involving Lehrman and Lorenz (see Lerner, 2002). Indeed, Lehrman's (1953) construal of experience in broad terms—following that of Schneirla (1949)—and the denial of the causal import of deprivation studies—laid the foundations for the establishment of a *general systems* view of development (Overton, 1973).

Despite the attempts of Anastasi and others to destroy the false dichotomy of nature versus nurture, the contentious debate continued. In the late 20th century, however, the influence of nativist population behavior geneticists began to be confronted by developmental psychobiologists who argued against the idea that behavior can be split into additive genetic and environmental factors (for discussion, see Partridge, 2011). In the typical behavior genetic approach, kinship studies, including those entailing the construction of heritability indices (see Bateson, Chapter 6, this *Handbook*, this volume; Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume, for critiques) are employed to avoid questions of process (Turkheimer, 2000), and developmental explanations are reduced to dividing the supposedly additive sources of between-group variation (gene, environment, and G $\times$ E additive interactions) across age (Scarr, 1992). For developmental psychobiologists, such as Gottlieb (1970, 1992, 2007), who took a developmental systems perspective, however, the issue of process is central. Thus, the questions asked as well as the methods employed by nativist behavior genetics are of a very different nature than those of the developmental systems or relational developmental systems approach (Overton, 2013).[1] From the relational developmental systems perspective, the central questions are not primarily about individual differences assessed through the division of additive variation across individuals. The questions for relational developmental systems investigators instead focus on process, and concern "intraindividual changes and interindividual differences in intraindividual changes across the life span" (Lerner & Benson, 2013a, p. 2).

Developmental psychobiologists such as Gottlieb rejected the metatheoretical assumptions of behavior geneticists and by extension, the additive methods that they employ (Overton, 2003). These objections have been outlined by various authors, including Griffiths and Tabery (2008, 2013) who highlight the fundamental and intractable differences in the assumptions of each approach (see also Bateson, Chapter 6, this *Handbook*, this volume; Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume). For developmental systems theorists, *interaction*—or more specifically *interpenetration* or *coaction*—characterizes all aspects of the developmental system. The fact that behavior genetics finds only statistical interaction effects of small magnitude is viewed as an artifact of methodology—because for the developmental psychobiologist (or relational developmental systems theorist), there can be no such thing as a main effect. The robust nature of the developmental system may produce what looks through the lens of the behavior geneticist's methods to be main effects, but such notions are meaningless to the developmental psychobiologist. For the latter, interaction effects cannot be understood through group means, and the behavior of the system can often best be understood by driving parameters outside of the normal range, which is primarily the domain of animal studies. These stipulations have been a constant source of frustration to behavior geneticists (Turkheimer, 2000).

One important source of evidence supporting a relational developmental systems perspective and strongly opposing a simplistic, split, or maturational (i.e., biologically determined) view of development comes from classic embryological work carried out in the early- to mid-20th century. This work was characterized by an organismic perspective, founded in the holistic notion that parts of a system can only be understood through their relation to the whole system, and that the behavior of a system cannot be predicted from—or reduced to—the simple aggregation of its parts (Pepper, 1942). Together with the earlier influence of von Baer (1828), the embryological research of Kuo (1939), Spemann (1938), Waddington (1957), and Weiss (1939) emphasized the hierarchical nature of development and showed how complex forms develop from simpler ones through the principles of differentiation and integration. As is argued below, much of the work in modern developmental biology has echoed and expanded on these themes, and provides strong evidence against more deterministic accounts. Two reasons for focusing on these biological influences here are that they can inform the study of brain development (and thus the development of brain-behavior relations; see Stiles, 2008) and that in many ways they relate to the current call for networks (i.e., systems) approaches in cognitive neuroscience (Sporns, 2011, 2014).

Organicism in embryology was a strong influence on parts of developmental psychology in the 20th century (Cairns & Cairns, 2006), with the *orthogenetic principle* of Werner (1948) and Piaget's (1977) concept of the *equilibration* process being partly based on evidence from the study of embryological development. More recently, Gottlieb's theory of *probabilistic epigenesis* emerged from this same organismic background (Gottlieb, 1992, 1998, 2007). As detailed elsewhere (e.g., Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume), probabilistic epigenesis is a central feature of the leading approach that formed the backbone of developmental psychobiology in the late 20th century. Probabilistic epigenesis is fundamentally an organismic, holistic principle that emphasizes the interconnected relational nature of the parts of the developmental system. From this perspective, conceptualizing these interconnections goes beyond simple notions of interaction to encompass a wider view of reciprocal, bidirectional, coacting, interpenetrating (←→) processes (Overton, 2013, Chapter 2, this *Handbook*, this volume).

As discussed by Gilbert and Sarkar (2000), the organismic framework within embryology did not go undisputed, despite its intrinsic appeal. One challenge for early moves toward organicism in embryology came from the allure of vitalism, which posited a mysterious, unknowable force

[1] As noted later in this chapter, *developmental systems* was extended to *relational developmental systems* (Lerner & Overton, 2008). As a consequence, in the following text, the term *relational developmental systems* is used whenever a distinction does not apply.

as the cause of developmental change. Hans Driesch, one of the pioneers of embryology in the late 1800s, rejected organicism and became a strong promoter of vitalism (Driesch, 1914). Despite such setbacks, in the principal challenge to organicism in the longer term did not come from vitalism but instead from genetic determinism, or the assumption that the genome is the fundamental causal agent in the development of a phenotype. In its stronger form, genetic determinism is the modern form of preformationism, in which the morphology and capacities of the organism are explained through their latent representation in the genes. From this perspective, development as a relational process is rendered irrelevant by the dominance of maturational (i.e., biologically determined), mechanistic patterns of gene activity.

Relational Developmental Systems

As noted earlier, the initial momentum toward an integrative account of the development of body, brain, and mind emerged from what could broadly be called developmental psychobiology. Since the early 1990s, related accounts have become increasingly prominent under the rubric of *developmental systems theory* (Johnston, 2010). In the context of developmental psychology, a foundational use of this term comes from the book of the same title by Ford and Lerner (1992), with this line of theorizing being more recently extended to *relational developmental systems* (Lerner, 2006; Lerner & Benson, 2013a, 2013b; Overton, 2006, 2010, 2013, Chapter 2, this *Handbook*, this volume; Overton & Lerner, 2012). The construct of the developmental system was also highlighted somewhat independently and in a different context by two philosophers of biology, Griffiths and Gray (1994). Each of these sets of authors drew on the work of Gottlieb and other theorists (e.g., Lehrman, 1970; Oyama, 1985) who had previously emphasized the importance of a systems perspective in the study of developmental process.

From a relational developmental systems perspective, the *explanandum*—what is to be explained—is, as stated above, how the individual organism becomes, and the *explanans*—the explanation—is the entire relational developmental system itself, which includes all biological and environmental resources available to the individual organism. This emphasis on the wider relational developmental system reflects what has been called the parity thesis, such that any one aspect of the system cannot be elevated in terms of its causal role (see Shea, 2011). On this view, parts of the relational developmental system can only derive their meaning from the context of the entire system (holism), and the explanatory power of one developmental resource cannot be elevated over another. The parity thesis relates to another fundamental tenet of the relational developmental systems approach, which is the rejection of a privileged role for genes (Bateson, Chapter 6, this *Handbook*, this volume; Ford & Lerner, 1992; Griffiths & Knight, 1998; Keller, 2010; Lickliter & Honeycutt, 2003, Chapter 5, this *Handbook*, this volume; Oyama, Griffiths, & Gray, 2001; Robert, 2004, 2008). Although relational developmental systems theorists acknowledge that genetic material is a necessary condition for cellular function, they emphasize that genes are not "unmoved movers" because they only become causally relevant through their involvement in the entire relational developmental system.

One related lesson from work in modern developmental biology is that specific genes do not solely determine major characteristics of bodily form such as segments, eyes, or wings. The same can be said for all bodily structures, including the brain (Stiles, 2008), and this principle extends to the development of more abstract characteristics such as symmetry or polarity (e.g., of hands, limbs, or eyes). These characteristics are not predetermined as an end result of gene expression, but instead arise through the organized activity of the relational developmental system (Minelli, 2009). Genes can be identified that are *involved in* the development of any bodily structure or characteristic, and changes to these genes—in specific temporal and spatial contexts—can impede or divert the typical course of development. However, the morphology of the brain and body clearly arises not through a highly specified genetic plan but through the reciprocal coaction of component parts of the developmental system.

Such findings from developmental biology have provided important insights into development as an epigenetic process that proceeds through reciprocal and dynamic coactions among coding and noncoding DNA, transcription and translation factors, the cytoplasm, and the intra- and intercellular environments more generally. From this perspective, the action and function of a gene depends on contextual factors, including temporal and spatial coactions with other genes and gene products. Related to these fundamental points, there have been important changes in the definitions of what constitutes a gene and the genome (Keller, 2011), and a reframing of the role of environmental influences on gene expression (Greenberg & Partridge, 2010; Slavich & Cole, 2013). Stiles (2009) notes the relevance of these issues for developmental psychology, particularly for its historical preoccupation with delineating the relative influence of inherited versus environmental influences. Indeed, the view from developmental biology more generally presents a vastly different picture than is suggested by the shopworn received formulations of the nature-nurture debate. The processes involved in the development of the nervous system provide a distinct rejoinder to simple claims of innateness (i.e., biological determinism—for discussion, see Stiles et al., Chapter 2, this *Handbook*, Volume 2). Instead, modern developmental biology has supported the organismic perspective of the early embryologists, whose perspective went on to influence the emergence of developmental psychobiology and developmental systems approaches.

The Relational Framework

One reason for an extended discussion of the relational developmental systems perspective comes from its rejection of simple notions of causation, a point which forces us to think closely about the relational ties among body, brain, and mind more generally. A related rejection is at the heart of the *relational* worldview (Overton, 2013, currently termed *Process-Relational* worldview; see Overton, Chapter 2, this *Handbook*, this volume), which has further implications for the questions about levels that are central to the current project. A worldview constitutes a metatheoretical framework "that both describes and prescribes what is meaningful and meaningless, acceptable and unacceptable, central and peripheral, as theory . . . and method . . . in a scientific discipline" (Overton, 2007, p. 154). Overton (2006, 2013) has written extensively on the contrast between a Cartesian-Split-Mechanistic worldview that imposes a split between levels, and a relational worldview that emphasizes their interdependence.

A central goal of this chapter is to promote the notion that adopting a relational framework can assist in addressing the questions about levels that currently constrain the creation of integrative approaches to the development of body, brain, and mind. To outline such an integration beyond that already accomplished in the discussion of embodiment, one potentially helpful approach is to note the similarities (and differences) between contemporary levels-based approaches and the explanatory framework proposed more than 2,300 years ago by Aristotle. In terms of its value for an integration of psychology and neuroscience, this approach not only allows us to frame current approaches to levels in historical context, but it also enables us to move beyond the separation of levels that is apparent in contemporary levels-based theories. In short, beginning with the multiple modes of explanation first put forward by Aristotle and placing those modes in a relational framework allows us to place the lessons learned about the embodied nature of neural processes into a broader, developmentally oriented paradigm in which the integration of different levels can be achieved.

In brief, Aristotle proposed that an explanation of a given phenomenon entailed the coordination of a set of four *aitia*, or what have become more commonly known as the *four causes*. Although Aristotle's four causes (efficient, material, formal, and final) are not frequently explicitly mentioned in contemporary psychological science (see, however, Blachowicz, 2012; Kuczynski & De Mol, Chapter 9, this *Handbook*, this volume; Overton, 2006, Chapter 2, this *Handbook*, this volume; Sokol, Hammond, Kuebli, & Sweetman, Chapter 8, this *Handbook*, this volume; Witherington, 2011, Chapter 3, this *Handbook*, this volume), they can be seen as foundational to many current approaches to different levels of analysis (Overton, 1991). Indeed, there are similarities between Aristotle's framework and the three levels of Marr (1982) that were discussed in some detail earlier in this chapter. To better understand the relevance of the four causes to contemporary theorizing about levels, a brief description of each is necessary. It should be noted that not all of the four causes map onto contemporary notions of causality, and as such it may be helpful to think of them as *explanatory factors* rather than causes per se (Caston, 2006).

1. *Formal* causes refer to *the way something is*—its form, structure, or organization.
2. *Efficient* causes refer to the forces or factors that move the object.
3. *Material* causes refer to what substances make the object.
4. *Final* causes are the end, goal, telos, or purpose of the object.

In modern usage, efficient and material factors are generally understood as mapping onto traditional explanatory causes, whereas formal and final factors can be seen as explanations related to the pattern, form, or organization of the object of interest (Overton, 2010, Chapter 2, this *Handbook*, this volume).

The efficient cause is perhaps the most intuitive of Aristotle's *aitia*, because it is closest to everyday notions of cause and effect. Efficient causes refer to observable factors or forces that effect change, are distinct from the object being acted on, and have a causal action that precedes the effect or outcome. Material causes are also observable factors, referring to the substance of which something is made. In contemporary formulations of levels of analysis, the material cause may correspond to the level of neurobiology (or to Marr's level of implementation); although as is discussed later, this mapping is not quite as straightforward as it might initially appear.

Formal and final pattern explanations are more abstract than efficient or material causes, but are no less essential for understanding. They are reasons or principles that provide intelligibility to the object and its evolution and, hence, intelligibility for the other types of explanation. Formal and final explanations are therefore necessary complements to efficient and material causes. In particular, the central importance of the formal and final explanation comes from their providing a structure or pattern through which the other kinds of explanation can be understood. As such, the formal explanation is central to any kind of systems explanation, such as the body-brain-environment system that is the foundation of the embodied approach. Furthermore, the final explanation is central to any kind of relational developmental system.

As noted by Aristotle, the four explanatory factors cannot be considered in isolation but must be seen as being inextricably interwoven in a relational sense. In this respect, the Aristotelian framework exemplifies a pluralist notion of cause, in which "no one perspective constitutes the gold standard of understanding: only when brought together as four unique vantage points . . . will the phenomenon be open to complete understanding" (Witherington, 2011, p. 73). It is this reciprocal relation that underlies discussions of *circular* and *downward* causality (Witherington, 2011; Chapter 3, this *Handbook*, this volume). Each new level of organization constitutes a dynamic system that contextualizes earlier levels and forms the base for later levels within which efficient and material causes operate (Overton, 2010). Of central importance here is the observation that although one can say the organization (form) and direction (final) of a system comes into being through efficient and material causes, these mechanical causes themselves presuppose an organization and direction.

Through its emphasis on the interconnected or relational nature of different kinds of explanations, Aristotle's framework appears to be particularly relevant to tackling the challenges related to the questions about development, neuroscience and levels that are at the heart of this chapter. So how might Aristotle's four causes be applied to look more closely at what is meant by different levels of analysis in developmental science, particularly with regard to questions about neuroscience? One signpost comes from the work of Overton (1991) who places the formal and final factors at a *competence* level, in contrast to a level of mechanisms or *procedures*, The latter can reflect Aristotelian efficient causes, when these causes are understood as relationally bidirectional and, hence, processes. The material cause is less prominent in Overton's framework, but can be viewed as a level of *hardware* that is similar to the implementational level of Marr (1982). Taken together, the levels of competence, procedures, and hardware are somewhat analogous to the computational, algorithmic, and implementational levels of Marr. However, what sets the framework of competence, procedures, and hardware apart concerns the relational interdependence of the levels and the central place of *development* for understanding this interdependence. These considerations can be sharply contrasted with the independence of the levels in the theorizing of Marr—whose work also mentioned very little, if anything, about developmental considerations.

The framework of competence and procedures originated in dual-systems approaches to the development of reasoning (Overton, 1991). There is some heterogeneity in how different theorists conceptualize dual systems, but in general the basic distinction is between an abstract, reflective, rule-based, propositional system for cognitive processing (closely related to the construct of competence) and a contextualized, associative system (i.e., the procedural level). Developmental aspects of this model have been discussed in some detail by Ricco and Overton (2011), who proposed that the procedural system can be seen as an early established, highly efficient but inflexible system, which operates in the context of a later developing, more flexible competence system. Ricco and Overton (2011) also discussed the similarity between the competence-procedures framework and other dual-systems approaches to the study of cognition such as those from Kahneman (2011), Stanovich (2009), and Tversky and Kahneman (1974) although none of these authors include much consideration of developmental factors.

In the theorizing of Overton (1991), the construct of *competence* reflects top-down design features of the system being explained, or the structure or organization that drives the activity of the system (i.e., the competence system like all self-creating, self-organizing systems is spontaneously active). One basic assumption is that this form of explanation—sometimes termed *pattern explanation*—is formulated at a level that provides a meaning context for a different but complementary level of mechanisms (i.e., the procedural level, which may also be considered to be *processes*). In turn, the mechanisms or processes serve to bring the formal level or the pattern explanation into being. This allows arrival at a relational frame of understanding in which both causal and pattern explanations are legitimized in scientific explanation, and the dialectic between them is appreciated and understood as fundamental to the scientific enterprise (Overton, 2006).

Although certain theoretical perspectives have included a key role for pattern explanations in the conceptualization of developmental process (e.g., most systems models, as well as Piagetian theory) much of contemporary developmental science has until recently tended to focus on mechanistic explanation to the exclusion of structural explanations. The background to this asymmetry is complex (see Overton, 2006, Chapter 2, this *Handbook*, this volume) and may be partly a consequence of the abstract quality of pattern explanations, which can lead to conceptual and empirical confusion. As discussed by Witherington (2011), such confusion is reflected in attempts to minimize or dismiss the importance of structural explanation, under the assumption that higher level forms have no causal powers, instead being inert epiphenomena arising from the activity of lower-level processes. A different but equally mistaken path is the reification of formal and final causes as entities that directly exert causal influence in the same way as efficient causes. Both of these conceptual confusions reflect a neglect of the fundamentally different but interconnected (i.e., relational) roles that formal and final causes play as explanatory factors (Witherington, 2011).

Even if the explanatory necessity of Aristotle's formal and final explanations is recognized, giving precedence to efficient causes still appears to be an easier option than a full consideration of both types of explanation. As noted by Wimsatt (2007), "we tend to be suspicious when we are called on to explain phenomena by going up a level" and that the dominance of reductionist methodology "implies a kind of explanatory priority, that things not explicable at a given level are to be referred to the next lowest level" (p. 216). However, the competence level cannot be ignored in the forlorn hope that structural explanation will become unnecessary if enough mechanisms or processes are described. Adopting such a position would present a conundrum that stretches far back in the history of philosophical and scientific thought, which is that every efficient cause cannot be caused by another efficient cause. Avoiding such pitfalls requires the understanding that mechanisms or processes at the procedural level must be organized in some way, and that in and of themselves, these processes or mechanisms have no context. It is this issue that brings the focus to competence as a different level of analysis, which as formal explanation becomes the *system* of a systems approach.

Neural Mechanisms[2] and the Mereological Fallacy

Given the preceding discussion, the question becomes how best to place neuroscience data in a relational framework. Neuroscience data make little sense in isolation and, as such, a level of hardware or implementation cannot meaningfully exist without relational ties to other levels. Sidelining a role for neuroscientific explanation (as in cognitivism) is clearly short-sighted, but on the other hand, integration presents a difficult challenge. Toward this goal, conceptualizing the relational ties between levels—and honing approaches to target cross-level questions—is of utmost importance for a successful integration of body, brain, and mind in developmental science. As noted earlier, the approach of framing neuroscience as occupying a causally neutral level of realization avoids having to specifically address the problem of the relation among levels (Miller & Keller, 2000). Although superficially reassuring, this approach is problematic and ultimately unsatisfactory. As an alternative, it may be tempting instead to try to accommodate neuroscience in two-level frameworks (e.g., of competence and procedures), without introducing an additional level of implementation or hardware. Such attempts relate to the usage of the term *neural mechanisms*, which reflects the identification of neuroscience data with the procedural level of mechanisms. However, through a relational lens, a level of mechanism, which in relational terms would be called *processes* (see Overton, Chapter 2, this *Handbook*, this volume) still requires a separate but interconnected level of organization (i.e., competence, or a systems level), and in this sense the isolated invocation of the concept of "neural mechanisms" remains limited in its explanatory power.

This issue relates to a larger problem in developmental science more generally, which is a tendency to highlight the explanatory role of mechanisms or processes in the absence of a consideration of what was described above as a competence level. One prime example concerns the

[2]See Overton, Chapter 2, this *Handbook*, this volume, for an extended argument that within any systems approach the term *mechanism* should be discarded and replaced by the term *process*.

use of looking time measures (which reflect subpersonal processes) to make inferences about social cognition in infants, prior to the manifestation of more flexible abilities in early childhood. Apperly and Butterfill (2009) discuss the potential utility that a dual-systems approach can play in resolving the related debate on infant social cognition. In a similar vein, Rakoczy (2012) noted that a full consideration of both systems (i.e., competence and procedures) is necessary for a full understanding of the development of theory of mind, and that any account that fails to do this is necessarily limited in its scope of explanation. Rakoczy further cautions that to confuse the two levels commits a "mereological fallacy" in which subpersonal processes—as properties of parts of a system—are equated with or substituted for personal-level properties of the whole system. Indeed, this very argument was originally raised by Bennett and Hacker (2003) in the context of neuroscience, such that an accumulation of neural mechanisms could not stand in as a full explanation of the properties of the individual.

ON THE DEVELOPMENT OF THE RELATIONAL SYSTEM

Returning to the competence-procedures framework (Overton, 1991), a consideration of the relational ties between levels naturally brings developmental considerations to the foreground (Overton & Dick, 2007). Competence as pattern can only be realized through the *developmental* course of reciprocal, bidirectional (←→) causes, with the procedural level of mechanisms (processes) only becoming coherent in the context of the pattern itself. This stipulation brings an awareness of the necessity of developmental science for relating different types of explanation. In short, *the puzzle of how levels are related to each other can only be solved in the context of developmental processes*.

From a broader perspective, it can be seen that when developmental considerations are added to an exploration of the relational ties between different levels, various fundamental questions emerge that lie at the heart of developmental science. How can new (novel) structures arise that are qualitatively different from the sum of their parts? How can activity at one level of explanation account for change at another (qualitatively different) level? How can the result of "doing more of the same" not simply be "more of the same"? It is worth noting that related puzzles underlie some of the most fundamental questions about the wider discipline of psychology itself, and it is worth briefly appreciating the scope of this problem. Although outside the primary focus of this chapter, understanding the relational ties of competence and procedures has distinct connections to the philosophical problems of intentionality, consciousness, free will, and agency. The shared question running through these problems fundamentally involves the relation between levels of mechanism (process) and meaning. Splitting and isolating these levels leads directly to the classic brain-mind or mind-body problem, which becomes an irresolvable mystery when viewed through the traditional lens of analytic philosophy and an associated Cartesian-Split-Mechanistic framework. By moving away from this paradigm, the transformative integration provided by a relational developmental systems approach offers a solution that is based on the fundamental premise that levels of mechanism/process and meaning cannot be split off and pitted against each other, but must be viewed as an indissociable complementarity.

Recalling again Aristotle's explanatory scheme, the level of competence (i.e., of formal cause) can be considered to be what something *is* (i.e., its meaning) in the abstract sense of a pattern or system (e.g., the visual system, the auditory system, the nervous system, or the system of consciousness). Simultaneously, competence is a *dynamic pattern* entailing both form (organization) and function (activity) as an indissociable relation. If the level of procedures or mechanisms (processes) is understood as the active means through which each new competence level comes into being, while simultaneously the competence level serves as a functional context for organizing the procedural level, it can be understood how the two levels of operate in a complementary fashion. From this viewpoint, the relation between competence (system, meaning) and procedures (mechanism-process)—as a dynamic tension in living systems—becomes the base of a truly developmental, constructivist perspective. Witherington (2011) operationalizes this tension as *circular causation* that recognizes both the emergence of form through process as well as the constraining, *downward* influence of form on process. The potentially transformative power of this fundamentally relational notion has been discussed by Overton (2006, 2010, 2013, Chapter 2, this *Handbook*, this volume), who has proposed that it can move us beyond the narrow confines of the nature-nurture debate and other dichotomies (e.g., brain versus mind) that currently constrain the wider discipline of psychological science.

A joint emphasis on development and circular causation leads to a concluding point and a future direction: The integration of the concept of the developmental system with the relational worldview has led to an understanding of the developing organism as "co-acting, co-developing processes functioning according to the reciprocal causality entailed by complex positive and negative feedback loops" (Overton & Lerner, 2012, p. 375). As such, the framework of relational developmental systems has been offered as a paradigm for the future of developmental science (Lerner, 2006; Lerner & Benson, 2013a, 2013b; Lerner & Overton, 2008; Overton, 2006, 2010, 2013; Overton, Chapter 2, this *Handbook*, this volume). As a paradigm, relational developmental systems recognizes the dynamic complexity of developmental processes and exposes the inadequacy of split approaches, which emphasize simple interaction and the elevation of one level of analysis over another. Living organisms are, therefore, understood as dynamic, adaptive, nonlinear, self-organizing, and self-regulating systems (Lerner, 2006; Lerner & Overton, 2008; Overton, 2006, 2010, Chapter 2, this *Handbook*, this volume). From this perspective, the notion of a system provides a formal explanation, with the directional features of adaptation and self-organization constituting a final pattern explanation (Overton, 2010). By further focusing on the reentrant quality of the connections among levels, relational developmental systems has at its foundation the concept of *development* writ large. In a complex system where the parts (or levels) are connected in an interpenetrating or coacting way, development is not simply about time per se, but instead concerns transformation and emergence (Overton, 2006). It is only through an awareness of this notion of reciprocal causality that an understanding can be reached of how the relational (and inherently developmental) ties between levels can provide a solid foundation for the study of brain, body, and mind.

CONCLUSION

The overall message of this chapter is that developmental science is at a key crossroads at the intersection of psychology, biology, and neuroscience. This location presents an opportunity to pursue an integration that can move beyond the dead ends that have been historically imposed by the Cartesian-Split-Mechanistic approach. One key feature of this integration entails embodiment, which integrates body, brain, mind, and social-cultural context. Sporns (2011) notes that one particular tenet of embodiment—the dynamic linkages of brain and body—may at first glance appear trivial. However, he reflects that the deeper implications of these linkages lie

> at the heart of what it means to be an autonomous organism. The essence of autonomy is self-determination—the actions of an organism within a physical and social environment continually perturb the rich web of dynamic interactions that make up brain and mind. (p. 324)

In line with the emphasis on embodiment in this chapter, Sporns (2011) further suggests that it is only through a networks (i.e., systems) approach that self-determination can be studied (see also Sporns, 2014). He further notes that the term *networks* does not solely refer to connections within the brain, citing the proposal by Ashby (1960) that coordination between parts of the brain need not take place via "some anatomically or histologically demonstrable tract or fibers" but can also take place as a result of the organism's own activity and through the effect that activity has on further neural activity. As emphasized throughout the current chapter, these considerations necessitate that neuroscience data can only be understood in the context of a wider developmental system that includes—but goes beyond—the brain itself (see also Byrge et al., 2014).

Looking ahead, this wider notion of networks does not negate the importance of the recent high-profile initiatives having the stated goal of mapping the patterns of connectivity within the human brain. These large-scale initiatives include the ongoing structural mapping of the human connectome, which has already generated a great deal of raw data (van Essen et al., 2013), as well as a proposal to map functional connectivity (The White House Office of the Press Secretary, 2013). The view developed in this chapter suggests that the interpretation of the vast amounts of data from these projects can only be meaningfully analyzed in the context of a relational approach. In addition, although it may appear to greatly add to the demands of what are already enormous challenges, developmental data are essential to understanding brain connectivity (Collin & van den Heuvel, 2013).

In discussing the need for complex systems approaches for understanding brain function, Sporns (2011) places the flurry of research on mapping brain connectivity in the context of another large-scale biological initiative—the Human Genome Project. He notes the initial but ultimately misplaced hope from some biologists that the data derived from the sequencing of the genome would reveal a complete understanding of human life. But although these hopes were dashed (for many of the reasons outlined in this chapter), Sporns notes that the genome project stimulated an awareness among biologists of the need for systems approaches in the study of how phenotypes arise. A similar opportunity is present for informing the understanding of brain function in terms of what can be gained by the recent large-scale brain mapping initiatives.

Finally, recent years have seen increasing emphasis on the inclusion of biological measures in developmental science. Although much of this research is carried out with concern for the theoretical issues involved, it is critically important that this turn toward the biological does not bring with it a limited view of neuroscience data as having elevated explanatory power than other kinds of data. As Overton (2010) has noted, to consider genes, neurons, or brain changes "to be sets of additive causes that drive development is to miss the point that these are all resources that the developmental system uses to grow" (p. 7). In this sense, work claiming to delineate "neural mechanisms" cannot be conducted in theoretical isolation from the concerns about embodiment and relational developmental systems as discussed in this chapter. In the context of this project, related considerations concern problems that can arise if brain processes are understood as mechanistically determined and changes in brain processes as the result of a split-off biological "maturation." Broadly, the argument presented in this chapter is that in order to forge a viable developmental science that includes the body, brain, mind, and the sociocultural world one must go beyond any idea of the brain as an isolated information processing device. The brain functions in the body of an active agent embedded within a wider developmental system and wider sociocultural context. This conclusion is by no means in opposition to an important role for neuroscience in the future of developmental science: Instead, it brings forth the hope of meaningful multilevel investigations that can move us toward integration rather than separation.

CONCLUSION 312
REFERENCES 314

The term *agency* refers to a person's autonomous control over his or her actions—but also much more than this, including a sense of what individuals can accomplish themselves and responsibility or ownership over one's actions. Common day-to-day intuitions suggest that notions of agency cut across a wide range of human experiences. References to agents and agencies abound in everyday language—from chemical agents to travel agents, from cleaning agents to government agents. What do these various uses of agency all mean, or even have in common? The present discussion of the development of human agency attempts to answer this question, as well as other questions and puzzles surrounding conceptions of agency. As it happens, there are no easy answers or solutions. Still, as a preview of where we hope to end up, the commonalities or continuities we see across various forms of agency—that is, chemical agents, travel agents, and government agents—whether they operate at the molecular level or at the macro, sociopolitical level, is that agents "get things done." That is, agents *act*, and by acting, they serve catalyzing and navigational functions in networks of relations, sometimes involving atomic particles, sometimes people, and sometimes nations.

Despite the importance that agency should hold in psychology, as the science of behavior, scholarly discussions of agency in the mainstream are relatively few and far between (for some notable exceptions, see Bandura, 1989, 2001, 2006; Brandtstädter 1998, 2006; Kuczynski & Parkin, 2007; Little, 2002; Martin, Sugarman, & Hickinbottom, 2010; Mascolo & Fischer, 2010, Chapter 4, this *Handbook*, this volume; McAdams, 2013). As a way to enrich these discussions and bring them closer to the mainstream, we must turn to everyday experience to clarify key features of our present account linking agency and action. We must also turn to other literatures outside of psychology, including philosophy and sociology, which have explored issues of agency. In philosophy, questions of agency have arisen in both metaphysics, with the issue of causality, and in moral philosophy, particularly with the problem of free will. In sociology, agency is typically contrasted with social structure, defining actions that originate in individuals against those that are rooted in societal impositions and constraints. From these diverse threads, our response to the initial question of "what do all these references to agency mean?" seems quite broad. It is so broad, in fact, that the inclination to comment on continuities across different forms of agency raises the additional question of whether there is anything distinctive or special about *human* agency. That is, on some accounts (e.g., Bidell & Fischer, 1994; Brandtstädter, 1998), the activities of any self-organizing system, human or not, constitute agency. But, as Witherington (2011) has cautioned, self-organizing activity "should not be confused with the deliberative, reflective agency associated with higher-order, emergent forms of psychological functioning like consciousness" (p. 81). Consciousness, and similarly robust forms of deliberative agency, connote a form of self-determination and control seen more typically in the psychological constitution of human beings (see Lewis, Chapter 11, this *Handbook*, this volume, on consciousness and agency). But even with this useful distinction between self-organizing agency and deliberative, reflective agency, the expressions of agency unique to human beings are quite varied. Agency can involve basic choices, such as an infant choosing where to cast her attention (e.g., Russell, 1996), or sophisticated narrative constructions of defining one's identity and marking the appropriation of particular normative values and principles (e.g., Blasi, 2005; McAdams, 2013; Sokol, Müller, & Chandler, 2013; C. Taylor, 1989).

Although the theoretical framework offered in our review is more of a sketch than a fully formed account, our premise is that *human agency is unique* insofar as persons develop a sense of self-awareness, or reflexivity, and personal meaning-making that is integrated with self-control abilities over the life span. Altogether—reflexivity, meaning-making, and control—give rise to a sense of personal agency and self-authorship that does not exist, or emerge, within other relational networks and social structures. The embeddedness of human agents in these structures and networks constrains, extends, and leads to new expressions of agency (Ratner, 2000). Reflexive agency itself develops within, and because of, these networks. Although agency is typically contrasted with some sort of limitation or restriction in the physical or social environment, here we turn to physical and social contexts less to describe the limits of agency and more to explain the *constitutive*, and thus, *developmental dimensions* of agency. In doing so, we adopt a relational view of agency (Furth, 1981; Macmurray, 1957; Overton, 2013) and work to move beyond the common *splits* or dichotomies (Overton, 2006, Chapter 2, this *Handbook*, this volume) in the literature, such as the *structure-agency* debate that has dominated sociology (e.g., Archer, 2000, 2003; Emirbayer & Mische, 1998; Giddens, 1984, 1991) or the *agency-communion* contrast seen in certain quarters of personality psychology (e.g., Bakan, 1966; Frimer & Walker, 2009; Paulus & Trapnell, 2008; Wiggins, 1991).

In this chapter, several important relational aspects of human agency, particularly those embedded in family, school, and community networks, are described as supporting the development of agency and self-determination in young people (Gestsdóttir & Lerner, 2008; Lerner, 2004; Lerner, Dowling, & Anderson, 2003; Mistry & Dutta, Chapter 10, this *Handbook*, this volume). These *social* structures go hand-in-hand with *psychological* structures constituting the emergence and development of human agency. The complicated work of defining agency, therefore, must capture its varied forms and expressions, extending from basic self-organization activities to richer psychological and cultural instantiations of self-authorship and shared meanings. Accordingly, the definition proposed in this chapter has three parts:

1. ***Biophysical agency*** constitutes the activities of a self-organizing system to regulate and sustain itself.
2. ***Psychosocial agency*** constitutes the deliberate, intentional acts of a self-aware system to determine a course of actions and construct meaning from them.
3. ***Sociocultural agency*** constitutes the dynamic patterns of shared values and norms of cultural systems, both past and present, to extend and limit (i.e., empower and constrain) individual and collective actions.

Before unpacking the different layers in this definition of agency, a more elaborate conceptual analysis and theoretical overview is needed to clarify the place that agency has had in the psychological literature. Given that this chapter is oriented toward developmental scientists, most of the emphasis is on making sense of the second part of the definition, or *psychosocial agency*.

OVERVIEW

Rather than being a coherent body of research, accounts of agency tend to be unsystematized and dispersed across scholarly literatures, in part reflecting disciplinary boundaries (Borstelmann, 1983), but also reflecting the lack of a common framework to tie various discussions together. In our view, psychology, particularly developmental science, will prove to be the nexus point and organizing structure to better unify these disparate accounts. Indeed, like other agency theorists, we see a crucial role in the constructivist roots of Piagetian and Vygotskian theory for investigating the dimensions of agency (e.g., Archer, 2000; C. Taylor, 1985).

Although psychological research has the potential to contribute to a coherent theory of agency, it can also contribute to important applications of the role that human agency has for social change. Or, to borrow from Giddens (1984), human agency is not simply about being able to act, but about being able to "'make a difference' to a pre-existing state of affairs or course of events" (p. 14). Understanding the nature of our own agency, as well as current limits in this understanding, can help us develop further the capacity for action in ourselves and in others, with relevance to social and moral development, as well as broader social movements. In this discussion we look to bolster treatments of the *capabilities approach* found in the work of philosophers and economic theorists such as Nussbaum (2011) and Sen (1992, 1999). This approach argues for *freedom* as the basis of development both at personal and societal levels, in much the same way that the developmental scientist, Lerner (2004), has described *liberty* as being at the heart of positive youth development and civil society. Educational institutions, in particular, hold a special place in promoting such freedom and liberty.

We begin our account, however, with an exploration of the roots of agency in physical causality and biological self-regulation. This section deals briefly with the work of Aristotle, before turning to conceptions of biological regulation that originate in embryology of the 19th century and its relation to evolutionary and developmental biology. At their core, the various conceptions of agency that are discussed throughout this chapter all require that an agent be *self-determining*. Although at a day-to-day level it may seem obvious that human beings can make volitional decisions, even merely choosing to look at one thing rather than another, self-determination has proven to be a major philosophical question in a universe that is, at least according to some materialist views, wholly determined and caused by external forces rather than internal choices and decisions. The question becomes especially relevant to psychology in considering what organisms are considered to be agentic, and at what point in the human life span agency is recognized.

From this starting point, we turn to questions of defining the opposite end of the spectrum: a fully developed form of moral agency. Before the emergence of self-determination in biological theory, philosophers faced the question of how to understand human freedom in a mechanistic worldview that seemed to be constricting the very possibility. The influential solution of Kant (1785/1959) was to carve out a separate realm for human autonomy. Kant's solution has shaped a great deal of modern thought on moral agency and expectations for the role of moral emotions, a sense of duty, and other important considerations. At the same time, his solution placed its own limitations on our understanding of agency that have set the stage for subsequent moral philosophy, as well as C. Taylor's (1985) writings on reflexivity—of the agent as self-interpreter and evaluator, able to reorganize in important ways an understanding of one's self and the world.

Next we explore the place of the agent in the social world, one filled with other agents and with social structures and institutions. In the sociological literature, the concept of *social structure* has often been set against individual agency. When we want to make something happen, what helps to achieve our goals, and what holds us back? The usual answer would be that the "*I*" makes things happen—with *my* ideas and *my* willpower, set against the constraints of society (e.g., laws and regulations) and the limits of my body. In a common way of thinking about the problem of freedom, with echoes in the philosophical literature, modern society and culture, and especially technology, bind us. And yet society and technology, as well as biology, are also what enables us to act and think.

After summarizing the backdrop of modern agency, we then turn to psychological and developmental questions. Some seminal thinkers, particularly Jean Piaget (Piaget, 1932/1965; 1936/1963; see also Russell, 1996) and Lev Vygotsky (Vygotsky, 1978, 1986; see also Valsiner, 1998), have adopted perspectives that reserve an important place for agency. Although this chapter does not offer a detailed account of either, we share the same constructivist impulses that these theorists have been shown to hold in common (see Bidell, 1988; Chapman, 1991; Tudge & Winterhoff, 1998). Broadly speaking, both the Piagetian and Vygotskian traditions begin with action and the active organism as fundamental to all development. Across the course of development, conscious reflection (Piaget & Inhelder, 1982; Piaget, 1977) and social communication (Vygotsky, 1986) increasingly play a role in the reorganization of action and in promoting the growth of agency (Piaget, 1974/1976a; Piaget, 1932/1965). After establishing this general outline, we turn to surveying several areas of developmental science that help clarify the nature of human agency and its origins.

Finally, we examine several practical implications of agency. Although the concept of agency has a clear kinship to psychological questions involving self-regulation and self-determination, it also shares important connections to questions of human freedom, social responsibility, and community or civic engagement (e.g., Lerner, 2004). Ratner (2000) has argued, “If agency has a social character that depends upon social relations, it is not intrinsically creative, fulfilling, or empowering. It only becomes so by creating social relations that will promote these characteristics” (p. 426). Accordingly, we argue that psychosocial agency is self-sustaining only insofar as people create and invest in the social and cultural structures that are necessary features of human agency. For human agency to flourish, development at the sociocultural level must foster participation, public debate, and democratic practices that empower individuals and create the conditions for social transformation (Alkire & Deneulin, 2009).

PHILOSOPHY OF THE ACTIVE ORGANISM

Agency is grounded in activity. But more than that, agency is grounded in self-directed activity. Although this type of activity is ubiquitous in our daily lives, its existence has been hotly disputed in both classical philosophical thinking and modern-day psychological theorizing. As we summarize later, the history of the idea of agency reveals a split between conceptions of a “physical” world, whether atom or brain, where activity is caused by outside forces, and a “mental” (and/or moral) world, where free will reigns (see Overton, 2006, 2013, Chapter 2, this *Handbook*, this volume). Agency is generally absent in the first view and ubiquitous, but impotent and removed, in the second.

Our goal is to rise above this debate and make self-directed activity the site of the emergence of agency. In our view, the psychological and philosophical work of *action theorists* such as Piaget and Vygotsky, and pragmatists such as John Dewey, who situate the growth and development of knowledge in the active organism, represent the best way forward in understanding agency. This means that developmental science has a particularly important voice in addressing issues of agency.

Why Agency Is Neglected

Given the many routine assumptions and everyday expectations that people hold regarding their own agentive abilities—formulating plans, making decisions, and committing to particular courses of action, to name just a few—one might expect to discover a wealth of information and research on human agency in psychology. This is not the case. As Sokol and Huerta (2010) have described, “talk of human agency in psychological circles . . . is the cocktail party equivalent of talking about religion or politics” (p. 46). Discussions of agency are relatively rare, and often strained, in the mainstream of psychology (for similar claims regarding agency’s neglect, see Frie, 2008; Little, 2002; Sugarman, 2007). Psychology’s neglect or even active aversion of agency appears to originate in its Cartesian foundations, which places a heavier emphasis on epistemic questions over problems of action (Martin & Sugarman, 1999; Overton, 2013, Chapter 2, this *Handbook*, this volume; Overton & Ennis, 2006). These issues are further compounded by narrow conceptions of causality drawn from the natural sciences, which restricts determinism to external causes and disavows self-organization (Bunge, 1959/1979). As Little (2002) has observed, the “dueling worldviews” that lie behind psychological theorizing form a central stumbling block in the exploration of agency. There is an overarching tendency to rely on a reductionist view of causes originating in singular structures, even while paying increasing lip-service to interactivism and relationalism (see also Bunge, 2000; Overton, 2013, Chapter 2, this *Handbook*, this volume; Overton & Ennis, 2006).

For much of modern psychology, just as for Descartes, the central problem has been to explain thought and its relation to the world, especially to *other minds* in the world. Problems of action have not been a central question in psychological research, and the relation between action and choice has not been extensively elaborated in the psychological literature. The central psychological problem has not been “how do I get this done?” but “how do I know what he or she is thinking?” As a result, the problem of agency, (i.e., the problem of acting in the world and interacting with others), has been subsidiary to the problem of other minds. We argue there needs to be a shift from the view of isolated Cartesian minds to one of action (see also Brandtstädter, 2006; Carpendale & Lewis, 2004; Heckhausen, 1999; Hobson, 2004; Mascolo & Fischer, 2010; Chapter 4, this *Handbook*, this volume; Overton, 2006, Chapter 2, this *Handbook*, this volume). In doing so, we join other theorists that, in the words of John Macmurray (1957), claim: "we should substitute the 'I do' for the 'I think' as our starting-point and center of reference and do our thinking from the standpoint of action" (p. 84). As Furth (1981) remarked, we must all come to recognize just how inescapable, even if only tacitly present, agentive questions are in many strands of research, particularly in developmental science.

We also acknowledge that accommodating agency into current psychological theories and frameworks is challenging. Our overriding argument is not that psychology has rejected the notion of choice, but rather the frameworks that have formed the operating context for theories, methods, and research in psychology make understanding agency difficult. When action—or behavior, as many psychologists default to saying—is explored, it is often from the perspective of an externally imposed determinism. The behaviorisms of Watson (1924) and Skinner (1974) are often held up as key examples of this deterministic view of causality. In most areas of psychology, action is not an inherent feature of living organisms, rather it is an outcome determined by forces outside the individual, such as environmental stimuli, or originating outside the individual's life history, such as in evolutionary or neuropsychological factors (e.g., Belsky, 2012; Bjorklund & Pellegrini, 2002; Ellis & Bjorklund, 2012; Greene & Haidt, 2002). The position adopted in this chapter, however, is that agency is epigenetic and relational in nature (e.g., Elder-Vass, 2010; Overton, Chapter 2, this *Handbook*, this volume; Turiel, Chapter 13, this *Handbook*, this volume; Witherington, Chapter 3, this *Handbook*, this volume). Agency cannot be found in the isolated motor neuron, the isolated social norm, or the isolated individual. Rather, in following a path of epigenesis, agency is a *constitutive* property of persons, or biological beings embedded in social relationships (Kuczynski & De Mol, Chapter 9, this *Handbook*, this volume; Martin & Sugarman, 1999; Mistry & Dutta, Chapter 10, this *Handbook*, this volume). Because agency is an embodied phenomenon (Overton, 2008, Chapter 2, this *Handbook*, this volume), it is a mistake to say that biological systems alone contain or define agency, just as it is a mistake to say human agentive capacities are granted solely through social regulation and cultural norms.

Levels of Reality and Causality

As the introduction suggested, the study of agency, whether human or otherwise, draws on different levels of functioning ranging from physical processes to sociopolitical structures. In our analysis of agency, three functional levels in particular—the biophysical, the psychosocial, and the sociocultural—coact and coconstruct human agency. The argument is that human agency is a psychosocial reality constructed from both "higher" sociocultural and "lower" biophysical constituents, while remaining irreducible to either.

Although it is common to distinguish different levels of functioning in any complex phenomenon (e.g., Marr's 1982 influential account of visual systems, or Dennett's 1987 well-known approach to characterizing mental life), much of contemporary science is dominated by reductionist tendencies to reveal more fundamental, or foundational, forms of reality by which to explain events and behavior (for discussion and critique of this tendency see Overton, 2013, Chapter 2, this *Handbook*, this volume). The direction such reduction takes—that is, whether explanations move "upward" to privilege sociocultural constructs or "downward" to prioritize biophysical constructs—often depends on where in the spectrum of the different social and natural sciences the investigation is first launched. Not surprisingly, social and natural scientists tend to select diverging analytic strategies. A baseball game, for instance, might be analyzed and described by a sociologist or anthropologist from a sociocultural level of cooperation and competition among groups of people. By contrast, the game might look very different to the physicist or physiologist who articulates a biophysical level of analysis involving the mechanical movements and muscle control that guide throwing, catching, and hitting a ball. Reducing the reality of the game, however, to either one of these descriptive levels captures only a partial explanation of what is happening when people play baseball or any other sport. Indeed *neither* the biophysical *nor* the sociocultural perspectives or stances offered in this case are sufficient. Socially constructed rules are just as real, and causally relevant, as muscle movements when it comes to baseball (for a similar argument regarding sociocultural practices and baseball, see Martin et al., 2010, p. 31).

In fact, games as different as baseball and chess can readily be seen as operating at multiple levels of reality at the same time. Neither the cultural conventions and social rules that stipulate how to play nor the biophysical mechanics embodied by a game's participants tell the whole story. Analysis at any one of these levels entails acknowledging the realities of the others, and ultimately, realizing the complex causal web involved in most human activities.

The same argument can be made for human agency. That is, it is possible to describe human agency solely in biophysical terms (e.g., Bargh & Chartrand, 1999) or solely in sociocultural terms (e.g., Ratner, 2000). Descriptions of this sort, however, tend to be reductionistic: they explain *away* human agency as a kind of ancillary or epiphenomenon (e.g., Wegner, 2003) with no substance and merit of its own, nor as a real causal force in human affairs. We take a different approach to agency. By acknowledging both the biophysical and the sociocultural as constitutive parts of human agency, we mean to promote a nonreductionistic account of agency that treats biophysical, psychosocial, and sociocultural levels as realities in their own right (see also Martin et al., 2010). These constitutive parts of human agency operate in a relational context and are not simply different descriptive "stances" that propose competing alternative analytic strategies. Agency, in various forms, is found at each of these levels and has real consequences for organized relational systems, particularly for humans.

The nested characteristics of these levels—the biophysical is nested in the psychosocial, which in turn is embedded in the sociocultural—has important implications for the kinds of causal relations that operate between the levels. Given the reductionist impulses just described, one might assume that because the origins of the biophysical level appear to temporally precede the other two this level must cause, or determine, what happens at the others. This assumption could be characterized as *biophysical determinism*. Conversely, because this nesting scheme also means that the sociocultural level broadly encompasses the biophysical and psychosocial, one might assume, on the other hand, that sociocultural phenomena are the root cause of these other levels. This assumption could be described as *sociocultural determinism*.

Neither of these two assumptions allows for a viable account of human agency. Nevertheless, although biophysical and sociocultural determinism run counter to the relational position for which we advocate, we must still make room for some kind of upward and downward causation between levels (see Witherington, 2011, Chapter 3, this *Handbook*, this volume). The way to prevent one or the other—upward or downward causes—from dominating an explanatory account of human agency, and thus leading to a form of determinism, is to imagine other ways of conceptualizing what *cause* means. Specifically, we must recognize that antecedent-consequent causal relations, or what some call *efficient causality*, provides only one of several ways of understanding causation (Bunge, 1959/2009; Marshall, Chapter 7, this *Handbook*, this volume; Overton, Chapter 2, this *Handbook*, this volume; Witherington, 2011, Chapter 3, this *Handbook*, this volume).

Biophysical Agency: The Disappearance and Reappearance of Self-Determination

Although our everyday intuitions about why and how people act make room for purpose and intentionality in describing causal relations, contemporary science has tended to view causality much more narrowly. Self-determination is often forced into an efficient causal account according to which one object or thing makes contact with another and propels it in some way. "Scientific orthodoxy," as Witherington (2011) has remarked, "carries with it a monistic view of all causation as temporal exchanges of energy from an antecedent to a consequent—in other words, as cause-effect relations" (p. 72). With few exceptions (e.g., Deci & Ryan, 1985; Marshall, Chapter 7, this *Handbook*, this volume; Overton, 2006, Chapter 2, this *Handbook*, this volume; Ryan & Deci, 2000), this view of causality has tended to dominate psychology. Historically, this has not always been the case. Conceptions of causality have shifted from a richer, though earlier classical account of causal explanation, to a less nuanced and far more restricted account that arose during the period of the Enlightenment.

The classical view is exemplified by Aristotle's four modes of causality: (1) *efficient causation*, which relates to our current understanding of causality through the application of external force; (2) *material causation*, the contribution of the materials in question; (3) *formal causation*, the contribution of the structure; and (4) *final causation*, the contribution of the goal or endpoint of events. Aristotle famously used the example of a sculptor to illustrate how these four modes of causality operate together. In the process of making a statue, the sculptor applies the strokes of the chisel (efficient causation), relies on the hardness of the marble (material causation), recalls the shape of the horse (formal causation), and has the goal of producing a thing of beauty (final causation). These four modes of causation were codeterminants of any process, and although efficient causation is the only to have persisted in much of neopositivistic contemporary scientific thought, the others have modern analogues as well (Overton, Chapter 2, this *Handbook*, this volume). For example, formal causation has echoes in the idea that DNA contains a *blueprint* for a phenotype—an idea we now know to be overly simplistic and misleading (see, e.g., Bateson, Chapter 6, this *Handbook*, this volume; Meaney, 2010; Misteli, 2013; Slavich & Cole, 2013). Similarly, material causation is often characterized in terms of items made of metal, plastic, or wood, whether baseball bats, canoes, or earrings. Each material has different respective properties that contribute to whether they break or bend, or are easy to lift, and so on.

Although we now know that final causes may be understood as regulative principles or principles of intelligibility providing *reasons* for the nature and functioning of the object or event under consideration (Overton, Chapter 2, this *Handbook*, this volume), what became especially controversial in philosophical and emerging scientific thought following the classical period was the role of final causation. In medieval religious thought, Aristotle's modes of causation were eventually assimilated into Christian theology and philosophy, particularly by St. Thomas Aquinas (1947). Final causation was attributed to the divine creator, the prime being, the unmoved mover, ultimate source of efficient causes, but not subject to efficient causation. As religious thought came under critical scrutiny during the Enlightenment, the question of final causation, where causes have some end or purpose, became especially unsettling and difficult to align with notions of a beneficent God. What was the final cause of the 1755 Lisbon Earthquake, which killed tens of thousands of Christian believers? This version of final cause was removed from other modes of causation and relegated to a more mysterious, transcendental sphere of existence, although aspects would persist in subsequent moral philosophy, as is discussed in the next section.

Gradually, with the emergence of the Cartesian-Split-Mechanistic worldview, efficient causation came to dominate Enlightenment thinking about causality, with other modes of causation, particularly final causes, deemed unscientific because they were not directly observable (Bunge, 1959/1979). Causality came to be restricted to the determination of an event by its antecedent: Event A causes Event B. This causality, which has been termed *Newtonian mechanical causality* (see Overton, Chapter 2, this *Handbook*, this volume; Prosch, 1964), is strongly connected to popular and philosophical conceptions of modern physical sciences. Causality is conceptualized as external to the object under consideration, with the implication that nothing is self-caused, most importantly, not human action. Agency is problematic for this mode of causation, because in acting deliberately, the agent seems to stand outside the efficient causal sequence.

The whittling away of different causal forms reached an extreme in the philosophy of David Hume (1888/1978), who posited that if causation is merely the succession of externally determined events, why is the notion of causation required at all? Hume's skeptical response was to relegate causality to an illusory mental and epistemological phenomenon, rather than a real property of the world. For our purposes, it is sufficient to note that both the doctrine of efficient causation and Hume's possibility of no causation at all exclude the possibility of agency. However, Hume's relegation of causality from an ontological category of things in the world to an epistemological category in the heads of the perceiver did have important implications for Kant's view of agency, discussed in the next section.

In the 18th and 19th centuries, along with improved microscopes, a very different interpretation of causation began to emerge within biological science. Experimental work demonstrated that embryos could be perturbed by external causes, and yet would go on to develop as typical organisms. This finding suggested that some sort of structuring feature was built into living beings (De Robertis, 2009; Gottlieb, 2002). Embryonic development showed that efficient causal events could be regulated by organisms themselves—as if reverting to a *formal* cause. Although these findings sometimes led to references to mystical vital forces, a more scientific account also emerged that saw life as *self-organizing* (Mahner & Bunge, 1997). This view was acknowledged and developed by some of the early pragmatist philosophers, such Charles Peirce, William James, and John Dewey, who attempted to infuse goals and choices into psychology (e.g., Dewey, 1896; Dewey & Tufts, 1908).

For complex reasons, this developmental story (see Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume) was overlooked in the so-called evolutionary *modern synthesis*, which joined neo-Darwinism and Mendel's genetics. Such simplistic causal thinking still can be located in some scientific quarters, particularly in anachronistic claims that genes *cause* behavior (see e.g., Dawkins, 1976; Tooby & Cosmides, 1990, 1992). Although modern biology has largely escaped misleading forms of causal thinking—creating, instead, room for complex causality and organismic self-regulation (Robert, 2004)—the doctrine of efficient cause is also still evident in many philosophies of science, persisting despite theoretical problems and evidence to the contrary.

Importantly, the biological view of self-organization provides a place for agency by highlighting how organisms are self-determining (Skewes & Hooker, 2009). External events form part of the causal system, but the organism as a self-creating, self-organizing system reopens the door for formal and final explanations. Self-organization itself provides a low-level starting point for the problem of agency (Bickhard, 2009; Witherington, 2014). Organisms are spontaneously active systems. To illustrate, Bickhard (2009) describes a bacterium on a sugar gradient as the basis for agency, as knowledge-in-action. If the bacterium fails to move up a sugar gradient, it eventually dies. But it may also incorrectly detect a sugar gradient in a toxic material, leading to death. This creates a place for evaluation, even if merely through monitoring one's own body. Intelligence-in-action emerges in the ability to monitor the world, making assessments, and fixing errors (Clark, 2013). Writ large, agency at this biophysical level also becomes a crucial dimension of evolutionary processes (Gissis & Jablonka, 2011; Gould, 2002; Jablonka & Lamb, 2005; Keller, 2010).

Psychosocial Agency: Self-Legislation and Self-Interpretation

Although modern biology has resuscitated the notion of self-determination, for the better part of the Enlightenment determination was seemingly restricted to external events. A tension was born during this period, and to some extent, has plagued philosophy ever since natural science emerged as a dominant way of knowing: *How can free will exist in a supposedly determined world* (e.g., Dennett, 2003)? The narrowing of causality to efficient causation, and then to a mere psychological category in the work of Hume, became the spark for Immanuel Kant's struggle with agency. Kant is the best known of a number of philosophers who grappled with the consequences of the Enlightenment for human freedom (di Giovanni, 2005). Kant (1785/1959) took restricted causation as his starting point and asked, as Schneewind (1992) put it, "Can we both take ourselves to be free and believe theoretically in a deterministic universe?" (p. 329).

Kant followed Hume to some extent by agreeing that causation, at least in the world we perceive, is a category of thought. His solution—of which a full account is too complex to detail in this chapter—was to place choice and freedom outside the world of experience. The world that we experience, the *phenomenal* world, as Hume noted, was one of mere coincidence and succession of events. But the *noumenal* world, the world as it truly is, or the *thing-in-itself*, as Kant put it, was quite different. With morality and free will outside of experience, these were thereby outside the deterministic laws of the physical world. However, humans had some contact with this noumenal world—otherwise, how else could there be a sense of freedom?

For better or for worse, Kant established his conception of agency by cleaving reality in two, creating two metaphysics: one of empirical science and one of morality. Although morality can have *heteronomous* aspects (i.e., laws originating from outside the individual), true morality relies on autonomous judgments (Reath, 2006; Schneewind, 1992; Turiel, Chapter 13, this *Handbook*, this volume). This creates several possibilities, but also several problems. Kant's views divorced the problem of agency from real life and arguably established unrealistic demands for achieving autonomy (Métayer, 2001; Slote, 1992). According to Kant, any and all influences on human decisions, such as feelings, family considerations, friendships, and so on, are considered heteronomous influences and external to agency. Agency, for Kant at least, is very limited to performing duties that meet some kind of rule (Reath, 2006). Critics have questioned where these rules originate and how are they are applied. Nevertheless, Kant's work returned agency to the foreground of philosophical discussion. Kant restored the notion of an agent that had to interpret and evaluate situations to decide what must be done.

The Kantian agent has duties in the world, the ability to choose, and to determine a course of actions. Still further, the Kantian moral project added another critical psychological dimension to agency: *reflexivity*. When C. Taylor (1985) argued that "[h]uman beings are self-interpreting animals" (p. 45), he was attempting, like Kant, to capture a psychological view of persons as reflexive beings. Still, Taylor's notion of agency, following Heidegger (1962), was also social-relational insofar as individuals were part of a preexisting social world (Martin & Sugarman, 1999, p. 17). Social circumstances may constrain agency, but because individuals have developed interpretive abilities, these circumstances also provide meaning-making opportunities, even when experiences are beyond individuals' control. This does not necessarily mean that agency is entirely epistemological. Certainly, reflexive forms of interpretation provide humans with the capacity to regulate and reevaluate their choices (C. Taylor, 1985; see also Bandura, 2006). But insofar as self-reflection is an action of persons embedded in social contexts and in relationships with others, it resists Cartesian (and Kantian) implications of being a disembodied form of consciousness (Martin & Sugarman, 1999). Although such social-contextual considerations were not very salient in Kant's thinking, they became particularly important in the work of his successor, Hegel (1770–1831).

Sociocultural Agency: Hegel and Sociological Thought

Hegel (1807/1977; see also Guyer, 1993) took the Kantian view of self-determination and put it back in the world. The Hegelian dialectic seeks to reconcile seeming splits, including those that Kant introduced between the realm of physics and the realm of freedom (Kuczynski & De Mol, Chapter 9, this *Handbook*, this volume; Overton, 2006, Chapter 2, this *Handbook*, this volume; Pippin, 1991). Hegel delineated a worldview in which activity was found at every level of existence. In Hegel's worldview, there was no denying agency; there was transformative activity originating in all the parts of a whole with no external forces per se. Different levels of activities resolved themselves into larger totalities, with distinctive dynamic forms transcending the previous levels, and "reconcil[ing] themselves into a 'higher' synthetic unity" (Bernstein, 1991, p. 294).

For historical reasons, Hegel's system largely focused on nation states as a critical level of activity. As a result, Hegel's influence loomed especially large on subsequent sociocultural accounts of agency. In a sense, the agency of the person, though readily acknowledged in Hegel's worldview, becomes lost in descriptions of higher levels of societal organization and cultural structures. Culture and the march of history, although emerging from the activities of persons, has a life of its own in Hegelian thinking, and when taken to an extreme, the active agent universe seems to override the individual agent.

This interpretation of Hegel's work has prompted questions regarding the extent to which individuals are free to make their own choices when born into societies with preexisting structures and institutions that constrain human agency. The field of sociology attempts to explain how social structures and social norms are transmitted across generations and change over time. The growing consensus among sociologists, emerging out of Archer's and Gidden's seminal work in the 1980s, is that sociological theories confront the "fundamental problem of linking human agency and social structure" (Archer, 1982, p. 455; Elder-Vass, 2010; Giddens, 1984; Ritzer, 1996), and understanding how human beings are both "free and enchained, capable of shaping our own future and yet confronted by towering, seemingly impersonal, constraints" (Archer, 1995, p. 65).

At times in its history, sociology has risked dissolving the agent into a reductionism of what Archer called "downwards conflation" (Archer, 2000, p. 19). People are conceived as determined by their society and culture. That is, the person is conceptualized as indeterminate matter, absorbing the sociocultural conditions from the outside in. A particular challenge for agency theorists is to explain whether personal narratives or life stories, which play a prominent role in the development of human agency, might, in fact, be the outcome of a strict cultural determinism. For example, Western cultures often consider the *self* to be a constant entity, whereas some indigenous cultures treat the self as an unfolding story influenced by events throughout life (Chandler, Lalonde, & Sokol, 2000). Each of these cultural constructions of selfhood has different implications for the agentic regulation of individuals and social relationships that sustain agency (Trommsdorff, 2012).

Despite the evident tendency within sociology to sometimes dissolve the agent into culture, human agency is also an unavoidable part of sociological analysis because social structures, such as rules and laws, although establishing powerful constraints on human action, still need someone to interpret them. They cannot, as Durkheim (1961) acknowledged, "be applied exactly and mechanically in identical ways in each particular circumstance. It is up to the person to see how it applies in a given situation" (p. 23). Although Durkheim is usually thought of as the paragon advocate of social structural determinism, he too clearly recognized the tensions between social structures and personal agency (Sawyer, 2002).

A Constructivist Synthesis: Agency and Piaget

Sociology, like many quadrants of philosophy and the natural sciences, struggles with questions of agency. But here again, with the point raised by Durkheim (1961), the issue of self-interpretation and self-awareness is identified as an important, and perhaps uniquely human, feature of agency. *Reflexive* views of agency, however, also raise important concerns. With the attribution of reflexive abilities to individuals, there is a risk of going too far and creating a psychologically unrealistic view of human agentiveness and self-awareness. In addition, the psychosocial dimensions supporting the emergence of agency implicate systemic, or relational, properties that may become unbalanced, particularly in cases where social conditions privilege or empower some individuals while disempowering and disenfranchising others. Recognition of such unequal social realities adds another layer to the moral considerations related to human agency and development—or what Lerner (2004) has called the constitutive conditions of *thriving*—and suggests there are close ties between social responsibility, or social justice, and agency (Lerner & Overton, 2008). Finally, to the extent that agency is dependent on biological, psychological, social, and cultural forms of living—that is, agency is *embodied* (Overton, 2008, Chapter 2, this *Handbook*, this volume)—it depends on conditions that are themselves fragile. To sustain and promote human agency, prudent use of the forms of life that enable reflexivity and self-awareness in the first place is required. These concerns and connections are described later in the discussion of civic agency and citizenship.

One way to address these issues begins with the recognition that the human organism is already spontaneously active. Both Piaget and Vygotsky, insofar as each were influenced by the work of Baldwin (Valsiner & van der Veer, 2000; Vidal, 1994), represent key proponents of this view of the active organism. Our focus in this section, however, will be exclusively on features of Piaget's theory. Ironically, although Piaget, as one of the founders of modern development science, understood self-determination to be a central characteristic of developing children, subsequent interpretations of his theory have been forced into a causal deterministic framework, in which stages (formal causes) are assumed to be efficient causes of action and behavior (see review in Carpendale, 2000; also, Chapman, 1988). Some aspects of Kohlberg's interpretation of Piaget (for further discussion, see Sokol & Chandler, 2004) provide an example of this causal deterministic framework by casting structures in the individual, rather than the individual's own reasoning, as the cause of moral thought and behavior (Rottschaefer, 1991).

Piaget did not use the term *agency*; instead he favored terms such as *intelligence*, *autoregulation*, and *will*. However, his theory is clear that structures (i.e., systems), whether sociological (Piaget, 1973, 1977) or biological (Piaget, 1974/1976a, 1976b), are insufficient to account for development without the organism's own autonomous regulative activity. The parts of an organism and the food it needs to live can each be present or available, but unless the organism consumes the food, the organismic system will fail. Such activity might seem a long way from what is usually understood as psychology, but, as is argued later, self-determined action is the necessary basis of a psychology that can accommodate agency. This is equally true for society. In his text, *Sociological Studies*, Piaget acknowledged that the "object of sociological knowledge is of vital interest to epistemology, since human knowledge is essentially collective" (Piaget, 1995, p. 30). In fact, "child psychology is a branch of sociology, concerned with the study of the socialization of the individual at the same time as a branch of psychology itself" (p. 36). But for Piaget, merely being present in this collective milieu is insufficient for children to gain knowledge; rather, they must construct knowledge from their actions within the collective. Or, as Piaget (1967) claimed: "I think that human knowledge is essentially active. To know is to assimilate reality into systems of transformations. To know is to transform reality . . . knowing an object does not mean copying it—it means acting upon it" (p. 15).

Initially, the child's knowing is best characterized as a psychology of action, not one of reflection or complex thought. Recognizing the endogenous actions of the organism as a basic form of agency radically restructures the epistemological problems that humans face. Rather than symbolically representing the world, and then acting based on those representations, children act and later in the developmental sequence come to reflect on action (i.e., representation becomes a later developmental achievement). Developmentally, sensorimotor and perceptual action leads to reflection (Müller, Sokol, & Overton, 1998; Piaget & Inhelder, 1982). Reflection increasingly plays a role in reorganizing action, and once reflection (i.e., the symbolic function) emerges, reflective action and sensorimotor action function together to co-constitute each other in a system of relations (Piaget, 1974), which create further opportunities for agentive development. To be clear, agency in its early sensorimotor action-based form is simply the ability to act independently, even if only partially, of external stimuli, or to "alter at will," as Russell (1996) remarked, "one's perceptual inputs—motorically or attentionally" (p. 3). According to Campbell and Bickhard (1986), who characterized Piaget's account as *knowing levels*, the first level is nonreflective, nonlinguistic activity, or *prereflective agency* (Martin & Sugarman, 1999, p. 18).

Piaget understood that the growth of an individual's will—that is, personal agency—was intimately connected to different levels of reflexivity (Sokol et al., 2013). Piaget argued that agency is a psychological process that closely resembles, and even draws on, the process of perspective taking. The will, according to Piaget (1954/1981), involves coordinating and integrating one's desires and personal values, just as perspective taking involves coordinating and integrating multiple points of view. In a short essay titled, *What is involved in a genetic psychology*, C. Taylor (1985) notes ways in which Piaget's views eludes the usual vices of objectivism. Suggestive of Campbell and Bickhard's (1986) knowing levels, Taylor argues that the person can, "contrast a higher, more clairvoyant, more serene motivation, with a base, more self-enclosed and troubled one, which we can see ourselves as potentially growing beyond" (C. Taylor, 1985, p. 67). Indeed, Campbell and Bickhard (1986) argue that the Piagetian approach has "convergences with hermeneutics" (p. 127) like that seen in Taylor's work, particularly regarding the importance of interpretation. In a sense, both the baby and the mature adult operate in one and the same world; and yet just as clearly they do not. The adult can interpret, understand, and organize the world and their actions in very different and symbolically meaningful ways. The sensation of being thrown around can be terrifying, if in a car accident, or fun, if on a rollercoaster (Campos, Dahl, & He, 2010).

Before such interpretive symbolic meaning-making can occur, however, agency is reflected in the sensorimotor ability "*to take up different mental orientations towards . . . objects*" (Russell, 1996, p. 74). This ability involves reflection at a sensorimotor level on a course of action (Müller et al., 1998). This presymbolic and "prelinguistic ground and its constraints are never lost, and can never be fully transcended . . . [i]n this respect the interactive model diverges sharply from those themes in hermeneutics that . . . reduc[e] the person to a local nexus of social relationships" (Campbell & Bickhard, 1986, p. 127). At the same time, "we must neither under- nor over-privilege human agency in our analytical approach" (Archer, 2000, p. 21). Humans are already active—agency is always present in the actions of the child even if operating in a very rudimentary form.

Summary: Why Agency?

Issues of agency run throughout philosophical theory, sometimes acknowledged, sometimes denied. At times, the very concept of agency has been rejected as a form of antiphysicalism or individualism, only to have agentive notions arise again as a necessary condition for explaining and understanding the lived human experience. The possibility of agency requires a broadened view of causation, wherein self-determination is understood as an authentic form of determination. At the same time, agency is not some omnipotent mystical power allowing people to do whatever they choose. Reflection on actions, reinterpretation of situations, and regrets for the past all aid in planning anew for the future, but even then, persons act in a world they do not wholly determine and where their actions bring unexpected and sometimes unintended consequences.

In the next section, we attempt to unpack the psychological agent. This effort runs up against the theoretical struggles described earlier, where psychology, under the historical constraints of a limited conception of causality in the natural sciences, has often attributed human action to neurons or reinforcement schedules, but rarely to the whole person operating in a physical and sociocultural world. Psychology also faces the problem of explaining how a self-determined actor can then go on to reflect on its own actions. Developmental science provides a particularly powerful way of understanding these issues and can outline a way forward.

PSYCHOLOGY AND DEVELOPMENT

The review of the conceptual background of agency demonstrates that issues surrounding agency have long puzzled philosophers. Because agency has often been understood in the framework of a philosophical debate with poles set at all or none, the main conceptual issue has typically been whether humans are wholly free (i.e., have agency) or entirely determined (i.e., do not have agency) in their conduct. With the advent of Enlightenment conceptions of mechanical causation and control, the response to this debate, especially in the natural sciences, tended to minimize human agency as either an illusion or epiphenomenon. Human lives, it seemed, were determined like other physical objects in the universe, even if not in foreseeable ways. By contrast, those trying to preserve human agency were often driven to take untenable ontological positions regarding the nature of the world or the extent of human psychological powers. That is, to be free, humans either participated in some kind of transcendental realm (e.g., were split between a noumenal and phenomenal world) or they possessed rich powers of self-reflection and self-transparency that ran counter to experience, and increasingly, to scientific evidence.

Agency, as a reality, did not fare well against dominant currents of a split Cartesian-Split-Mechanistic worldview (Overton, 2013, Chapter 2, this *Handbook*, this volume). However, especially in the developmental sciences, this Cartesian paradigm has progressively fallen into disrepute and been replaced by a relational perspective, asserting the primacy of activity over passivity, organization over uniformity, and change over stasis (Overton, 2006, Chapter 2, this *Handbook*, this volume). This movement has opened new possibilities for exploring agency, including the exploration of how different forms of agency emerge over time, and how agency exists in social relationships rather than being a process encapsulated in the individual. Following from our relational developmental systems perspective the review of the psychological literature that we undertake in the following section begins by working to undo the long-standing freedom-determinism antinomy inherited from the Cartesian-Split-Mechanistic perspective, and reframing human agency in terms of the origins and sources of psychological functioning that support self-determination. To do this, we begin with a taxonomical system for organizing the various psychological approaches to agency that makes use of a distinction between *internalist*, or individualist, and *externalist* approaches to psychological life (Sugarman & Sokol, 2012). In the end, the relational developmental systems stance we adopt will entail features of both internalism and externalism as we shift our focus to the psychosocial developmental processes that blur the endogenous and exogenous characteristics of human agency.

Internalist Approaches to Agency: Idealism and Materialism as Cartesian Splits

Within the split Cartesian-Split-Mechanistic framework, agency is often characterized as a feature contained solely within or inherent to an individual—that is, as an endogenous feature of persons. This *individualistic*, or *internalist*, characterization of human agency has manifested in two broadly different ways. The first, or *idealist* form, of internalism maintains a dualistic or split view of individual minds as being distinct from the external physical world. According to this view, human agents posses a capacity to reflect upon their immediate circumstances and, through their choices and actions, alter themselves and their life conditions in ways that seems to drive a wedge between human existence and the causal forces that affect the rest of the universe. The second, or *materialist* form, of internalism accords with contemporary attempts to naturalize, and often reduce, individual mental life to more basic, physically determined, properties. On this view, the notion that persons somehow hold a unique ability to control their actions, or assert their personal wills, is minimized or even denied. Both idealist and materialist forms of internalism reflect Cartesian assumptions regarding the nature of mind and matter.

Idealism

At the heart of internal-idealism is the view that human agents, by virtue of psychological structures and processes (e.g., executive processes, metacognition, self-regulation, self-control, self-concept, self-efficacy), are the ultimate causal source of their choices and actions. In many ways, internal-idealism credits human persons with the *prime mover* capacity attributed to divine authority in classical and medieval theological conceptions (R. Taylor, 1958). Because, on this view, a wide gap is seen to separate human agents from other causes in the world, *agent causation* and *event causation* are understood as ontologically distinct (Coole, 2005). Moreover, because the sources of agency are internalized within individuals, this view of agent causation suggests a "well metaphor" (Côté & Levine, 2002, p. 55) according to which individuals draw on internal psychological capacities to align their choices and actions with their inner potential, transcendent being, or other homeostatic processes (e.g., Baumeister, Schmeichel, & Vohs, 2007; Blair & Ursache, 2011; Grouzet, 2013; Hofmann, Schmeichel, & Baddeley, 2012). Internalist appeals to agent causation, at least in this idealist version, often are made on humanistic and phenomenological grounds (e.g., Grouzet, 2013) in view of an everyday understanding of ourselves as persons who plot their own course in life and experience the exercise of their capacities for freedom of choice and action: the sense of personal agency. It is not simply that human agents produce effects by their actions, but also that they experience a sense of personal agency through the self-referential awareness of intentions, actions, and outcomes. In turn, as Bandura (1989, 2006) has studied, self-referential awareness of causal efficacy is understood to act reciprocally as an instrument of agentive development.

Materialism

Although there are some appealing features of the idealist view, its ontological assumptions generally run counter to the materialist trends in contemporary science. This establishes the context for the reactive counterresponse found in materialist versions of internalism. Internal-materialism rejects agency as being unique in the physical world. Internal-materialism, like its idealist counterpart, retains the Cartesian split of the separateness of individual minds, but maintains that psychological agency has little explanatory utility once it has been distilled from the structural and functional properties of causal interactions at the physical level. At root here is the ontological doctrine of *physicalism*: The physical realm is causally complete. All things, including mental phenomena, are constituted by basic physical entities, and the physical and biological sciences provide sufficient conceptual means to represent all extant phenomena, psychological or otherwise (e.g., Churchland, 1986; Kim, 1996). For physicalists, the experience of psychological agency and, for that matter, all mental events can be explained totally by reduction to biophysical terms. Human choice and action are considered the result of neurophysiological mechanisms (i.e., efficient and/or material causes) that are internal to individuals, but operate outside and prior to their awareness and control. Consequently, the self-referential features of agency to which humanists and phenomenologists draw attention are merely epiphenomenal events that simulate what is occurring neurophysiologically. They are little more than a "user illusion" (Nørretranders, 1999) and ultimately play no role in the control of action.

One vein of psychological research takes this materialist position through positing unconscious automatic processes of human thought and action, which operate outside awareness and conscious control (Kihlstrom, 2008). In both cognitive and psychoanalytic theories of automaticity, although individuals may have conscious awareness of their thoughts, they are nevertheless unaware of the processes by which these are evoked. Hasher and Zacks (1979) argue that automatic processes function independently of conscious intentions and, being biologically determined in origin, "should be widely shared and minimally influenced by differences in age, culture, education, early experience, and intelligence" (p. 360). Bargh and Ferguson (2000) and Wegner (2002) also argue that automaticity pervades thought, action, and experience, and that any so-called intentional behavior can be reduced to automatically operating processes unavailable to awareness. Wegner argues further that "we are not intrinsically informed of our own authorship and instead must build it up virtually out of perceptions of the thought and the actions we witness in consciousness" (p. 218). In other words, our personal sense of agency is a fabrication.

Various studies have been interpreted as support for unconscious or preconscious sources of agency. Libet's (1985, 2004) and Walter's (1964) investigations of the timing of conscious volition are prime examples. Each author claims to have discovered a readiness potential prior to subjects' awareness of willing a behavior. Sparked by such findings, other researchers have attempted to show how our sense of agency can be derived from neuronal events that initiate motor responses. Wegner and Wheatley (1999), for instance, have demonstrated that research participants primed with thoughts relevant to an action, in turn, experience a sensation of having initiated that action even when they themselves did not perform it. Also, in a series of studies exploring self-regulatory abilities, Baumeister and colleagues (Baumeister, 2003; Baumeister, Bratslavsky, Muraven, & Tice, 1998; Baumeister et al., 2007; Muraven & Baumeister, 2000; Muraven, Tice, & Baumeister, 1998) have shown that cognitive resources for self-regulation may be depleted from one domain of activity to the next and negatively affect individuals' self-control. The implication of these findings, Bargh (2008) remarks, is just how little of human conduct appears to involve conscious choice and intention.

Externalist Approaches to Agency: Biophysical and Sociocultural Reductionism

Externalism stands as the counterpoint to both forms of internalism, although it too admits variations and similar kinds of splits. At their core, externalist views make clear that purposeful activity is differentiated by agents' particular orientations toward and relationships with worldly objects, locations, and events (Malpas, 1999). That is, the constitution of agency cannot be considered in isolation from the contexts to which it is related and within which it takes place. Attention to context alone, however, is not what leads to split, reductionistic conceptions of agency. Rather, stronger claims about the biophysical or sociocultural *sources* of agency within externalist approaches are responsible for this.

Biophysical Reductionism

Naturalistic, or biophysical, externalism holds that the outward orientations of agents to particular objects, locations, and events are a consequence of the way in which those orientations enable evolutionary adaptations (Burwood, Gilbert, & Lennon, 1999). Agency consists not only in the neurophysiological activity of human brains and bodies, but also is the result of the evolutionary history of *Homo sapiens*, during which agentive capacities have been selected as a means to meet the demands and constraints of the biophysical world. The basis of naturalistic externalism is belief in a universal superordinate evolutionary process that governs the living world and drives the actions and development of all animate beings, including humans (see, e.g., Belsky, 2012; Ellis & Bjorklund, 2012; Ellis, Schlomer, Tilley, & Butler, 2012, as examples). As such, agency is firmly embedded in the natural order. Still, as Bandura (2006) points out, "the creative power of human agency generally is downgraded in evolutionary accounts of human behavior, especially in the more biologically deterministic views propounded in psychological evolutionism" (p. 173). In other words, agency on this view begins to resemble other materialists' claims that any sense of personal agency an individual may have is merely an illusion or form of self-deception. Prominent advocates for naturalistic externalism have included E. O. Wilson (1978), Pinker (1994, 2011), Tooby and Cosmides (1990, 1992), and Dawkins (1976), whose famed notion of the "selfish gene" characterizes humans as "survival machines" whose actions are driven by evolutionary processes that function to ensure successful genetic development.

Sociocultural Reductionism

Sociocultural externalism is similar to its naturalistic counterpart but holds that agency is constituted as an artifact of sociocultural forms and practices, instead of being the result of evolution. From this perspective, sociocultural structures and practices are cast as the causal agents of psychological capacities. Individuals are the locations of intersecting forces by which they are constituted and enabled as actors. Agency and other psychological characteristics are produced and sustained by the structures and functions of social, cultural, political, economic, educational, and other institutional arrangements. These ideologically prescribed structures and practices in which we are embedded from birth regulate, organize, and channel individual activity to conform with varying culturally specific timetables for the appropriation and enactment of social norms, roles, and statuses (e.g., Hogan & Astone, 1986; Neugarten, 1979). As Rose (1998) describes:

> Agency is an effect, a distributed outcome of particular technologies of subjectification that invoke human beings as subjects of a certain type of freedom and supply the norms and techniques by which that freedom is to be recognized, assembled and played out in specific domains. (p. 187)

This understanding of agency resonates, as well, in Bourdieu's (1990) notion of the *habitus*, which emphasizes how human conduct is "coherent without springing from an intention of coherence and a deliberate decision; adjusted to the future without being the product of a project or a plan" (p. 51).

The perspective of sociocultural externalism has a rich history in the social sciences. Although its most contemporary expressions are reflected in the *structure-agency* debates in sociology (e.g., Archer, 2000, 2003; Bourdieu, 1990; Elder-Vass, 2007, 2010; Emirbayer & Mische, 1998; Giddens, 1984, 1991), the roots of sociocultural externalism can be found in Durkheim's (1949/1893) seminal work. In seeking to differentiate sociology as a distinct discipline differing from both biology and psychology, Durkheim asserted the priority of *social facts*. Social facts, Durkheim proposed, consist of material and nonmaterial social structures that regiment thought and action in ways that strongly constrain agency and render psychological explanations superfluous. However, many contemporary sociologists now agree that agency cannot easily be dissolved by structure. Emirbayer and Mische (1998), for instance, claim:

> The concept of agency has become a source of increasing strain and confusion in social thought. . . . At the center of the debate, the term agency itself has maintained an elusive, albeit resonant vagueness; it has all too seldom inspired systematic analysis, despite the long list of terms with which it has been associated: selfhood, motivation, will, purposiveness intentionality, choice, initiative, freedom, and creativity. Moreover, in the struggle to demonstrate the interpenetration of agency and structure, many theorists have failed to distinguish agency as an analytical category in its own right—with distinctive theoretical dimensions and temporally variable social manifestations. The result has been a flat and impoverished conception that, when it escapes the abstract voluntarism of rational choice theory, tends to remain so tightly bound to structure that one loses sight of the different ways in which agency actually shapes social action. (pp. 962–963)

Emirbayer and Mische (1998) argue that the sources of agency cannot reside solely in social structure, but also inevitably are to be located in the psychological capacities of individuals. Agency, as they describe, is incarnated as an internal conversation with dialogical structure that takes its shape from, and within, transpersonal interactions and sociality. However, they also are explicit that, "while transpersonal contexts do both constrain and enable the dialogical process, such contexts cannot themselves serve as the *point of origin* of agentic possibilities, which must reside one level down (so to speak), at the level of self-dynamics" (p. 974; emphasis added).

The Relational Developmental Alternative

Taking our lead from Emirbayer and Mische's (1998) critical remarks about impoverished views of agency, the foregoing overview of internalist and externalist perspectives on the origin and development of agency serves to clarify the challenges inherent to split Cartesian-Split-Mechanistic accounts of the relations between persons and contexts. That is, although various perspectives on agency may pay lip service to the idea that both person and context are necessary pieces in the puzzle of agency, the fact remains in these models that either (a) persons tend to fade into context (i.e., externalism), or (b) context is omitted in favor of endogenous characteristics of individuals (i.e., internalism). The fundamental reason for this is that each account, whether externalist or internalist, ultimately views person and context as two pure forms—bodily sphere and social sphere—that *causally* (efficient, material) interact in an additive fashion to produce what are termed agentive (intentional, purposeful) acts. What is needed is a relational model in which person and context are not merely causally related, but are *co-constitutive*. This model begins from a neutral monism in which idealism and materialism are themselves relational concepts (Overton, 2013, personal communication), and proceeds to understand agency as the relational epigenetic coconstruction of internal-external parts of the whole person.

One implication of a relational developmental systems account of agency is that psychosocial processes and structures extend well beyond the usual boundary conditions of an individual's skin. Accordingly, agency necessarily includes context as constitutive, and not as merely accidental or arbitrary factors influencing the direction of individuals' actions. The sources of agency are shared by individuals and their contexts, and cannot be reduced to one or the other. Or, as Piaget (1932/1965) remarked: "There are no more such things as societies qua beings than there are isolated individuals. There are only relations . . . and the combinations formed by them, always incomplete, cannot be taken as permanent substances" (p. 360). In this regard, the theoretical work of Vygotsky (1978, 1986) also counts as an influential example of relationalism, particularly in the characterization of the *General Genetic Law of Cultural Development*.

> Any function in the child's cultural development appears twice, or on two planes . . . on the social plane, and then on the psychological plane. First it appears between people as an interpsychological category, and then within the child as an intrapsychological category. . . . Social relations, or relations among people, genetically underlie all higher functions and their relationships. (Vygotsky, 1978, p. 57)

Although Vygotsky's emphasis on interpersonal sociocultural processes is sometimes treated as a form of sociocultural determinism, such a view misses how his theoretical contributions also stress the dynamic self-organizing activities of persons (Cole & Wertsch, 1996; Tudge & Winterhoff, 1993; Valsiner, 1993; Valsiner & van der Veer, 2000). The *General Genetic Law of Cultural Development* captures how psychological phenomena, such as agency, are constructed and shared across individuals and social contexts. The fluidity between *inter*- and *intra*-psychological contexts, and the coconstructive processes that allow this movement back and forth, are not only central for Vygotsky and a coconstructive, relational interpretation of his work (see Overton, 2006, especially p. 63), this interpretation of Vygotsky also advances our review of the milestones found in the development of human agency.

Developmental Dimensions of Psychosocial Agency

A growing number of psychologists have begun to address critical features of the psycho-sociocultural constituents of human agency and its development. Programmatic investigations of agency in the developmental literature are still rare, although Sugarman and Sokol (2012) have identified several prominent threads of theory-driven research warranting further attention. These include the works of Bandura (2001, 2006), Martin and colleagues (Martin, 2005, 2006, 2007; Martin & Sokol, 2011; Martin, Sokol, & Elfers, 2008), Russell (1996), and Stetsenko (2002, 2005, 2008; Vianna & Stetsenko, 2006). Each of these investigators targets different features of psychosocial functioning, as well as different points of the developmental course. Recounting these efforts is not the primary goal of this chapter. Instead, we want to identify other strands of research that, although perhaps less systematically organized, nevertheless stand to contribute to key facets of agentive development especially in children and young people. Our main focus will be on psychosocial agency: *the deliberate, intentional choices of a self-aware system to determine a course of actions and construct meaning from them*. But we also describe some of the early precursors—and key developmental building blocks—to reflective forms of psychosocial agency that are evident in the basic sensorimotor and perceptual functioning of infants, as well as in early social interactions. Nascent knowledge of others' intentionality and an early sense of self become evident over the first year of life through infants' social interactions with others (Nelson & Fivush, 2004). Given that babies are born into a community of other agents, human agency is psychologically and socially co-constituted from birth.

Although there is a notable tendency to think of agency as a *capacity* that individuals *possess* to one degree or another, we have argued that viewing agency as a *process*, particularly a *relational* process, stands to be a more promising avenue for future research. In this regard, we have suggested that agency is a distributed phenomenon, not a singular psychological faculty or module. Nor, do we argue that human agency is necessarily consolidated in a single individual. That is, as Frie (2008) has explained, "agency is not a fixed entity that conforms to traditional definitions of free will. It is an active process ... [which] can never be divorced from the contexts in which it exists, yet neither can it be wholly reduced to these contexts" (p. vii). As a multilayered psychosocial process, human agency is never entirely here nor there, all because it is distributed, not only across ontogenetic time, but also across people and their relationships to each other (see Sugarman's 2008 discussion of persons as relational agents). Or again, as Vygotsky has characterized when describing other higher mental functions, human agency manifests *interpsychologically*. Applying this concept to agency prompts us to search for agency in children's earliest interactions with caregivers and in the family, and with increasing age, in a broader circle of relationships with others, such as teachers and peers (see Bronfenbrenner & Morris, 2006; Grolnick & Raftery-Helmer, 2013; Kuczynski & Parkin, 2007).

Importantly, in addition to Vygotsky's relational characterization of psychological functioning, he has also used the notion of *interfunctionality* to describe particular mental processes. He wrote, using memory as an example:

> [W]ith a change in developmental level there occurs a change not so much in the structure of a single function (which, for example, we may call memory) as in the character of those functions with the aid of which remembering takes place; what changes is the interfunctional relations that connect memory with other functions. (Vygotsky, 1978, p. 49)

Consider, for a moment, the implications of replacing the references to *memory* and *remembering* with *agency*. This would suggest that what changes in development are the functions of agency and the ways in which agency is connected with other functions. Luria (1966/1980), who elaborated on Vygotsky's view of interfunctionality, described functional systems as consisting of "a complex dynamic 'constellation' of connections, situated at different levels ... that, in the performance of the adaptive task, may be changed with the task itself remaining unchanged" (p. 22). Agency is a similar sort of constellation, which may manifest in multiple ways through various functions.

A more contemporary interfunctional approach, which also identifies important parts of the psychosocial constellation constituting agency, has been suggested by Nelson and Fivush (2004). They describe the various functions associated with autobiographical memory development through 5 years of age, including basic endogenous or intraindividual aspects, such as early memory capacities in the first year of life and the later emergence of language and representational abilities, along with more exogenous or interindividual aspects that are social and communicative in nature. Our exploration of agency draws on similar functions, from perceptual and sensorimotor, to symbolic and linguistic, to sociomoral. Altogether these processes form the psychosocial backbone around which agency takes shape at various levels, and when missing, may grossly diminish or change the developmental course of agency, leading at times to atypical outcomes (Davidson & Shahar, 2007; Gallagher, 2004). In addition, an important assumption for this account is the degree to which development saturates the multiple layers and aspects of human agency. Time marches on not only for agency, but also for each of the other processes that contribute to agency's development. We therefore assume that the contributions of psychological and social processes that support agency development are in reality not separable, but are co-constitutive of each other and coact together over time.

Sensorimotor and Perceptual Functions

Healthy infants begin life with an impressive array of psychological functions that have their origins even before birth, as part of prenatal biophysical development (see Lickliter & Honeycutt, Chapter 5, this *Handbook*, this volume). These functions contribute to the earliest manifestations of prereflective agency. Here we include infants' earliest sensorimotor and perceptual abilities to visually orient, detect, and sustain attention to the dynamic events that their environments afford. Such affordances, as E. J. Gibson (1982) has noted, "are the essence of what we perceive" and already action-oriented as the "things we can eat, or write with, or sit down on, or talk to" (p. 60). That is, affordances are "opportunities for action in the environment of an organism" (Sanders, 1999, p. 129). Perceptual functioning, given the agentive assumptions embedded in the notion of affordances (J. J. Gibson, 1986), has its roots in what can be done or accomplished with a perceptual object, that is, "its functional possibilities and uses" (E. J. Gibson, 1988, p. 24). Accordingly, although we acknowledge the significance of early sensorimotor and perceptual achievements of infants to detect differences between animate and inanimate objects, we do not presuppose any biologically determined conception of self or others as agents. Nor, do we make any claims that agency emerges in some modular sense, as have some other researchers (e.g., Spelke & Kinzler, 2007) who argue for an innate core knowledge system that governs representations of agents and their actions, with innate here meaning "biologically determined" rather than simply "present at birth" (see Bateson, Chapter 6, this *Handbook*, this volume). Rather, we take the view that psychosocial forms of agency first arise from more basic biophysical processes associated with infants' earliest sensorimotor acts, including perceptual acts, such as visual attention to dynamic events in their world, and from this basis, other agentic forms of understanding and behavior are constructed over time. For example, the ability to visually detect action in the environment and to "parse" visual streams occurring in the world may support agency at the beginning of life along with underlying basic sensorimotor capacities to anticipate, and eventually to cognitively represent through symbolization, recurring sequences of external objects. Statistical learning—that is, the ability to anticipate or detect regularities and probabilities with perceptual events—is another psychological function likely to be necessary, though certainly not sufficient, for early forms of agency. Strong evidence for statistical learning has been reported as early as 8 months (Hay & Saffran, 2012; Lany & Saffran, 2013; Saffran, Aslin, & Newport, 1996). Thiessen (2011) has argued still further that statistical learning could constrain development more generally, including "infants' learning of visual patterns" (p. 462) and early sensitivity to goal-directed movement in their visual field.

Woodward's work, in particular, has been central to researchers' understanding of infants' developing conceptions of action, animacy, and intentionality. Woodward and colleagues' research (e.g., Hamlin, Hallinan, & Woodward, 2008; Sommerville, Woodward, & Needham, 2005; Woodward, 1998, 2009), in conjunction with studies from other labs (e.g., Biro & Leslie, 2007; Király, Jovanovic, Prinz, Aschersleben, & Gergely, 2003), indicates that midway during the first year of life infants begin to demonstrate sensitivity to goal-structured actions presented to them in laboratory experiments. For example, Woodward demonstrated that 6-month-olds selectively encoded actions in terms of agent-goal relations (Daum & Gredebäck, 2011; Woodward, 1998) for motions carried out by actors, although not for motions of inanimate objects. By 7 months of age, babies selectively imitate both completed and uncompleted actions of actors on objects (Hamlin et al., 2008; Mahajan & Woodward, 2009), suggesting that they were sensitive to actors' underlying intentions and were not just simply reproducing completed actions on objects that they had witnessed. Nine-month-olds failed to imitate actions presented as performed by an inanimate mechanical device unless they had first witnessed an actor using the device in a goal-directed manner. Additionally, Cannon and Woodward (2012) demonstrated that 11-month-olds also systematically anticipated goal-directed reaches by an actor toward an object. Sommerville et al. (2005) speculated that "[t]his basic ability to construe action with respect to external goals may form the cornerstone for an understanding of goals as abstract entities that guide human action and govern event sequences" (p. B2). Woodward and others (Cannon, Woodward, Gredebäck, von Hofsteen, & Turek, 2012; Sommerville, Hildebrand, & Crane, 2008; Sommerville et al., 2005) have also provided compelling preliminary evidence that suggests that babies' self-produced actions may play an especially important formative role in knowledge about agency via the capacity to attribute goals to others' actions.

Unsettled is the persistent question of whether the seeds of agency are found first in awareness of the world or awareness of the self. In an interfunctional approach such as ours, neither needs to be privileged or given developmental priority. In a related vein, Rochat has argued (2003, 2010, 2011) for an embodied self-awareness from birth that is prereflective or implicit (see also Martin et al., 2008, for a similar view). Embodied accounts (e.g., Overton, Müller, & Newman, 2007), including Rochat's work, challenge traditional views that symbolic capacities and language are essential for self-awareness. Rochat (2011), in particular, has adopted a coemergence perspective through which self-awareness in conjunction with "feeling experience" transform active organisms into "volitional actors" (p. 110). On this view, infants' perceptions of their own bodies, both posturally and "situated in the environment" (Rochat, 2010, p. 738), precede more explicit forms of awareness of the self-as-agent. Self-produced action from birth is argued to yield proprioceptive information that is "self-specifying" (Rochat & Striano, 2000; see also Rochat & Hespos, 1997). Rochat (2010) further argues that this preconceptual self-awareness is fundamentally relational because it is derived from the infants' embodied experiences of *relations* between the implicit early self and the environment, including the social environment. According to Rochat (2010), newborns have "an implicit sense of the body as an identity that is differentiated, organized, and situated in the environment" (p. 738).

He reviews evidence that babies demonstrate awareness of themselves as "an entity that is situated, physically bounded, organized, and an agent in the environment" (p. 738) and that this entity with development becomes "recognized, evaluated, and labeled as an intrinsic part of the concept of 'Me'" (p. 738). Behaviorally, the implicit, embodied ecological sense of newborns, which would correspond to a minimal self-consciousness, is immersed in socially shared and socially mediated interactions, which Rochat (2010) indicates are supported over the developmental course by children's emerging symbolic and linguistic functions, as well as folk psychologies, or theories of mind. We turn to a closer examination of these functions next.

Symbolic and Linguistic Functions

The prereflective forms of agency evidenced in infants' early proprioceptive, perceptual, and, sensorimotor actions manifest in richer and more powerful ways with the emergence of symbolic and linguistic functions. Both Piaget and Vygotsky recognized the significance of symbolic functioning, of which linguistic development is a part, for the reorganization and control of individuals' actions (Chapman, 1991). Symbolization, in effect, drives a wedge between individuals and their environments, ultimately providing a way "to transcend a present situated activity context and create a new one" (Valsiner, 1998, p. 388). Commenting particularly on Vygotsky's conception of agency, Holland and Lachicotte (2007) noted that "without semiotic mediation [i.e., symbolic functioning] people would be buffeted about by the stimuli they happened to encounter as they went about in the world. Instead, semiotic mediation provides the means for humans to control, organize, and resignify their own behavior" (p. 115). Indeed, as young people develop, the possibility of resignifying one's own conduct—past, present, and future—opens new agentive avenues (Martin, 2008). As Modell (2008) has claimed: "Our sense of agency is enhanced not only through physically embodied acts but also through the creation of new meaning" (p. 42). This is one of the main reasons why philosophers, such as Charles Taylor discussed previously, argue for the centrality of self-interpretation in the development of agency.

In addition to the ways that symbolization promotes, as Vygotsky (1978) has said, "emancipation from situational constraints" (p. 99) and, as Piaget (1971/1967) noted, the "bursting of instinct" (pp. 366–367; see also Müller et al., 1998), language becomes a means by which children learn more explicit ways to articulate and reflect on their competencies as purposeful agents. Such learning becomes possible "Because linguistic symbols are both subjective and perspectival, when children learn to use words and linguistic forms in the manner of adults, they understand that the same objects and events are construed variously in relation to different points of view" (Martin, 2008, p. 103). Children's references to themselves provide a particularly interesting case in which early word use appears to promote perspective taking and agentive development (Budwig, 1989).

Personal pronouns—*I, me, mine, you, yours*—are categorized as deictic utterances, in that whereas other words for people typically have stable referents (e.g.*, grandma, Blake, Alice)*, the referents of personal pronouns are always specific to social-relational contexts in which referents change depending on who is uttering them. Deictic terms, therefore, can demarcate different physical perspectives and ownership (biophysical agency), differences in interpretation or views (psychosocial agency), and even demarcations of cultural and group inclusion (sociocultural agency). As noted by Smiley, Chang, and Allhoff (2011), personal pronouns "do not refer to particular people but rather to the roles they occupy in relation to one another in interaction" (p. 77). Thus, the referent of *I* when a child announces proudly to her mother "*I* threw the ball" shifts when the mother tells the child "Now *I* threw it." In effect, children's mastery of the system of personal pronouns demonstrates that they can "encode the range of roles they occupy in interaction—mover, agent, controller, experiencer . . . and the complementary roles of their partners" (Smiley et al., 2011, p. 78).

From birth on, young language learners are routinely exposed to self- and other-referencing pronouns (e.g., *I* versus *you*) in the language directly addressed to them and indirectly when adults converse with others in their company. However, because symbolic functioning is a later arriving developmental accomplishment, so too is their use of personal pronouns. It is not until around 18 months, then, that the linguistic use of personal pronouns emerges, with *I* usually preceding *you* (Smiley et al., 2011; Stipek, Gralinski, & Kopp, 1990). Production of possessive personal pronouns—*my, mine*—occurs only as early as 15 months but usually later (Hay, 2006; Saylor, Ganea, & Vázquez, 2011). Coinciding with these linguistic achievements in personal pronoun use, particularly the usage of *mine*, is a surge in children's declarations of *no*, or the a verbal attempt to negate the will of others (Hay, 2006). This finding suggests an important milestone in children's agentive expressions. That is, children's use of possessive personal pronouns appears to help advance their self-interests in interactions with others.

The use of personal pronouns is, among others, one signal that the child is attaining a *first-order, reflective agency*. Given that children's earliest use of personal pronouns coincides with classic mirror self-recognition (Lewis & Brooks-Gunn, 1981; Lewis & Ramsay, 2004), Lewis (2003; Chapter 11, this *Handbook*, this volume) concluded that these verbal and behavioral forms of self-knowledge signal the emergence of an explicitly conscious representation of self, the recursive understanding of "I know that I know." In much of the developmental literature, this level of self-knowledge is argued to be a nascent "theory of mind," or one of the critical steps toward understanding the mental lives of others. However, the theory of mind tradition has assumed, in a split Cartesian vein, that an individual's access to their own mind is relatively unproblematic. If the ability to represent oneself (and others) is instead thought to develop, it might be better characterized as a "theory of agency" (Russell, 1996; Sokol & Chandler, 2003), or children's ability to reflect on themselves as agents in the world.

Language and social interaction play a foundational role in the process of the development of reflective agency, and they are also a source of individual differences. Parents and other caregivers use language to refer to the child's own and others' agency in everyday conversations. Caregivers' comments may serve to spotlight children's, as well as others', agentive actions and their consequences. For instance, mothers have been studied using *mind-minded* language (Meins et al., 2003) and *mental state talk* (Taumoepeau & Ruffman, 2006, 2008) to discuss their children's interests and activities. These conversations begin well before the child reaches the symbolic representational level of knowing that ushers in language and reflective agency. Once a symbolic reflective sense of agency emerges, and with it language, children will begin to use these terms associated with caregivers in social interaction with parents and others who differ in their use of mental state talk. These differences can influence the child's own linguistic development and social understanding (e.g., Denham, Zoller, & Couchoud, 1994; Jenkins, Turrell, Kogushi, Lollis, & Ross, 2003; Recchia & Howe, 2008; Ruffman, Slade, & Crowe, 2002; Wellman, 1990).

Although there has been much speculation concerning the relation between mental representation and linguistic functioning (for review, see Carpendale & Lewis, 2006), little research has conceptualized age-related changes in linguistic and self-representational skills in terms of agency. If this body of research is recast as part of the development of an "objective awareness of me" (Courage & Howe, 2002), children's early symbolic and linguistic development seems absolutely central to the emergence of a first-order level of reflective agency. Bretherton and Beeghly (1982), who were among the first to document the mental state vocabulary of young children, found that children's mastered the use of volitional words (i.e., *want, need, have to, can*) before emotion (e.g., *feel*) or cognition (e.g., *think*) terms. Perhaps unsurprising to parents, Bretherton and Beeghly (1982) also found that nearly all toddlers used the word *want*; similar patterns of acquisition were reported in a study with German-speaking youngsters (Kristen, Sodian, Licata, Thoermer, & Poulin-Dubois, 2012). These volitional terms can also be expanded to include expressions about needs (e.g., Hay, 2006), goals and intentions (Recchia & Howe, 2008), or references to preferences or lack thereof (*care, like*, *dislike*).

Interestingly, parents also initially use more agentic terms when talking to young children, that is, those dealing with desires (e.g., *like, want*), relative to other mental states (e.g., *think, know*), only subsequently stabilizing relative to other mental state terms (e.g., Jenkins et al., 2003). These early conversations seem directed more at the child's actions, "providing labels such as 'want' and 'like' for the child's mental states . . . [and] also will often simply entail a plan of action for satisfying the child's desires" (Taumoepeau & Ruffman, 2006, 2008, p. 299). Nelson (2005) claims that children will acquire language and concepts about their own and others' minds in the course of conversations with others, and, similarly, Harris, de Rosnay, and Pons (2005) concluded that "language makes a difference" (p. 72) in both children's own linguistic skills and the specific language input of those with whom children interact. Certainly, children's earliest self-assertions—*Let me do it! I want to do it!*—coupled with parents' reactions to these utterances, whether support, opposition, or dismissal (e.g., Recchia & Howe, 2008) may serve as a possible starting point for individual differences in the development of reflective agency. Family talk, in this sense, is likely to further scaffold children's emerging sense of agency, as well as contribute to individual and cultural differences that come with age in more highly reflective forms of agency (e.g., Trommsdorff, 2012). Accordingly, we draw attention to the possible interpersonal, relational, and pragmatic functions of language in children's acquisition of more explicit expressions of agency, some of which appear in changing linguistic functioning and others in articulating intersubjective processes (e.g., theory of mind).

Variability in children's personal pronoun use may also depend on parental linguistic patterns (e.g., Smiley et al., 2011). Smiley et al.'s conversational analysis of family talk replicated prior studies describing variation in the extent to which parents' discourse featured a mix of self- and other-referring pronouns and names in different sentence positions (i.e., as grammatical subjects, objects, or possessives) or other patterns of use, for example using persons' names more often than pronouns, or alternatively using pronouns more frequently than names. Although more research with larger and different samples is needed, results provided preliminary evidence that parental input may contribute to individual differences in children's rates of acquisition of self- and other-referring pronouns. Given that there appears to be variability in parental input of terms for person-reference, it is possible that there is also variability in the way parents incorporate these linguistic forms into utterances that highlight or diminish attention to agency. As we describe in the next section, different kinds of family talk have been shown to relate to other aspects of agentive development, particularly as they are expressed through children's self-regulatory skills.

Regulatory Functions

Although regulatory functions in dynamic self-organizing systems do not necessarily require symbolic operations, it is no coincidence that at the reflective level of agency language development facilitates considerable growth in children's self-regulatory abilities (Winsler, Fernyhough, & Montero, 2009). Language, in many ways, becomes a lever for ratcheting up prereflective and practical forms of activity to higher reflective levels (Müller, Carpendale, Budwig, & Sokol, 2008) and lending new avenues for guiding action. Or, as Fernyhough (2010) has noted in the context of regulatory functions, basic prelinguistic self-regulatory processes, such as monitoring, inhibiting, and planning, "begin to relate interfunctionally" (p. 63) in new and richer ways through developing linguistic abilities. Fernyhough (2010) further states: "[C]hildren gain enhanced control over their own behavior when words which were previously used to regulate the behavior of others, or which others used to regulate the child's behavior, become employed in regulating the self" (Fernyhough, 2010, p. 63).

To the extent, then, that agency is conceptualized as the self-conscious reflective ability to choose and plan actions, it has been characterized in the developmental sciences, as *self-regulation*, or sometimes, *executive functions* (see McClelland, Geldhof, Cameron, Wanless, Chapter 14, this *Handbook*, this volume). In fact, Bandura's (2006) description of "the four core properties of human agency" (p. 164)—*intentionality, forethought, self-reactiveness, and self-reflectiveness*—all revolve around the self-regulatory functions of monitoring one's conduct, responding to feedback, setting goals, and making plans. As these concepts suggest, self-regulatory processes are typically seen as higher-order functions involved in the control and monitoring of thought and action (Carlson, 2005; Kerr & Zelazo, 2004), but also situated in the broader psychological system of the developing person (Dick & Overton, 2010). A question that frequently arises in the self-regulatory literature is just *who* the self or executor is, particularly as these processes are sometimes identified with subpersonal brain regions, rather than the whole person. In such accounts, the executor, or decision center, is "little more than a homunculus" (Baddeley, 1998, p. 524), showing how prominent split Cartesian tendencies in psychology admit to the necessity of human agency, only then to submerge agentive processes external to the identity of the individual (Dick & Overton, 2010).

Some of the roots of the self-regulation literature can be located in the functional approaches of Luria (e.g., 1973) and Vygotsky (for further discussion, see Zelazo, Carter, Reznick, & Frye, 1997), who argued that self-regulation was coconstructed, shared with others, and socially distributed (Luria, 1980/1966). From a developmental perspective, it is clear that children develop the ability to plan and control their actions in and through social contexts (Sokol, Müller, Carpendale, Young, & Iarocci, 2010), whether through a parent's help in solving a problem (e.g., Hammond, Müller, Carpendale, Bibok, & Liebermann-Finestone, 2012) or in regulating negative emotions, or controlling certain prohibited behaviors (Kochanska & Thompson, 1997). This fact highlights how the development of agency is co-constituted in social interactions with others who play a prominent role in scaffolding children's early self-regulatory experiences. That is, getting things done and accomplishing one's goals—even perhaps the goal of simply getting from here to there—occurs initially with the help of others, especially caregivers, before children are able to effectively self-regulate in more independent ways. Although this may seem like an obvious conclusion to anyone watching a young child learn to walk or crawl, it has profound consequences for conceptions of agency.

More specifically, differences in patterns of social interaction have been associated with differences in agentive control. To illustrate, Perez and Gauvain (2010) reviewed studies of children's planning skills in family contexts. Summarizing an earlier study (Gauvain & Huard, 1999), Perez and Gauvain (2010) show how parenting styles, as measured during observations of parent-child discussions at home, differentiated children's planning skills. Specifically, children whose parents were more authoritarian "initiated fewer planning discussions in middle childhood and adolescence than did children whose parents used other parenting styles" (p. 371). In addition, Gauvain and Perez (2005) longitudinally investigated family practices and routines that provided a social context for planning skill development in 7- to 9-year-olds. They found that with increasing age both Latino/a and European American children participated at increasing levels in everyday planning of organized activities, but also that group differences emerged. Specifically, "European American families and more acculturated Latino families, consistent with a value of child independence, planned their informal activities more often than did children in less acculturated Latino families" (Gauvain & Perez, 2005, p. 380).

These findings described by Gauvain and Perez (2010) raise the question of whether the development of agency may vary in significant ways across cultural contexts. Using a language development analogy, Ratner (2000) proposes that diverse manifestations of human agency are influenced, at least in part, by broader sociocultural patterns of interaction and meaning-making.

> Everyone has the capacity for language and everyone expresses some language to some degree. However, the specific kind and level of language that a person expresses depends upon her position in a particular society. In the same way, agency is merely a potential (capacity) which must be developed through social intercourse into a specific form. Throughout the world, individuals no more possess the same kind of agency than they use the same language. (Ratner, 2000, p. 426)

Work by Trommsdorff (2012) and others (e.g., Markus & Kitayama, 1991) suggests that Ranter's analogy might not be far from the mark. Trommsdorff (2012) has argued, in particular, that "different cultural demands foster different developmental pathways for regulation" (p. 22), which in Asian contexts often manifest in intentional forms of self-restraint, whereas in Western contexts more typically results in promoting self-achievement. In a related vein, Lerner (2004) indicates that "how a person must function to manifest structurally valued regulation will vary from social-cultural setting to setting" (p. 89), noting that many democratic societies value individual freedom and social equality. Finally, McAdams (2013) makes a more general case that cultural contexts "set norms and constraints on behavioral expression . . . provide timetables, scripts, and strong priorities for the agent's articulation of goals and values . . . [and] provide the psycho-literary menu off of which [a person] chooses the very images, metaphors, and narratives that can be used to make narrative identity" (p. 286). These latter choices become especially important within the context of self-appropriation processes that contribute to the development of agency through the construction of moral identities (Blasi, 2004a).

Moral Functions

Notions of human agency are especially salient in the research literature on children's moral development. Much of this attention is owed to the highly influential contributions of Kohlberg (1981, 1984). Following Piaget, Kohlberg not only adopted a constructivist approach to development, which assumed basic agentive self-organizational properties of socio-emotional-cognitive growth, he also argued that moral acts are necessarily purposeful and intentional. That is, both moral and immoral acts turn on the mental states underlying persons' actions (Turiel, 1990, 2010, Chapter 13, this *Handbook*, this volume). Citing acts of disobedience to illustrate (e.g., Henry David Thoreau's tax evasion to protest military appropriations), he described, just as Immanuel Kant did in the prologue to *Groundwork for the Metaphysics of Morals*, "when the question is of moral worth, it is not with the actions that we see that we are concerned, but with those inward principles of them which we do not see" (Kant 1785/1959, p. 23). The overt protests of Gandhi or Martin Luther King Jr. carried moral significance because they were rooted in principles of justice and fairness. Without this, they would have been cast as "rebels without a cause" and their actions as mere acts of noncompliance or rule-breaking. Accordingly, Kohlberg targeted in his research the "inward principles" that structured moral reasoning. By documenting the developmental changes in these moral reasoning structures, he showed how moral agency is constructed over time as individuals confront various dilemmas and grapple with day-to-day moral decisions.

A similar exploration of moral reasoning was present in Piaget's early work, particularly *The Moral Judgment of the Child* (1932/1965). Although this work is more generally a critique of the social determinist tendencies apparent in Durkheim's sociology, Piaget used examples of children's reasoning to illustrate differences in the interpretation of moral rules and the agentive processes at work in their construction. In a now classic set of interviews, he described children's understanding of accidental versus intentional moral infractions (i.e., breaking cups). Children's responses in these interviews suggested at least a nascent conception of "responsible agency" (C. Taylor, 1985), or the idea that intentional actions reflect a person's will and carry with them a kind of ownership that opens individuals to moral scrutiny and accountability. Piaget's claims about all this sparked, in turn, a litany of studies (for reviews, see Karniol, 1978; Keasey, 1977; Lapsley, 1996, esp. Chapter 2; see also Grueneich, 1982; Karniol, 1980) attempting to determine exactly what children understand about moral accountability and when persons' intentions become a critical feature in children's responsibility judgments.

This early work on children's responsibility judgments has resurfaced in studies of children's conceptions of moral emotions, where again questions of human agency appear to play a critical role (Krettenauer, Malti, & Sokol, 2008). In studies investigating what young people understand about the emotional consequences of victimizing others, children generate responses that tend to either privilege individuals' personal agency (i.e., whether they fulfill immediate desires) or conform to moral standards (i.e., whether they refrain from harming others). Specifically, in what has become known as the "happy victimizer phenomenon" (Arsenio & Kramer, 1992; Keller, Lourenço, Malti, & Saalbach, 2003; Lourenço, 1997; Murgatroyd & Robinson, 1993; Nunner-Winkler & Sodian, 1988), early school-aged children tend to attribute positive emotional states (i.e., "happy") to both themselves and others who meet their immediate goals, even if others have been harmed along the way. By contrast, slightly older children attend more to the normative constraints of a situation and, as a result, attribute negative emotions reflecting remorse or guilt for violating moral standards. This shift in children's emotion attributions has led researchers, such as Harris (1989), to claim that the turning point in reasoning about emotional matters, and particularly acts of victimization, comes when young people acquire a new recursive layer in their views about others' agency, or, as he put it, a shift from "seeing people as simply agents" to "seeing them as observers of their own agency" (p. 92). Central to this account, which Harris acknowledges borrows heavily from the classic writings of other early pragmatist philosophers (e.g., Cooley, 1902), is the idea that children eventually come to internalize an *external audience* that, in the end, allows them to evaluate their own and others' actions from a more distant, third-person perspective. Not coincidentally, Harris's views are in accord with claims in the perspective-taking literature (e.g., Martin et al., 2008) suggesting that agentive possibilities are constituted by individuals' abilities to reframe situations and see alternative courses of action for others and themselves (Martin, 2008).

Building, at least in part, from these findings on children's conceptions of moral emotions, other developmental researchers (Bergman, 2004; Colby & Damon, 1993; Damon, 1984) have argued that individuals' *moral selves* are constructed from the earliest expressions of human agency, or the *will*. Blasi (2004a, 2004b, 2005), in particular, has suggested that disjunctures in children's emotion attributions, like the happy victimizer phenomenon, are an indication that moral rules—although certainly known and understood by young children to some degree—remain unintegrated with respect to their developing self-system, and therefore lack motivational force. Integrated moral selves emerge with the development of the will. Blasi, relying heavily on Frankfurt's (1988) philosophical work, notes, "In willing, one appropriates certain desires . . . and makes them especially one's own, investing oneself in and identifying oneself with them" (Blasi, 2004b, p. 342). These first-order desires do not begin as one's own nor do they initially manifest themselves in orderly ways, but all of this changes as individuals develop their own agency. As he claims, "[i]n agency, the subjective self feels the owner; the sense of mineness is its central feature" (Blasi, 2004a, p. 12). Accordingly, it is over the course of development that second-order desires and volitions begin to emerge and create the structures needed to regulate more immediate, first-order desires (Blasi, 2005). As Blasi (2004a) describes,

> The will is structured through appropriation and rejection of one's characteristics. Whatever their origin—biological or social—these characteristics (desires, motives, inclinations, traits) are given facts about people's lives. But people have the capacity to desire to have or not have some of these characteristics (second-order desires); they may even want for these second-order desires to be effective in determining one's actions and ordering one's life (second-order volitions). (p. 14)

Self-appropriation, according to Blasi's model, is the principle vehicle by which agency is made manifest in individuals' moral selves.

Although Blasi has attempted to characterize the moral self in developmental terms, he has been criticized (e.g., Nucci, 2004a, 2004b) for overly emphasizing adolescent forms of self-understanding and neglecting developmentally earlier psychosocial processes contributing to moral agency and selfhood. Working to address these criticisms, Krettenauer (2013) has proposed a model of moral selfhood that has its roots in the different forms of agency found in early and middle childhood. He calls these: *intentional, volitional*, and *identified agency*. Each marks an important transition in young people's moral selves and develop in hierarchical fashion, although over the life span all three forms of agency may coexist. Krettenauer's (2013) treatment of the moral self has some common features with our own interfunctional views of the development of agency and draws from many of the same multilayered, psychosocial processes. However, Krettenauer does not acknowledge the earliest forms of human agency outlined earlier in this chapter.

According to Krettenauer (2013), evidence of an early form of intentional agency (or what could be characterized as first-order reflective agency) is found at the intersection of 2- to 3-year-olds' basic folk psychologies (Wellman & Phillips, 2001), their prosocial impulses to help others (Dunfield, Kuhlmeier, O'Connell, & Kelley, 2011; Eisenberg & Mussen, 1989; Warneken & Tomasello, 2009), and their abilities to distinguish between social-conventional and moral rules (Nucci, 1981; Smetana, 2006, 2011; Turiel, 1983, 2010, Chapter 13, this *Handbook*, this volume). Children's use of mental states such as beliefs, desires, and intentions—the early conceptual building blocks of individuals' theories of mind—becomes an important tool for harnessing their nascent prosocial impulses and conceptions of moral rules to construct the first moral desires on which they act. These early moral desires, although an indicator of a developing moral self, are unstable, however, and readily give sway to outside influences. The young child's moral will is not entirely her own, or, in Piagetian terms, it is more heteronomous than autonomous.

The preschool-aged child's fleeting moral self begins to stabilize with the emergence of what Krettenauer (2013) calls volitional agency, or increasing self-regulatory abilities, which promote success in delaying gratification (Mischel, 1974; Tobin & Graziano, 2010) and imagining a temporally extended sense of self (Barresi, 2001; Moore, 2010). These growing abilities are especially critical in allowing children to reflect on future conditions that are contingent on present decisions, and then to prioritize particular desires over others. Or, as Piaget (1981/1954) would say, to construct a *conservation of values* (see also Sokol & Hammond, 2009), which "consists of subordinating a given situation to a permanent scale of values" (Piaget, 1954/1981, p. 65). Importantly, decisions about which values to prioritize may not be moral, especially given the egoistic and instrumental ways that young children tend to reason (Svetlova, Nichols, & Brownell, 2010). Moreover, the degree of internalization of particular values, moral or otherwise, may be superficial, and largely the result of external impositions. On the other hand, values that are integrated with aspects of one's identity, or what Krettenauer (2013) calls identified agency, reflect a deeper personal commitment to valued norms and the realization that behaving according to such norms is a form of self-expression.

Krettenauer's (2013) ideas regarding identified agency draw particularly from Deci and Ryan's (2000, 2002) *Self-Determination Theory*, which also posits a close connection between internalization of norms and self-regulatory processes. In Self-Determination Theory, the two most autonomous modes of self-regulation occur when a person has either *identified* with or *integrated* a particular norm. On the identified level, individuals express a basic personal agreement with a norm or societal expectation, whereas on the integrated level norms are experienced as self-ideals that the person does not want to betray. That is, although norms or values may initially be imposed on young people, they may still choose to personally value certain norms or standards (i.e., identify with the norm) and synthesize them into their own belief system (i.e., integration). In this way, a social expectation, say of parents or teachers, may be transformed into a personal goal or motive. This process resembles Blasi's (2004a, 2004b) notions of self-appropriation and taking *ownership* of particular values.

Although the burgeoning literature on moral selfhood (e.g., Lapsley & Narvaez, 2004) holds a great deal of promise for capturing the central features of human agency, another prominent strand of the moral development literature merits consideration. The growth of *moral character*, much like our discussion of moral selves, has also been described in agentive terms. Specifically, Berkowitz and Bier (2005) define character as "*the composite of psychological characteristics that serve to promote moral agency*" (p. 268, italics in the original; see also Lapsley & Narvaez, 2006; Sokol, Hammond, & Berkowitz, 2010). Not only does this definition capture the interfunctionality of character, just as we have tried to do here with agency, it also further highlights how the growth of human agency implies social responsibility and promoting civic virtue, especially in educational contexts. Indeed, rising interest in the study of civic engagement (Lerner, Fisher, & Weinberg, 2000; Sherrod, Torney-Purta, & Flanagan, 2010) and civic education (Althof & Berkowitz, 2006; Haste, 2010) has important ties to developmental research on moral agency (e.g., Youniss & Yates, 1997) and moral identity (e.g., Hart, 2005). As Hart, Atkins, and Donnelly (2006) have pointed out, "Participation in community service provides a real-world context in which participants can explore moral questions, engage in moral discourse, perform moral actions, and reflect on complicated moral issues. It is for these reasons that community service has been extolled as a context for moral development" (p. 644).

Although these connections to community service are no doubt important, still others (e.g., Lerner, 2004) have argued for a deeper, constitutive relation between moral development and civic engagement. Youniss' insights on fostering the growth of civic life, in particular, stem from early work elaborating on Piaget's (1932) view of moral agency and the different social-relational dynamics associated with adult caregivers and peers (Youniss, 1978, 1980, 1981, 1987; Youniss & Damon, 1992). Although Piaget was never as overtly political as his peer Wallon, idealistic notions of transcendence and democracy are seeded in Piaget's earlier writings (Vidal, 1998), and come to fruition in Youniss and his colleagues' research on civic engagement and democratic participation (e.g., Yates & Youniss, 1996; Youniss, McLellan, & Yates, 1999). Here we can see an important parallel between moral agency and civic growth. Civic life, much like young people's moral lives, occurs within a broad field of power differentials that are experienced through symmetrical and asymmetrical relationship structures (e.g., parent-child, peer-peer). These relationships, in turn, promote, as well as constrain, to differing degrees the development and expressions of civic agency. Some relationships, especially those rooted in democratic forms of participation and mutual reciprocity, appear to promote an understanding and commitment to social justice and the need for sociopolitical transformation; whereas as others, particularly more didactic or less participatory social relationships, lead to attitudes and priorities that conform to social convention and preserve the status quo (Kahne & Sporte, 2008; Moely, Furco, & Reed, 2008; Moely & Miron, 2005; Westheimer & Kahne, 2004).

Evidence showing these important ties between moral and civic life leads to further questions regarding the extent to which human agency, characterized here at a psychosocial level of agency, may be tied to a broader view of sociocultural dynamics in which patterns of shared values and norms could further empower individuals' actions. Or, drawing from Giddens (1984), to what extent is agency more than just "being able to act" and instead about "being able to make a difference" (p. 14) in one's own and others' lives? To properly answer this question, we must turn to issues of political or civic agency: the power for individuals and groups to bring about effective change in collective life, or enact social change (Coole, 2005). By concluding our investigation and analysis with a discussion of civic agency, we want to further emphasize why human agency is best understood as a relational phenomenon.

CIVIC LIFE AND THE SOCIOCULTURAL DIMENSIONS OF AGENCY

By exploring the sociocultural dimensions of agency—or, from our earlier definition in the introduction: the dynamic patterns of shared values and norms of cultural systems, both past and present, that extend and limit (i.e., empower and constrain) individual and collective actions—we do not mean to suggest that people, for whatever more proximal or localized powers over their actions they possess, are from a broader, societal level passively tossed about by the cultural and historical currents that envelop them. Certainly history and culture have an impact on human life, but like Elder-Vass (2010) and other social scientists (e.g., Archer, 1996, 2000; Giddens, 1984; Loyal & Barnes, 2001), we take the position that acknowledging human agency is still compatible with social influences on individual behavior: "Human action may be affected by social causes without being fully determined by them" (Elder-Vass, 2010, p. 87). But even beyond such claims, we have argued that human agency is unique because persons are at the nexus of biophysical and sociocultural constitutive forces that also empower them to act according to their own wills, even if will here must be conceived in psycho-social-relational terms. That is, human agency, or "the will," is always embedded in a complex system of relations (Bandura, 2001), making a person less about being "biologized, psychologized, or sociologized," as Lerner and Walls (1999) have remarked, "[r]ather, the individual is 'systemized'" (p. 13).

The systemized, or relational developmental systems view we hold offers an explanatory framework for reconciling claims about human agency with the sociocultural factors that also empower and constrain individuals' actions. Our view has much in common with Lerner and Wall's (1999) notion of *embeddedness*, or "that any level of analysis is reciprocally related to all others" (p. 11). It also has affinities with Bandura's sociocognitive views, which frames agency as *triadic reciprocal relations* (Bandura, 1989, 2006), or the system of "internal personal factors, in the form of cognitive, affective, and biological events, behavioral patterns, and environmental influences [that] all operate as interacting determinants that influence one another bidirectionally" (Bandura, 2001, pp. 14–15). As Bandura (2001, 2006) has gone on to argue, the implications of such multilayered, bidirectionality (←→) is that human beings—by monitoring their biological systems, receiving social feedback, and anticipating future outcomes—can effectively adapt their conduct and their environments to further enhance their agentive capabilities. Lerner and Walls (1999) take a similar position in recognizing that "individuals, in action with their changing context, [are] seen to provide a basis of their own development" (p. 9). Changes to these contexts may apply in more immediate and perhaps subjective ways, such as when individuals set an alarm clock to change their sleeping behaviors. They may also apply more collectively, such as when groups of people establish voting policies and procedures to further empower (or perhaps curtail) opportunities for sociopolitical change. What makes these claims particularly compelling, especially when applied to views about civic life, is that *human agents produce the conditions for their own agency*. Or, as Ratner (2000) has remarked, "Agency is only enhanced by enhancing social relations which constitute it" (p. 426).

Social Capital and Human Capabilities

The idea that human agentiveness is constituted in the currents and connections of human relationships suggests another important layer of meaning to the work of collective organizations and community agencies promoting various dimensions of civic life and the public good (e.g., education and health care access, career consultation and training, neighborhood safety and business opportunities, recreational services). Many beneficial human services and resources can be seen to flow from the collective efforts of such groups. But, another benefit or asset—one that is certainly hard to quantify or pinpoint—appears to be embedded in the relational networks themselves that these social organizations form. In sociological quarters, this asset has often been called *social capital* (Bourdieu, 1985), a way of characterizing the inherent positive value of particular kinds of social networks. Some of the benefits of social networks flow directly as private goods to individuals participating in those networks. For example, informal social networks are often useful to someone who is searching for a job. Other benefits of social networks are considered public goods. When communities are well organized with dense networks of neighbors, the neighborhood will experience lower crime rates, which benefits even those who do not live there.

As Portes (1998) has noted, the notion of social capital is not particularly new in sociology, having close affinities to the benefits of social life described in the seminal contributions of Durkheim and Marx. Still, the idea has gained import, especially in current day public policy circles, because of the compelling way it captures "positive consequences of sociability" in "nonmonetary forms . . . of power and influence" (Portes, 1998, p. 2). Just as we have described human agency, the power of social capital is relational in nature.

> Whereas economic capital is in people's bank accounts and human capital is inside their heads, social capital inheres in the structure of their relationships. To possess social capital, a person must be related to others, and it is those others, not himself, who are the actual source of his or her advantage. (Portes, 1998, p. 7)

Recognizing this relational power, particularly for the development of young people, Coleman (1990) has defined social capital as "the norms, the social networks, and the relationships between adults and children that are of value for the child's growing up. Social capital exists within the family, but also outside the family, in the community" (p. 334).

Although relationships are critical, social capital is not merely a matter of social bonding through shared norms and values (Bankston & Zhou, 2002). Increasingly, social capital is described in agentive terms, as a way of meeting goals and facilitating actions, both personally and collectively. "Social capital theory," according to Bankston and Zhou (2002), "envisages shared norms as part of the production of capital only insofar as the norms promote productive behavior" (p. 287). Accordingly, Coleman (1988) has also characterized social capital in terms of its function: "some aspect of social structures . . . [that] facilitate certain action of actors—whether persons or corporate actors—within the structure" (p. 98; see also Coleman, 1990, p. 302). Human action is moved to the foreground in such definitions of social capital, and the background becomes the "[s]ocial networks, relationships, and norms . . . the stages in the production of goal-oriented behavior" (Bankston & Zhou, 2002, p. 288).

Some of the definitional ambiguities about social capital, particularly whether normative structures or goal-directed acts should be prioritized, appear to be a holdover from the structure-agency debates in sociology. Such either-or divisions tend to cloud what should otherwise be obvious. Social capital, like human agency, is a relationally constituted process, not a material thing. As Bankston and Zhou (2002) have argued, "The tendency to confuse definition with causation is a consequence of confusing a process with a substance" (p. 289). Our claims about human agency are similarly process-oriented, but this makes the social-relational backgrounds in and through which human agency emerges—that is, those "stages" on which goal-oriented behavior take place, as Bankston and Zhou (2002) would say—all the more critical. This is especially the case when considering sociopolitical issues of governance and citizenship.

Human agency and autonomy is as much a function of individuals as their social conditions (Barber, 1984/2003). Taking a relational view, and emphasizing the coconstructive aspects of human thriving and civil society, Lerner (2004) has argued that agency hinges on "increasing consistency between an individual's behavioral attributes and those characteristics of personal and social functioning requisite for maintaining and enhancing developmental regulations associated with liberty" (p. 91)—the ideals of American democracy. Such a view emphasizing the sociopolitical conditions of democracy can be applied to social capital as well, such as in the influential work of Putnam (2001). Putnam's (2001) exploration of social capital and democracy in the United States led him to study the connections between social capital and educational achievement. Putnam (2001) found that revitalizing community life appears to be a prerequisite for improving American education. In addition, there is a strong correlation between social capital and educational performance, even stronger than that between socioeconomic or racial characteristics and educational performance. He argues that rather than blaming teachers, curriculum, young people, or school administrators, the actual "culprit for the educational misadventure of American youth over the past several decades may be the civic lethargy and social disengagement of American citizens" (p. 87).

Capabilities Approach and Agency

A similar point regarding the relation between education and democracy has been made by political philosopher Martha Nussbaum (2006). Her claims that "Nothing could be more crucial to democracy than the education of its citizens" (Nussbaum, 2006, p. 387) harkens back to the appeals of the founders of the United States when arguing for the creation of American colleges and universities.

> [N]othing is of more importance to the public wealth, than to form and train up youth in wisdom and truth. Wise and good [people] are, in my opinion the strength of a state: much more so than riches or arms, which under the management of ignorance and wickedness, often draw on destruction. (Benjamin Franklin, 1750, as cited in Harkavy & Hartley, 2008)

Nussbaum's (2006) appeals, however, are not necessarily aimed at just lending support to American democracy. Rather, they are directed more globally to concerns regarding human rights and development on an international scale. Nussbaum's arguments are part of the *capability approach*, a philosophical perspective pioneered by economist Amartya Sen (1992, 1999).

The capability approach has become influential over the past two decades as a normative framework for assessing social arrangements, social justice, equality, and quality of life, as well as for designing economic and public policies aimed at development (Robeyns, 2011). From a public policy perspective, it presents an alternative to the typical way of assessing the state of a nation based on financial income and economic growth, usually captured in numbers such as gross domestic product (GDP). The approach argues, instead, for a *people-centered* perspective of human well-being (Alkire & Deneulin, 2009), emphasizing assessment strategies that target health, education, nutrition, political freedoms, human security, and environmental sustainability. For this reason, the approach is understood as the basis for a theory of social justice, but also as an evidence-driven enterprise seeking empirical support for its arguments to reduce social exclusion and inequalities and to enhance global justice. According to Sen (1992), "A person's capability to achieve functionings that he or she has reason to value provides a general approach to the evaluation of social arrangements, and this yields a particular way of viewing the assessment of equality and inequality" (p. 5). As the central question behind such assessment, human agency becomes a clear focal point: "What is each person able to do and to be?" In other words, when evaluating societies on the extent to which basic human welfare and justice are being met, the capability approach takes each person as an end in themselves, "asking not just about the total or average well-being but about the opportunities available to each person" (Nussbaum, 2011, p. 18) for positive growth and to make choices. Within this approach, human development is fundamentally understood as “the process of widening people’s choices” (United Nations Development Programme, 1990, p. 9), not simply for the sake of increasing the number of choices individuals have, but as the basis for bolstering the general “quality” of human life (Alkire & Deneulin, 2009, p. 34). Expressions of agency must, therefore, strike a balance between the effective power of individuals and more collective responsibilities and commitments to others. Depriving others of choices, especially as a way to harm or humiliate, is not a form of agency in the capability approach. “Agency,” as Alkire and Deneulin (2009) note, “expands the horizons of concern beyond a person’s well-being to include concerns such as solidarity” (p. 37).

Social Responsibility and Empowerment

Acting out of concern for others’ well-being is not without pitfalls and unexpected negative consequences. Responsible agency does not erode the agency of others; rather, it should empower others. Individuals and organizations offer many charitable forms of humanitarian aid, especially in terms of food and shelter, to meet others’ most urgent and basic needs. But it can be argued that even the compassion behind these generous actions work against empowering others. As Sen (1999) argued, “people have to be seen . . . as being actively involved—given the opportunity—in shaping their own destiny, and not just as passive recipients of the fruits of cunning development programs” (p. 53). For this reason, Rao and Walton (2004) argued for a shift in social policies that diverge from emphasizing *equality of opportunity* to those that promote *equality of agency*—that is, from interventions where the underserved and marginalized are essentially powerless to “creating an enabling environment to provide the poor with the tools, and the voice, to navigate their way out of poverty” (p. 361). If properly designed, these environments can promote effective agency for everyone involved.

Still, to be successful in the creation of empowering environments, the philosophical outlooks behind both public- and private-sector humanitarian efforts, and perhaps even the meaning of citizenship, need to change. Most state-centered conceptions of social policy, as they currently stand at least, view citizens as *recipients* of state-delivered programs. By contrast, market-led versions of social welfare, originating in the private sector, tend to see clients as *consumers*. Arguably, consumers may participate by exercising choice from a range of services, but even here the level of agency is limited to the kinds of services being offered. Cornwall and Gaventa (2000) have argued for an alternative approach to social policy that treats citizens not only as “users or choosers, but more as active participants who engage in making and shaping” (p. 2) social policy and provisioning. Barnes (1999), in describing user groups in the disability rights field, has similarly argued that direct involvement of users in processes of decision making over public service provision “demonstrates their capability to be active agents ‘making and creating’ the services they receive, rather than simply consuming them” (p. 84). These further reaching claims regarding the centrality of civic agency in constructing social policy align closely with the views of the capability approach (see also Lerner, 2004, especially Chapter 5).

Citizenship and Educating for Democracy

Emphasizing agency, as the capability approach and others in the public policy sphere have done, raises important conceptual issues about the nature of participation, citizenship, and social policy itself. Cornwall and Gaventa (2000) have argued that the concept of social citizenship should be expanded to include not only concepts of social rights, but also of social responsibilities exercised through agency based on self-action and self-identity, and of social accountability achieved through direct forms of democratic governance. Following from this view, democratic participation is understood as a fundamental right of human beings. Lister (1998) argued, for example, that the

> right of participation in decision-making in social, economic, cultural and political life should be included in the nexus of basic human rights. . . . Citizenship as participation can be seen as representing an expression of human agency in the political arena, broadly defined; *citizenship as rights enables people to act as agents*. (p. 228; emphasis added)

Whether citizenship, on such a definition, really is best conceived as a basic human right, it should be clear that the social conditions needed to support citizenship are the same as those needed to optimize and sustain human agency. Moreover, such a view of citizenship returns us to our initial claim that human agents create the conditions for their own agency. They accomplish this not only by promoting, creating, and participating in democratic social structures and procedures, but also by ensuring that citizens are properly educated to engage in such participation (Bergan, 2005). Citizens, as Barber (1984/2003) has noted, are not born, "but made as a consequence of civic education and political engagement in a free polity" (p. xxix).

Democratic Engagement

Increasingly the role of education around the globe is being connected to notions of citizenship and social responsibility. This connection is evidenced by broadly construed programs such as the United Nations' "Global Education First" initiative (2012), which lists "global citizenship" as a main priority, or the Council of Europe (2007), which claims that higher education must lead to "preparation for life as active citizens in democratic societies" (cited in Bergan, Harkavy, & van't Land, 2013, p.16). In the United States especially, higher education was envisioned to promote democratic ideals and the skills of citizenship. Such a democratic vision, for instance, was part of Thomas Jefferson's rationale for founding the University of Virginia, and Benjamin Franklin's efforts at the University of Pennsylvania (Benson, Harkavy, & Puckett, 2011; Thomas & Levine, 2011). This vision also carries through to the seminal works of American pragmatist philosopher, John Dewey (1916), who argued that civil society is rooted in education, and in progressive educational leaders such as Boyte (2008, 2009) who asserted that the central aim of colleges and universities in the 21st century should be the development of civic agency.

Educating for citizenship, according to these views, describes a cultural stance, or a way of being and interacting, as opposed to the promotion of specific political platforms or agendas. In his discussion of the role that universities play in democratic societies, Ottersen (2013) claimed,"[Democracy] is about form rather than content" (p. 37), echoing a position taken by Dewey (1916) that democracy is "primarily a form of associated living, a conjoint communicated experience" (p. 93; see also Saltmarsh & Morton, 2011). As such, democratic education "presupposes mutual recognition and the acceptance of divergences of opinion, of the right to be heard, of the obligation to listen to others and of respect for common norms" (Ottersen, 2013, p. 37). Similarly, Boyte (2008) has claimed that civic education must emphasize the capacities of citizens to work collaboratively across differences such as partisan ideology, faith traditions, income, geography, and ethnicity to address common challenges, solve problems, and create common ground. Democratic citizenship is more than just making political decisions; it fundamentally means making a public life together. For this reason, educating for citizenship can be argued to have less to do with gaining knowledge about democratic institutions and elections, and more to with what American poet Walt Whitman called "the highest forms of interaction between men, and their beliefs" (cited in Mack, 2006, p. 149). "To be literate as a citizen," as former university president, Richard Morrill (1982), has stated, "requires more than knowledge and information; it includes the exercise of personal responsibility, active participation, and personal commitment to a set of values. Democratic literacy is a literacy of doing, not simply knowing" (p. 365; cited in Jacoby & Associates, 2009). In other words, democratic literacy is a form of human agency.

Community Service

This *literacy of doing*, as Morrill (1982) suggests, is one of the key reasons that democratic education is commonly tied to academically based community service (Benson et al., 2011, p. 63), or what is more popularly called *service-learning* (Brandenberger, 2006; Bringle & Hatcher, 1995; Rhoads, 1997). Service-learning is an instructional tool by which teachers utilize volunteer activities outside of the classroom to guide students' understanding of concepts specific to academic courses and disciplines. One characterization of service-learning suggests that direct experience or "contact" with challenging realities, as Kolvenbach (2000) says, has greater educational value than exposure to abstract "concepts"—that is, "When the heart is touched by direct experience, the mind may be challenged to change" (Kolvenbach, 2000). Perspectives on service-learning particular to the psychological sciences are increasingly available in the literature (Bringle & Duffy, 2006; Kenny, Simon, Brabeck, & Lerner, 2002; Sokol & Kuebli, 2011) and generally seen as rooted in the prominent psychological theories of Piaget and Erikson (Brandenberger, 2006; Youniss & Yates, 1997), as well as Dewey (Saltmarsh, 1996)—all significant contributors to our understanding of the development of human agency. The civic value of service-learning, though, has its clearest expression in work that attempts to integrate moral development with academic learning (e.g., Colby, Ehrlich, Beaumont, & Stephens, 2003; Youniss & Yates, 1997).

Even if academically guided volunteer experiences offer constructive avenues for democratic growth and the development of actively engaged human agency, the sociorelational dynamics of service contexts set important constraints on the development of civic agency. Returning to the notion of solidarity, or mutual empowerment, described by proponents of the capability approach, community service needs a backdrop that avoids casting students' activities as merely charitable acts. As Barber (1992) has remarked: "The language of charity drives a wedge between self-interest and altruism, leading students to believe that service is a matter of sacrificing private interests to moral virtue. The language of citizenship suggests that self-interests are always embedded in communities of action and that in serving neighbors one also serves oneself" (p. 249). Dewey (1908) also argued against notions of charity that assumed "the continued and necessary existence of a dependent 'lower' class to be recipient of the kindness of their superiors" (p. 348; cited in Saltmarsh & Zlotkowski, 2011, p. 63). Charity has a tendency to reinforce hierarchical power structures (i.e., "power over" others; see Kreisberg, 1992) and relational asymmetries (e.g., more skilled or competent, more financially stable, more social capital *versus* less) that fortify the distinction between self and other, and ultimately builds a split "us-versus-them" mentality. This view runs counter to more relational democratic forms of action aimed at seeking "the public good *with* the public, and not merely *for* the public" (Saltmarsh & Hartley, 2011, p. 20, italics in original). Civic agency against a democratic backdrop signals a form of solidarity that emphasizes "doing with" others. The basis of such relationships promotes mutuality, or relational symmetries, that breakdown differences between individuals and blur self-other distinctions (i.e., "power with" others; Kreisberg, 1992). The result is a communal perspective: We are all in this together.

In educational contexts in which community service is a salient part of the curricular experience, students are often surprised when instructors suggest that their volunteer efforts might run counter to democratic ideals and actually *disempower* people (Boyte, 2008). That is, volunteer efforts can sometimes erode the confidence and capacities of those being helped by individuals with so-called credentialed expertise. In the United States especially, many institutions have grown away from their original democratic purposes as they have become more focused on discipline-specific pedagogy and research. The result has been a growing technocracy, particularly among larger, research-oriented universities. Technocractic relations weaken civic agency (Saltmarsh & Hartley, 2011). "When [democratic] learning is absent, graduates come to understand themselves as detached experts providing service *for* people, not as citizens working *with* fellow citizens on public problems" (Boyte & Mehaffy, 2008, p. 3). Thus, human agency is undermined. As a way to counter these potentially negative consequences of community service, civic engagement programs have begun to incorporate notions of social justice (see Lerner, 2004; Lerner & Overton, 2008). These justice-oriented programs focus on teaching interpersonal relationship skills, such as learning to work with others with whom one disagrees, reading the political and cultural dynamics of settings, learning how to act in open-ended situations with no predetermined outcomes, respecting others' capacities for self-directed actions, and being responsible for one's own actions and accountability to one's peers (Boyte, 2008). By emphasizing social justice, the disempowering aspects of assisting others can be reversed, leading to more agentive outcomes.

CONCLUSION

The relational developmental systems conception that frames our views about human agency makes clear that the most basic form of agency is already present in the dynamic, self-organizing activities of living systems. From the earliest point in the development of persons, agency manifests in different forms and grows through the interrelations of various biopsychosocial functions. These functions can be organized into the general levels that we proposed in our introduction and elaborated throughout the main sections of the chapter.

- ***Biophysical agency*** constitutes the activities of a self-organizing system to regulate and sustain itself.
- ***Psychosocial agency*** constitutes the deliberate, intentional acts of a self-aware system to determine a course of actions and construct meaning from them.
- ***Sociocultural agency*** constitutes the dynamic patterns of shared values and norms of cultural systems, both past and present, to extend and limit (i.e., empower and constrain) individual and collective actions.

The most flexible and richest forms of agency seen in adulthood build from developmental processes evidenced throughout the life span: infants' sensorimotor and perceptual functioning, toddlers' symbolic representational and linguistic functioning, the child's self-regulatory functioning, and adolescents' and young adults' moral functioning. The outline we have offered here by surveying parts of the developmental literature provides some of the conceptual structure needed to frame a more robust relational developmental systems picture of how agency pervades human life, and yet through its diverse expressions and manifestations often eludes systematic study. We have acknowledged and drawn from the notable exceptions to our claim that agency is a neglected area of research. That is, the works of Bandura (1989, 2001, 2006), Brandtstädter (1998, 2006), Martin (2008; Martin et al., 2010), Russell (1996), and others have made significant contributions to our understanding of human agency and its development. We bypassed a thorough review of many of these particular contributions in order to draw together relevant theoretical perspectives and research findings that have not always been framed as part of the development of agency. This approach freed us to explore a diverse range of literatures, including many of the philosophical cornerstones that have influenced the psychological study of agency, and sometimes led away from a viable conception of human agency. Our approach has also allowed us to introduce relevant contributions from the literature on civic and democratic engagement, particularly as a way to better understand the importance of sociocultural expressions of agency and the social conditions that enable human agency to thrive. Lerner (2004) and his colleagues (e.g., Lerner et al., 2000; Lerner & Overton, 2008), in particular, have examined many of these social conditions, concluding that the democratic ideals of liberty, equality, and justice stand to promote youth development in the most positive and healthy ways, as well as coactively contribute to the growth of civil society.

In our review, we specifically emphasized the theoretical value of the *capabilities approach* (e.g., Nussbaum, 2011; Sen, 1992, 1999) to our understanding of human agency, especially at the sociocultural level of policy and program formation, and we began to illustrate programmatic efforts within higher education designed to promote engaged citizenship and democratic participation, that is, a sociocultural manifestation of agency. Different kinds of experiential learning, or service-learning (e.g., Bringle & Duffy, 2006; Kenny et al., 2002; Rhoads, 1997; Saltmarsh, 1996; Youniss & Yates, 1997), have not only been central to these educational efforts at colleges and universities, this active form of learning for individuals—or what some have called a *literacy of doing* (Morrill, 1982)—has direct ties to the development of personal agency, and clearly show ways that psychosocial forms of agency can be promoted and sustained through efforts directed at the sociocultural level. In short, service-learning, as well as other forms of community engagement, provide compelling and rich examples of the ways by which "individuals, in action with their changing context, [are] seen to provide a basis of their own development" (Lerner & Walls, 1999, p. 9)—or what we characterized as *human agents producing the conditions for their own agency*.

Agency, then, is woven throughout human experience. We see agency in psychosocial functions—from sensorimotor and perceptual to symbolic representational and linguistic, from self-regulatory to moral—that contribute to its growth over the life span. Moreover, agency is embedded in the fabric of sociocultural forms and practices as persons create the conditions to promote and sustain their own agency. Expressions of civic agency and the societal structures that support these expressions are just as critical, and relevant to a programmatic investigation of human agency, as manifestations of personal agency in toddlers' language development or experiences of planning in children's households. The relational developmental systems framework—and the biophysical, psychosocial, and sociocultural levels of organization—that we have adopted in this chapter should make expressions of agency more identifiable for future investigations, as well as allow us to draw out important parallels in the structures of agency that are organized at different functional levels. We conclude here by briefly noting one such parallel between the way Piaget (1954/1981) has described the psychological structure of the will, or personal agency, and Palmer (2011) has characterized the structures of engaged, democratic citizenship, or civic agency.

Piaget (1954/1981) claimed that the will is not a psychological faculty per se, but a process involving the coordination and integration of an individual's desires and personal values, operating in much the same way that perspective taking does in coordinating multiple points of view (see also Sokol et al., 2013). As an individual's will develops over time, these processes help to organize different, often conflicting, desires that are nevertheless held together in a dynamic tension made possible by the construction of higher-order values and principles. Palmer (2011) describes democratic citizenship in a similar fashion, or as "learning to hold tension creatively" (p. 71) in the many perspectives that are part of public life, in order to "generate a sense of personal voice and agency" and to further "strengthen our capacity to create community" (p. 45). As Parker (2011) argues, democratic forms of government are "designed not to suppress our differences but to keep the energy of their tension alive so that it [can] animate the body politic" (p. 75). This comparison suggests that democratic institutions and a citizen's participation within them hinge on a similar kind of creative tension that animates an individual's will. We believe that further explorations of personal and civic agency, as well as comparisons such as this one, stand only to enrich our understanding of the development of human agency more generally, and the particular ways that we can further empower ourselves and others.

REFERENCES 363

Socialization is the process by which individuals are socially guided to become competent members of their society and culture. More broadly, socialization is a process of cultural reconstruction by which individuals in each new generation are guided to construct some semblance of cultural continuity. The ecology of children includes multiple sources of social guidance such as parents, peers, schools, media, and emersion in the practices and social meanings of the surrounding culture (Kuczynski & Knafo, 2013). However, parents—including all primary caregivers acting in the role of parents—are regarded as the most important agents of socialization, who lay the foundations for the child's subsequent interactions with the world outside the family.

Prior to the 1970s, theories about the causal nature of social guidance in socialization tended to be linear and deterministic. Wrong (1961), for example, suggested that the focus on ideas such as conformity to social norms and roles and stable transmission of values between generations, evident in research at that time, assumed that society is much more integrated than it really is and that human nature is much more conforming and socialized than it really is. A turning point for socialization theory occurred when new ideas appeared that drew attention to the importance of child effects (Bell, 1968); the agency of the child (Rheingold, 1969); and bidirectional causal processes in parent-child interactions (R. M. Lerner & Spanier, 1978; Lewis & Rosenblum, 1974; Sameroff, 1975a, 1975b). It can now be argued that socialization is a process of constant adaptation and change throughout the life span. In childhood, change in the process of socialization is driven by both development of the child's skills, behavior patterns, ideas, and values, as well as change in ecological contexts in which self-regulation is required (McClelland, Geldhof, Cameron, Wanless, Chapter 14, this *Handbook*, this volume). In adulthood, change in social development is driven by the expectations and experiences of shifting life-span transitions and contexts, such as parenthood, marriage, and work. The parental role itself requires constant change and resocialization as parents adapt to the direct impact of having children as part of their environmental context (Palkovitz, Marks, Appleby, & Holmes, 2003) and as they adapt to life transitions as well as social changes in the surrounding culture. Thus, socialization is a phenomenon that involves not only continuity and conformity but also change and the emergence of novelty. Parents often depart from the framework of their own childhood experiences and rear their children with values that differ from those that were acquired in their own socialization. Children and parents evaluate and may reconstruct for themselves behavior patterns and values different from those of the previous generation. It is the new emphasis on qualitative change and novelty that brings the study of socialization into the realm of developmental science.

During the unidirectional era, the parents' causal role in children's socialization was considered to be direct and uncontested (e.g., Sears, Maccoby, & Levin, 1957). Although many of the parenting variables, dimensions, strategies, and styles that continue to be discussed today were identified, this was an era that was more concerned with the outcomes of childrearing—catalogs of associations between broad parent variables conceptualized as antecedents and child variables conceptualized as outcomes. However, there was little research on the underlying processes of social interactions and continuous developmental and contextual change by which antecedents became transformed into child outcomes.

Kuczynski's (2003) review of the early socialization literature revealed a number of implicit background assumptions that supported a mechanistic and linear model of causality in parent-child social interactions. Kuczynski identified four such assumptions: a *unidirectional model of causality*, a *model of unequal agency* where parents were considered to be active and children passive in the process of socialization, a model of context that considered parents and children interacting as *separate unrelated individuals*, and a model of *static unequal power*.

In the parent-child relationship these background assumptions of socialization theory were gradually challenged and replaced. Important milestones along the way included the ideas of dialectical transaction (Sameroff, 1975a, 1975b), the idea of social interactions in relationship contexts (Hinde, 1979; Maccoby & Martin, 1983), and the idea of parents and children constructing and interpreting their interactions with each other (Grusec & Goodnow, 1994). In place of the unilateral assumptions, Kuczynski (2003) proposed a reformulated set of bilateral background assumptions—a *dialectical model of bidirectional causality*, considering parents and children as *equally agents, culturally embedded relationships as context* for parent-child interactions, and a model of *interdependent power asymmetry* in parent-child interactions. Kuczynski argued that these bilateral assumptions provide a better fit for understanding contemporary knowledge about the dynamic nature of parent-child social interactions.

Dynamic concepts such as bidirectional causality, contextual specificity, and child agency receive wide endorsement at the theoretical level (e.g., R. M. Lerner, 2006; Overton, 2006, Chapter 2, this *Handbook*, this volume; Sokol, Hammond, Kuebli, & Sweetman, Chapter 8, this *Handbook*, this volume). However, these ideas have not not been implemented to a significant extent in socialization research and practice. In a comment on the state of the socialization literature, leaders in the field (Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000) stated that textbooks, empirical studies, and popular opinion often continue to favor views of parental influence as linear and deterministic.

The parenting style literature presents an example of this linear deterministic approach to socialization. Baumrind's (1971) conception of *parenting styles*, a typology based on different combinations of parental control and parental warmth has dominated the socialization literature for 50 years. This work has drawn attention to an important pattern of parenting. However, Darling and Steinberg (1993) observed that despite consistent evidence that the authoritative style—parents who are warm but firm in the exercise of control—leads to competent children, the underlying processes of social interaction remained and remain unclear. Indeed, the constituent practices underlying the construct of *firm control* are still being debated (Baumrind, 2012; Farkas & Grolnick, 2010). Moreover, there is little conceptualization of *warmth* as a parenting practice or analysis of the causal role of warmth in determining the reported outcomes. Direction of effect has also been disputed. For example, Lewis (1981) argued that measurements of the authoritative parenting style conflated the parent's behavior with that of the child and left open the possibility that the parent's control style was an adaptation to children's preexisting dispositions for compliance. Stattin and Kerr (2000) found that parental knowledge of children's activities, which was once understood to be a consequence of the parental control practice of monitoring, is more strongly predicted by children's voluntary disclosure to parents. Extending their analyses of the child-influenced measurement of parental knowledge to parenting styles Kerr, Stattin, and Özdemir (2012) found that measures of parental control that focused only on parental behavior resulted in weaker association with adolescent adjustment than traditional measures of control that include items based on parental knowledge. Moreover, adolescent behavior predicted changes in parenting style, and these child effects were stronger than parent effects.

Research on parenting styles is an example of a literature where there has been an imbalanced focus on the predictive utility of abstract variables to the detriment of an understanding of underlying process. Correlational research, including, structural equation modeling, is useful in identifying associations between broadly conceived parent and child variables but does not illuminate the intervening processes of social interaction and relationship formation that underlie abstract measured variables. Moreover, the implied static, decontextualized conceptions of parental behavior and linear notions of their effects are simply not valid (Holden & Edwards, 1989). Accumulating additional correlations between child outcomes and decontextualized parental behaviors has limited usefulness for advancing knowledge on the process of socialization (see also Peterson & Bush, 2012). The challenges are conceptual and no amount of statistics will advance knowledge without commensurate innovations in the conceptualization of variables and processes.

Implementing dynamic developmental models of socialization is difficult because it requires a knowledge translation process between different levels of theoretical analysis including: worldviews, ontological/epistemological frameworks, substantive theory, and models and variables developed for particular areas of enquiry. Ideally, substantive theory should guide the choice of methods for collecting data and the constructing of empirical findings. However, even this depiction of knowledge translation is limited because it considers only the case of the scientist creating knowledge for its own sake. Another level of analysis, is knowledge translation to the level of practice which, in the ideal of the science practitioner model, the therapist, social worker, or service provider looks to research for practical guidelines for assessment, and intervention.

Researchers who work at different levels of analysis, metatheoretical, theoretical, empirical, and applied are often different people with different interest in engaging in abstract concepts. This situation creates a potential for gaps in knowledge translation between the levels of analysis. Theoreticians working at the metalevel of overarching frameworks may or may not engage the interest of empirical researchers and may use terminology based on a background knowledge that is not shared. This lack of translation makes the ideas inaccessible to researchers when connections to specific phenomena have not been made explicit. In turn, empirical researchers may or may not influence the work of practitioners. Applied scientists often have little use for the theoretical concepts and the findings of empirical research. This is because empirical research often produces findings whose meaning is rendered abstract by research designs that require aggregation of variables and generalization to populations rather than individuals or social relationship who are the real-world context of practitioners (Smedslund, 2009). Abstract concepts and findings offer little direction when applied to clients who are agents who make choices about what they want therapy to look like, what homework they are willing to do, and whose reality is highly contextualized and arises from diverse experiential histories.

Success in the flow of knowledge translation requires scientists who have a foot in each of the adjoining levels of theoretical analysis such that knowledge flows in both directions at each level. There is a need for research efforts that translate metatheory to the study of substantive phenomena or to translate the products of substantive theory and empirical findings into a form that can be communicated to or applied to real people in real-life circumstances. The goal in this chapter is to propose such a translation from metatheoretical metaphors based on dialectics to substantive theory (the dialectical/transactional approach of social relational theory) to implications for applied practice.

TWO METAPHORS FOR SOCIALIZATION: THE ONE-WAY ARROW AND DIALECTICS

Metaphors have been and continue to be foundational in scientific theories and models constructed for the purpose of understanding socialization and parent-child relationships (Kuczynski, Lollis, & Koguchi, 2003; Overton, 1991). The approach to metatheory in this chapter is to examine two underlying metaphors of process in socialization research, the one-way arrow → and dialectics ←→. The one-way arrow, which corresponds to a *mechanistic* ontology that considers phenomena in terms of decontextualized behaviors, passive reactivity, continuity, and linear outcomes (Overton & Reese, 1973). The conception of *dialectics* in this chapter is consistent with the organismic-contextualist conception of Dynamic Systems Theory (Witherington, 2011, Chapter 3, this *Handbook*, this volume) as well as the Relational-Developmental-Systems approach (R. M. Lerner, 2006; Overton, 2013, Chapter 2, this *Handbook*, this volume; Overton & Lerner, 2012) that emphasize dynamic coaction that characterizes the relations among components of any system.

Early socialization research was influenced by the one-way arrow metaphor (i.e., parent → child) that reflected cultural ideas of parents as shapers of children's development (Kuczynski et al., 2003). Research associated with the one-way arrow tended to conceive of parents and children as static bundles of traits that behave in predictable, unchanging, and consistent ways, and analyses of parents and children, respectively, as agents and objects or causes and effects.

The mechanistic conception of socialization was preserved in early models of bidirectional influence between the parent and the child during social interactions. Sears (1951) conceived of social interactions as an interconnected series of stimulus–response sequences in which each person's behavior was simultaneously a reaction to the other's previous behavior and a stimulus for the partner's subsequent response. These exchanges have been conceptualized in various ways. A child may reciprocate a parent's smiles or irritable responses with smiles or irritable behaviors of their own; a parent may soothe a crying child in the manner of a homeostatic control system (Bell & Harper, 1977), or a parent and child may reciprocally provide contingent negative reinforcement for each other's coercive behavior (Patterson, 1982). Empirically such models translate into an emphasis on continuity or additive, incremental change over time, instead of transformation; impact of early experiences, instead of adaptation; and transmission and shaping instead of construction and problem solving.

The principal alternative metaphor in psychology is dialectics (Overton, 2006, Chapter 2, this *Handbook*, this volume; Valsiner, 2012). Dialectics is a metatheory about the dynamic nature of all phenomena. All phenomena and every process consist of an opposing system of forces that actively relate to produce continuous qualitative change. This basic idea of dialectics has appeared in Western and Eastern cultures throughout history and has been communicated in a variety of metaphors. For example the "thesis–antithesis–synthesis" metaphor suggests that the mind recognizes an inherent contradiction in ideas and in the struggle to overcome the resulting tension, forms a new synthesis that temporarily resolves the contradiction in a novel way. Similarly, the yin-yang, ☯, metaphor from Chinese philosophy describes how polar opposites or seemingly contrary forces are inherently interconnected and interdependent in the natural world, and how they give rise to each other in the process of relating. Overton (2006, Chapter 2, this *Handbook*, this volume) interprets dialectics as described, but includes several subsumed concepts such as the *embodied mind*, which captures the behavioral, symbolic, and biological nature of individual functioning in a relational context.

The metaphor of dialectics conveys a view of causality that is more complex but more realistic and experientially recognizable than the metaphor of the decontextualized, one way, cause → effect arrow metaphor commonly used in socialization research. Dialectics draws attention to ideas of context, change, and nonlinear synthesis. This approach is a metaphor that is better fitted to modeling lived experience. A popular website, Dialectics for Kids (http://home.igc.org/-venceremos/index.htm), argues that dialectical processes are so pervasive that they are the basis for the everyday understanding of physical, biological, and psychological phenomena and that even children can quickly grasp the ideas.

> Dialectics is a tool to understand the way things are and the way things change. Understanding dialectics is as easy as 1–2–3. One-Every thing (every object and every process) is made of opposing forces/opposing sides. Two-Gradual changes lead to turning points, where one opposite overcomes the other. Three-Change moves in spirals, not circles. (What the Heck is Dialectics? http://home.igc.org/~venceremos/whatheck.htm)

Dialectical ideas are present in all *organismic* approaches (e.g., Overton, Chapter 2, this *Handbook*, this volume; Overton & Reese, 1973) and are implicit in theories and research that emphasize the importance of human agency and in the process of meaning construction. These domains of scholarship include research on social cognitions in social and developmental psychology, relationship theories, attachment theory, and ecological theory (Glassman, 2000). In short, aspects of dialectics have had an important impact on psychology but the origin of the ideas in dialectics have not always been explicitly acknowledged or comprehensively unpacked for use in research and practice. Constructivism (Smetana, 2011), social constructionism (Morrow, 2003), and social cognitive theories (Grusec & Goodnow, 1994) share with dialectics the core assumption of human agency, even if they are not comprehensive or consistent in considering the full implications of a dialectical approach. Advances in these areas can be made with a more complete implementation of a dialectical perspective within a transactional model of socialization.

There are alternative approaches to dialectics and different systems have drawn on different features of the dialectic concept as well as fundamental conceptual differences. Reese (1982) distinguished dialectical idealism from dialectical materialism. In dialectical idealism syntheses are conceptualized as states of continuously better integration as contradictions are resolved. An example is Piaget's stage theory of cognitive development. Dialectical materialism assumes that there is no "ideal" state toward which synthesis progresses. Examples include contextualist dialectics in personal relationship theories (see Baxter & Montgomery, 1996, for a review). Contextualism focuses on action in the here and now, and on contradictions that appear in those acts. The approach to dialectics in this chapter is contextual-organismic in nature (see Overton, 2006, Chapter 2, this *Handbook*, this volume; Witherington, Chapter 3, this *Handbook*, this volume). This approach is integrative and while asserting the importance of holism and contradiction, includes a focus on the developmental implications of the concept of *synthesis*. Synthesis is a critical concept for understanding nonlinear outcomes that result from the coactions of contradictory components in the whole.

The Transactional Model

The *transactional model* of development proposed by Sameroff (1975a, 1975b, 2009) is a model of qualitative change. Children and the environment are engaged in continual transformation as each responds to new emerging characteristics of the other (see Figure 9.1). According to

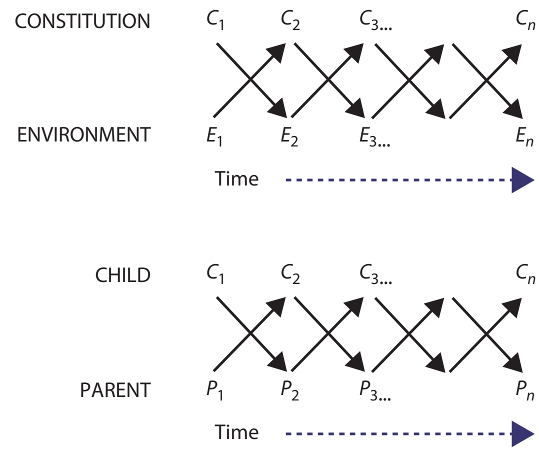

Figure 9.1 The original transactional model and its adaptation for parent-child transactions.

Source: From "Early Influences on Development: Fact or Fancy?" by A. Sameroff, 1975, *Merrill-Palmer quarterly*, *21*, pp. 267–293. Copyright © 1975 by the Wayne State University Press. Reprinted with permission.

Sameroff (1975b),"The child alters his environment and in turn is altered by the changed world he has created" (p. 281). Sameroff (1975a) asserted that the underlying process of the child's transactions with the environment was dialectical in nature. "In every developing system, contradictions are generated and it is these contradictions which provide the motivation which lead the organisms to the higher level of organization found in developmental series" (p. 74). The innovation in the transactional model concerned the qualitative transformations occurring in the parent and the child over time. Conceptually, the model anticipated current dynamic systems approaches that emphasize the dynamic nonlinear and mutually constitutive relations between the individual and its context (Overton, 1975, 1991).

Despite the importance of the transactional model for consolidating the idea of bidirectional influence, few researchers have taken up the challenge of Sameroff's dialectical conception of transactional processes. Instead, most have interpreted the parent to child and child to parent directions of causality as discrete arrows, which lead to a conception of bidirectionality in terms of reciprocal exchanges of behaviors (Kuczynski & Parkin, 2007). For example, in social interactional theory (Patterson, Reid, & Dishion, 1994) bidirectional influences are linear and the elements are not changed by their experience with other elements.

A major concern of the transactional model was to improve prediction of both child and parent outcomes (Sameroff & Chandler, 1975). In the original depiction of the model presented at the top of Figure 9.1, Sameroff

(1975b) highlighted the child's temperamental constitution and its dynamic relation to the distal environment such that both the environment and the child were equally important in the process of mutual transformation. However, as noted by Sameroff (2009), the compelling examples of the role of contradiction in microsocial transactions occurring between parents and children promised to illuminate the understanding of underlying proximal socio-emotional processes. When applied to parents and children (Figure 9.1, bottom) the location of the transaction was the change in meaning that occurred as parents and children attempt to make sense of the contradictions generated by their interaction. As stated by Sameroff (1975b):

> The contradiction that has occurred consists between a meaning system which sees the child as an object to be manipulated, and one which sees the child as a center of needs and desires existing independently of the needs and desires of his parents. . . . The dialectical model would posit at each stage the contradictions with which the mother is faced in trying to understand her child. (p. 77)

More generally, contradiction and qualitative change occurs whenever an individual changes a representation of an event causing the individual to think or act differently than before the change (Sameroff, 2009). Although this conception shares assumptions with symbolic interactionism (Mead, 1934) about the capacity of human agents to interpret each other's behaviors, it added dialectical assumptions concerning the role of contradiction is producing qualitative change.

Despite introducing a dialectical model for understanding social transactions, Sameroff did not fully explicate how an organismic-contextual model of dialectics can inform assumptions about parents and children and the processes by which they relate to each other. The dialectical transactional model was ahead of its time and required a framework of supportive theoretical models and empirical knowledge regarding parent-child relationships. This chapter outlines a social relational theory perspective to explore how reformulating conceptions of context, antecedents, processes, and outcomes using dialectical conceptions of transaction supports the study of dynamic parent-child socialization processes as well as provides direction for clinical application. The chapter uses the core idea of transaction (Sameroff, 1975a, 1975b) as a building block for new applications of the model for understanding the dynamics of parent-child relationships, and the nature of bidirectional influences that occur during transactions.

Social Relational Theory

During the past decade, Kuczynski and colleagues (Kuczynski, 2003; Kuczynski & Parkin, 2007, 2009; Kuczynski, Pitman, & Mitchell, 2009) have been developing social relational theory as an open-ended dialectical framework for studying socialization processes in the family in a more dynamic way than was possible under mechanistic assumptions of socialization. In social relational theory, parents and children are considered to interact as human agents as components of a culturally embedded social relationship. A distinctive feature of social relational theory is that it places equal emphasis on the perspectives and actions of children as well as those of parents. In addition, parent and child agency is understood using the principle of *holism in a dialectical context*. Thus, although the model draws attention to the separate goals and interpretations of parents and children, both parents and children are assumed to cope with or resolve conflicting views because they share a continuing interdependent relationship. The model also assumes a dialectical concept of causality that is interpreted through the dialectical metaphors of contradiction and synthesis. Contradictions give rise to uncertainty that creates opportunities for novel syntheses, which sets the context for further developmental change. Dialectical bidirectional influence ←→ comes about during social transactions as parents and children interpret or construct meanings from each other's behaviors and resist, negotiate, and accommodate each other's perspectives within the constraints of their relationship (Kuczynski & Parkin 2007). This concept of causality is consistent with other complex models of causation, including *reciprocal determination* (Overton & Reese, 1973), *fusion*, (Greenberg, 2011; Partridge, 2011), *relational bidirectional ←→ causality* (R. M. Lerner, 2006), *relational ←→ causality* (Gottlieb & Halpern, 2002; Overton, 2006, Chapter 2, this *Handbook*, this volume), and *circular causality* (Witherington, 2011, Chapter 3, this *Handbook*, this volume).

The discussion in this chapter is limited to bidirectional ←→ influence in parenting as it pertains to children's development. However, an implication of the transactional model is that the act of parenting is also a driver of the parent's continuing adult development and socialization. The argument is that people who become parents, have children as part of their environment, and are involved in the bidirectional childrearing process, follow a different developmental trajectory than people who do not engage in parenting roles (Palkovitz et al., 2003). Having children in parents' environment has a massive impact on all aspects of parents' lives, and their outcomes as individuals (Ambert, 2001; De Mol & Buysse, 2008a).

In the next sections, each dialectical concept is described at the level of dialectical metatheory and this is followed by translations of its implications for research on socialization and parent-child relationships within social relational theory. A subsequent section considers the implications of a social relational theory for clinical interventions in families.

HUMAN AGENTS: THE INTERACTING COMPONENTS IN THE DIALECTICAL WHOLE

The nature of a phenomenon in dialectics is an ontological question that is dependent on the specific subject matter. For the phenomenon of socialization in the family, the question is whether parents and children should be regarded as living, active agents coacting as components in a long-term relationship context, implying an organismic-contextual ontology, or should they be regarded as inert, passive objects whose properties are independent of context, implying a mechanistic ontology. *Agency* refers to the active contribution of human beings as components–parts—of a complex dynamic causal system. The parts of a holistic, dynamic, dialectical system are inherently active, self-organizing, self-regulating, and change independently of external forces. In fact, the very definition of self-organization is "a process of creating structure and order without explicit instructions or guidance from outside" (van Geert, 2003, p. 654). In contrast, the elements of a mechanical system—defined as an aggregate of elements—are inert, and change only when some external force or efficient cause is applied.

Social relational theory makes a number of stipulations as a complex starting point for conceptualizing agency in parent-child relationships. First, parents (or caregivers) and their children are equally human agents with inherent capacities to make sense of the environment, initiate change, and resist domination by others. Second, although parents and children are equally agents, they are unequal in power. Third, the dynamics of parents' and children's agency and asymmetrical power must be understood in the holistic context of their mutual relationship. This complexity reflects a considered attempt to transcend historical problems regarding agency as a theoretical construct. As reviewed by Kuczynski (2003) these problems include the narrow disciplinary or topic-bound definitions of agency; uneven attribution of agency to parents and children, cultural barriers to the perception of children's agency; and insufficient analysis of the relation of agency to other concepts such as "influence" and "power." The following sections emphasize the perspective of children's agency because it is children's agency that historically has been discounted in the socialization literature. Subsequently, the implications of considering parent and child agency in parallel are discussed.

Universal Manifestations of Agency

The universal aspect of agency refers to the ontological assumption that to be human is to be an agent. People are intentional, self-organizing, proactive, self-regulating, and self-reflecting organisms who actively contribute to their life circumstances (Bandura, 2006; Deci & Ryan, 2002, Overton, Chapter 2, this *Handbook*, this volume) and the foundations for agency are present at birth. Analytically, agency can be partitioned into three aspects *autonomy*, *construction*, and *action* (Kuczynski, 2003). However, in practice, these aspects represent motivational, cognitive, and behavioral features of agency that are coordinated in a single process. Individuals construct because they act, and autonomy motives reflect and protect the individual's inherent need to function as agents.

Autonomy

Autonomy is the motivational aspect of agency and refers to a universal motive for self-determination and self-preservation. *Self-determination* refers to the system of basic human needs for competence, relatedness, and autonomy as described by self-determination theory (Deci & Ryan, 2002). Needs for feeling effective in one's ongoing coactions with the social environment, for feeling connected to caring for and being cared for by others, and for perceiving that one is the origin or source of one's own behavior even when actions are influenced by outside sources, are inherent characteristics of being human. Fulfilling these needs are essential for growth, an integrated self, and psychological well-being. *Self-preservation* is the motive that results when a person's ability to fulfill his or her needs is blocked or thwarted in areas and contexts that matter to the person. An important manifestation of self-preservation is resistance (Brehm & Brehm, 1981). When people experience threats to their behavioral freedoms, experience impositions of meanings or standards that contravene their self-constructed understanding of social situations (Turiel, 2010, Chapter 13, this *Handbook,* this volume), or perceive injustice, they attempt to restore their autonomy through overt and covert resistance. Even in contexts of extreme oppression, where it is not safe to resist overtly, people express resistance in indirect, covert, and creative ways (Scott, 1990). The idea that resistance is a manifestation of autonomy development is found in classic theories of toddler negativism (Wenar, 1982). However, parallels between phenomena of toddler negativism and resistance in adulthood suggest that although its form may change, resistance is a continuing theme in development throughout the life span (Kuczynski & Hildebrandt, 1997).

Construction

Construction refers to the capacity of parents and children to interpret their coactions with the environment and to create new meanings from their experiences. The construction of meaning necessarily entails both emotions and cognitions. This inclusive definition of construction is informed by the concept of *embodied action*, the idea that people are active agents with a particular kind of lived body (Andersen, 2007; Overton, Müller, & Newman, 2008). Embodiment refers "not merely physical structures, but *the body as a form of lived experience, actively engaged with the world of sociocultural and physical objects*" (Overton, 2006, p. 48). The *body as form*, represents the holistic integration of the biological dimension of life, the *body as lived experience actively engaged* represents the integration of the psychological person, and the *body actively engaged with the world* points to the integration of the sociocultural and physical context. Thus, embodiment entails the synthesis of how we, as active agents (psychological persons), influence and are influenced by our biological and sociocultural worlds.

During the 1990s, developmental researchers began to adopt a view of children as actively constructing their knowledge and values in the process of socialization (Grusec & Goodnow, 1994; Kuczynski, Marshall, & Schell, 1997; Lawrence & Valsiner, 1993; Smetana, 2006). All internalized products of socialization, even that of intergenerational similarity must be constructed by children from the messages and reactions presented by their social context. Parents are active in packaging the message so that children can accurately interpret and accept the parent's perspective (Grusec & Goodnow, 1994). However, the constructive capacities of children places limits on parental influence. Both the interpretation and the acceptance of the message ultimately depend on the child's agency.

According to *social domain theory* (Smetana, 2006; Turiel, Chapter 13, this *Handbook*, this volume) children make sense of social situations by interpreting received messages, and acting on these interpretations. In this way the child constructs distinctions among various domains of values including those that are moral (avoiding harm, justice, equal treatment fairness), conventional (situation specific standards of appropriate behavior), prudential (safety and well-being), and personal (preferences). They also develop different modes of reasoning to work through conflicts and dilemmas and use principled rationales to defend their positions on future occasions. Further, according to the social domain position, to the extent that parents provide domain-appropriate information and use domain-appropriate socialization strategies they may promote their children's moral development. Lawrence and Valsiner (1993, 2003) argued that the potential for innovation occurs not only as children internalize social messages but also as they apply (externalize) their constructed knowledge for their own purposes in the social world. Through the child's interpretation of the social context and through their appropriation of these meanings for their own purposes, personal sense is given to the ideas, messages, roles, and relationships that pertain to the person's culture.

Action

To act, "means being able to intervene in the world or to refrain from such intervention, with the effect of influencing a specific process or state of affairs" (Giddens, 1984, p. 14). The term *action* is used in preference to behavior because emphasizes the guidance of behavior by internal processes including meanings, intentions and goals. Following Brentano (1874/1995), all acts, even those occurring at the most sensorimotor level of functioning, intend some object; thus, all acts are intentional. However, this fact does not mean that all acts are self-consciously intentional. People may be unaware (i.e., lack self-conscious or symbolic intention) of the reasons for their choices (De Mol & Buysse, 2008a), or for the meanings underlying their emotional responses (Patterson et al., 1992) during social interactions.

Updates on the growing understanding of the actions and strategies that children use to influence parents have been presented with regularity in research reviews over several decades (e.g., Grusec & Goodnow, 1994; Kuczynski, 2003; Maccoby & Martin, 1983). The new discoveries generally take the form of learning to "see" agency in what was previously perceived as passivity, reactivity, or submission. Thus, young children's nonverbal behaviors such as smiles and cries (Rheingold, 1969) or their approach and avoidant attachment behaviors in stressful situations (Cummings & Schermerhorn, 2003) have been reinterpreted as actions that reward and punish parental behavior. In other instances, agency has been located in phenomena were the child was previously conceptualized as passively complying with parental control. For example, Kochanska, Kim, and Boldt's (2013) research on children who are receptive toward the parent's agenda or complied willingly to parental requests indicates that agency can occur within compliance. As well, Stattin and Kerr (2000) found the sources of parental knowledge of adolescents not in parental control through monitoring and surveillance but through children's voluntary self-disclosure.

Research on parental discipline is especially compelling in revealing children's agency because disciplinary encounters are contexts where parents are assumed to have more power to set agendas and enforce outcomes (Hoffman, 1975). Children have been found to influence parents in all phases of the discipline encounter. Depending on the issue, children may challenge parents about the definition of the transgression, for instance, whether the behavior is under the jurisdiction of the parent or the child (Smetana, 2006). Children between the ages of 2 and 5 develop strategies that are increasingly assertive and skillful for challenging parents in overt conflict (Kuczynski & Kochanska, 1990). In middle childhood and early adolescence, children effectively use their own coercive strategies to evade or sidetrack the parent's ability to enforce compliance and to intimidate parents into avoiding future confrontations (Patterson, 1982). They also show a growing complexity of overt and covert strategies for resisting unwelcome parental requests and for achieving their own goals (Kuczynski, Pitman, Parkin, & Rizk, 2011). Parkin and Kuczynski (2012) found that adolescents express overt resistance assertively and engage in an array of covert forms of resistance when they wish to avoid confrontation. For example, they may comply with parental requests in a minimal way following the letter, but not the spirit, of parental requests. Alternatively, they may behaviorally comply, but cognitively reject the parents' message (Parkin & Kuczynski, 2012). Adolescents strategically manage parents' knowledge of their activities and whereabouts, thereby undermining parents' ability to intervene in aspects of their lives that children wish to keep private (Smetana, 2011; Tilton-Weaver & Marshall, 2008).

Individual Differences Supporting Exercise of Agency

There are also individual differences, originating in biology, experience, and context that affect the quality of expression and effectiveness of agency. For example, the concept of embodiment (Andersen, 2007; Overton et al., 2008) suggests that each individual has a qualitatively unique style of expressing agency comprised of characteristic patterns of action and ways of interpreting the environment, and unique concerns and intensities regarding their experience of autonomy. Thus, concepts such as "personality" or "temperament" can be reframed as reflecting embodied qualities in the expression and experience of agency.

Individual differences in the expression of agency can also be considered as reflecting differences in *interpersonal power resources* (French & Raven, 1959). Although all humans are agents, they differ in the resources that they have to support their actions as agents. (See J. Lerner et al., 2012; R. M. Lerner, Lerner, Bowers, & Geldhof, Chapter 16, this *Handbook*, this volume; Overton, 2010, Chapter 2, this *Handbook*, this volume, for further discussions of system resources.) Stated in another way, parents and children are equally agents but they are unequal in power. Conceptualizing power as resources allows a dynamic and nuanced assessment of the assets that parents and children bring into their social interactions with each other. Kuczynski (2003) described three categories of power resources that pertain to both parents and children: individual, relational, and cultural.

1. *Individual resources* include the capacities to back up or resist influence attempts with physical strength and capacity to reward. Individual resources also include expertise, information that can be brought to bear in rational arguments, as well as the capacity to think ahead, and to set goals.
2. *Relational resources* are an individual's access to personal relationships as a support for their exercise of agency. This happens when individuals can enlist the aid of others to act for them when they cannot exert direct influence or when they act collectively to achieve goals that are beyond the scope of individual action (Bandura, 2006). In the sociological literature a parent's or child's personal relationships in the family and outside of the family is an important component of the concept of *social capital* (Morrow, 1999). An example of a parent's use of relational resources includes acting with a spouse in a parental alliance or accessing social supports such as friends and community relationships to achieve a socialization goal. Children's effectiveness as agents is greatly enhanced by relational resources. For example, children rely on their relationships with parents to

obtain social and material resources for themselves as well as access to other resources under the parents' control. They may also enlist the support of parents to intercede for them with their siblings, or with peers, teachers, and mentors outside of the home.

3. *Cultural resources* refer to the rights, entitlements, and constraints conveyed to individuals by the laws, customs, and practices of a culture. For example, parents draw from culture their legitimate authority to define certain of their children's actions as "misbehaviors" and to set and enforce compliance to their rules. Culture may also be an important source of the child's power. Western culture is notable for recognizing numerous rights of children for appropriate standards of care, rights to education, freedom from maltreatment, as well as providing norms for expression of autonomy. Such norms constitute resources that legitimize and enable children's power and puts constraints on the kinds of power that parents can exercise over children. In cultures where children are accorded fewer rights or other resources, children continue to act, interpret, and resist as agents, but their effectiveness as agents will be diminished and the way they express their agency will take qualitatively different forms that are afforded by their cultural context.

Assumptions About Unequal Power and Causality

The assumption that power between parents and children is unequal or asymmetrical is fundamental to any understanding of parent-child relations. Parents have more knowledge, physical strength, control over resources, and their legitimate authority is endorsed by culture (Maccoby, 2000). Although asymmetrical power in parent-child relationships is indisputable, the argument that parents have more power than children has been a conceptual barrier preventing deeper acceptance of such concepts as bidirectionality (←→) and the significance of the agency of the child. For example, in response to a growing literature on child effects, Hoffman (1975) used the argument of unequal power to reinstate a unidirectional interpretation of causality in socialization. His argument was that, child influence notwithstanding, parents *must* have more influence because parents have more power to back up their roles as influence agents than children.

Kuczynski (2003) acknowledged that there is unequal power between parents and children but questioned implicit conceptions of unequal power as a fixed imbalance in resources that determined the direction of causality in a mechanistic way (i.e., more power is equated with greater causality). A static conception of asymmetrical power is not useful for understanding many ordinary phenomena of everyday family life. Frequent parent-child conflict, child assertion and resistance, parental receptivity to children's influence, and parental vulnerability and loss of influence in families presenting at clinics (Kuczynski, 2003) suggest that parents do not exercise or experience power in a way consistent with a model of static asymmetry. Kuczynski (2003) proposed that unequal power in parent-child relationships can be conceptualized as a dynamic *interdependent asymmetry*.

- Power is a bilateral phenomenon such that both children and parents have individual, relational, and cultural resources to draw on to support their actions as agents. Because of their inherent capacities to engage in interaction and to provide rewarding and aversive responses to parental efforts (Rheingold, 1969), even infants have individual resources.
- The parent-child relationship is crucial in understanding the dynamics of power in parent-child interactions. The assumption is that power dynamics between persons in an interdependent long-term relationship differs from power relations between complete strangers (Kuczynski, 2003). For instance, parents and children can make predictions gained from knowledge regarding the others' personalities, preferences, and vulnerabilities gained in the long-term relationship (see holism: the systemic context, this chapter), and an implication of interdependence is that both parents and children are receptive and vulnerable to the others' influence. These power dynamics stem from their distinctive relationship context and are not available to unrelated dyads.
- The relative power inequality between parents and children is dynamically negotiated during social interaction. Porta and Howe (2012) found that the relative power between parents and children and the specific power resources used by them change according to context throughout the day. Moreover, the young child's immature self-regulatory capacities (Kopp, 1982; McClelland et al., Chapter 14, this *Handbook*, this volume) paradoxically place constraints of the kinds of demands that a parent can realistically make of their child and constrain parents to follow the pace of the child's capacities. The child's individual resources, including social skills, rapidly increase throughout development so power differentials in various resources will vary considerably across age. By adolescence, the individual's physical

strength, expertise in various areas (peer culture, use of technology), and persuasive skills may match or become greater than those of the parent.

The construct of interdependent asymmetry suggests that research should explore how various power resources enter into parent-child transactions to produce dynamic changes in relative power. Consistent with the dialectical perspective in social relational theory, transactions between individual, relational, and cultural resources in parent-child relationships create novel syntheses such that both parents and children are receptive and vulnerable to each other's influence.

Contribution of Agency Perspectives

A focus on human agency clarifies the causal contributions of parents and children to the process of socialization. Future research would benefit from a focus on questions regarding process: What does the child do and think regarding parental actions in different contexts, at different ages, and in relation to their different parents? These research questions require equal attention to what parents do and think with regard to children's actions. Considering parents and children as equally agentic can guide researchers to ask parallel questions about parent-child influence and agency. The same basic understanding of agency is also the best guide for research designed to explore the social strategies, goals, motives, and interpretive activities of both parents and children.

An enhanced focus on children's agency is a corrective strategy regarding the neglected aspects of children's actions and constructions in the process of socialization. Valsiner, Branco, and Dantas (1997) coined the term *filiating* to counter the unidirectional implications of *parenting* and to focus attention on the child's actions and perspectives in the parent-child relationship.

An enhanced focus on parental agency can also lead to a better understanding of what parents contribute to the socialization of children. According to Holden and Edwards (1989), parental behavior has not been studied in a way that illustrates parental intelligence. These authors argue that parental behaviors, dimensions, and styles have been studied in a static decontextualized way that is not consistent with what is known about the dynamic, relational bidirectional ←→ and situational specific dependency of parental behavior. "Typically, the surveys portray children as generic, parents as trait-like and unthinking, and parent-child interactions as unidirectional and a-contextual" (Holden & Edwards, 1989, p. 490). Moreover, the preponderance of research on parental behavior such as discipline has studied parents in a reactive mode, when children have already transgressed and parents have relatively few options in responding to a problem that has already occurred (Holden, 1985). This means that measurement approaches that focus exclusively on decontextualized discipline strategies do not give parents much scope to display intelligent behavior.

Examples of approaches that do shed light on parental intelligence highlight parental agency. Holden's (1985) conception of *proactive behavior* emphasizes parents' use of long-term or short-term future-oriented strategies that prevent problematic behaviors from occurring in the first place. Research on parental goals emphasizes the contextual nature of complexity of parental actions and the competing goals that they consider when responding to a child's transgression (Dix & Branca, 2003; Hastings & Grusec, 1998; Kuczynski, 1984). The concept of *meta-parenting* (Holden & Hawk, 2003) conceives of parenting as a process of problem solving and reflection, before during and after specific childrearing situations. In addition, models of *mindful parenting* (Duncan, Coatsworth, & Greenberg, 2009) promise to shed light on parental cultivation of intentional awareness to parent-child interactions thereby aiding their conscious self-regulation of their parenting actions.

Another direction for research to consider is the joint agency of parents and children in their transactions with one another. There is a need for concepts that consider parents and children interacting "as if" they recognized each other's agency, thus anticipating and accommodating each others' interpretive capacities, autonomy motives, and different perspectives. This would be a logical development in the history of socialization research that can be conceptualized as beginning with a unilateral perspective of agent/object relations, and moving to a bilateral perspective of parents and children engaged in agent-agent transactions. However, for a full dialectical perspective to be implemented, an additional step is needed: and that is to consider parents and children interacting as components in the holistic context of their shared relationship.

HOLISM: THE SYSTEMIC CONTEXT

The principle of holism refers to the systemic structure of phenomena in which interdependent parts or components always exist in a dynamic context. As conveyed by the yin-yang metaphor of unity of opposites, the structure of systems in dialectics is both complex and dynamic because systems contain contradictory components that coexist side by side in a tension-filled state. Moreover, the whole and its components are mutually constituted such that the components dynamically interact not only with each other but also with the context that they mutually make up. An important implication is that the *whole is different than the sum if its parts*. That is, individual components must be understood as interrelated parts of a whole system because neither individuals nor their social or physical environments are causal on their own.

It must be recognized that any system under consideration is part of a larger whole system of relations, each of which constitutes a different level of analysis. Whole and part are relative terms because wholes are embedded in larger wholes and the specific meanings of these terms change according to the context in which they are applied (Overton, 2006, Chapter 2, this *Handbook*, this volume; Wagoner, 2011). Biologists have long recognized that organisms are complex hierarchically organized systems, in which higher processes regulate lower processes. Gottlieb (1991) visualized the components of the system as interconnected bidirectional ←→ levels of analysis extending all the way down from individual behavior to neural activity and genetic activity and all the way up to the social environment and culture (see Figure 9.2). This bidirectionality is the reason that Gottlieb and colleagues (e.g., Gottlieb, 2003; Gottlieb, Wahlsten, & Lickliter, 2006) and others (e.g., Overton, 2006, Chapter 2, this *Handbook*, this volume) have argued that the concept *coaction* or *transaction* should replace the term *interaction* except when referring to statistics of the linear ANOVA model. There are continuous bidirectional ←→ influences between parent-child social interactions and physiological and neural process of parents and children (Bugental, Olster, & Martorell, 2003). Similarly, individuals in family relationships, peer relationships, and cultural contexts constitute overlapping systems that have properties that

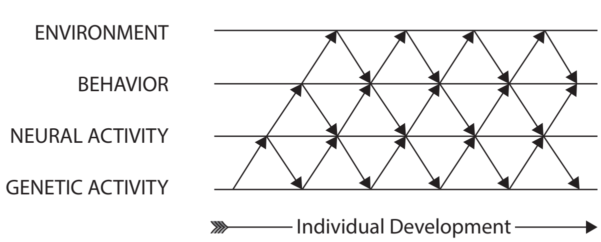

Figure 9.2 Bidirectionality joining biological to individual to social environment (Gottlieb, 1991).

cannot be reduced to the individuals within it. To make dialectical systems amenable to research, it is necessary to apply the principle of hierarchical organization (Wagoner, 2011) in which a given system is isolated for study while acknowledging relations to biological and cultural systems in which they are related.

HOLISM IN SOCIAL RELATIONAL THEORY

An important step in a dialectical analysis is to describe the structure of the whole, and the complex causal relations between the whole and its components. In social relational theory, the minimum level of analysis for the whole is the parent-child relationship. Socialization throughout the life span occurs within a system of close personal relationships (Reiss, Collins, & Berscheid, 2000). Different relationships, including relationships with parents, siblings, peers, teachers, and other adults (Piniata, 1999), come into salience as contexts for socialization as children develop. Thus, in selecting the parent-child relationship as a context for development it is important to recognize that it is a subsystem of a larger system of relationships that are relevant for the phenomenon of socialization.

The dialectical concept of the parent-child relationship as a systemic context departs from treatments of parents and children in unidirectional socialization research. The unidirectional parent-child socialization research tradition operates on the assumption of a decontextualized relationship of isolated interacting individuals. The dialectical research approach, on the other hand, conceptualizes a relational parent-child context of coacting agents embedded in an enduring, interdependent relationship. A classic example of the decontextualized approach is illustrated in the early behavioral model of parent-child interaction and parental management (Patterson, 1997) that focuses on the immediate reinforcement and punishment contingencies of behaviors exchanged in the present. Neglect of relationship context in theorizing about causality may help to explain why the idea of child influence as well as bidirectionality ←→ has met with resistance historically. It is only when one considers the special features of the parent-child relationship as a context for parent and child actions that the very idea that children influence parents despite differences in power makes sense.

Another example of the departure of the dialectical perspective from the traditional decontextualized perspective concerns the measurement of relationship attributes. The traditional approach considers relationship attributes (e.g., parental warmth) to be individual qualities whose linear associations to outcomes are studied. According to dialectical social relational theory, the parent-child relationship is not a static variable. Rather, it is a dynamic process that emerges from and contributes to the dynamics of social interactions. Parents and children are not only influenced by the relationship context but also construct the relationship through their coactions as agents. Phenomena such as enhanced bidirectional ←→ influence between parents and children, the experience and exercise of agency, and the dynamics of power, stem from the relationship context (Kuczynski, 2003; Kuczynski & Parkin, 2007).

WHAT IS THE PARENT-CHILD RELATIONSHIP?

A legacy of the traditional decontexualized approach is that there has been little analysis of the structure of parent-child relationships or of dynamics that emerge from the relationship as a whole. Instead, socialization research has traditionally been constructed around separate parenting functions such as control, teaching, caregiving, and attachment. There has been little attention paid to how these functions relate to each other within the parent-child relationship or the implications of the whole relationship context for the dynamics of parent-child interactions within each function of the relationship.

Dialectical social relational theory draws from general theories of personal relationships (Hinde, 1979; Kelley et al., 1983) and attachment (Bowlby, 1969), as well as the applications of these theories to the parent-child relationship (e.g., Collins & Madsen, 2003; Maccoby & Martin, 1983). Central to most theories is the distinction between a social interaction and a social relationship. *Social interactions* are discrete, moment-to-moment exchanges between individuals, whereas *social relationships* incorporate the psychological and historical context between two individuals beyond the immediate interaction. Two basic properties of the relationship are interdependence and time (Kelley et al., 1983). A relationship requires the *interdependence* of the relationship partners, the degree to which the behaviors, emotions, and thoughts of two people are mutually and causally interconnected. Thus, interdependence means that a close personal relationship must involve bidirectional ←→ influence. *Time* concerns the timeline of close relationships that endure and involve strong frequent and diverse interconnections over time. Hinde's (1979) theory of relationships elaborated the process by which relationships are constructed out of a history of interactions. As dyads accumulate a history of interactions over time, they form relationships, and the emergent relationship subsequently becomes context for future interactions. Hinde and Stevenson-Hinde (1987) describe the process in this way:

> When two individuals interact on successive occasions over time, each interaction may affect subsequent ones, and we speak of . . . having a relationship. Their relationship includes not only what they do together, but the perceptions, fears, expectations, and so on that each has about the other and about the future course of the relationship, based in part on the individual histories of the two interactants and the past history of their relationship with each other. (Hinde & Stevenson-Hinde, 1987, p. 2)

Psychologically, the relationship is a cognitive construction, that represents more than the sum of interactions that objectively occurred in the history of the relationship (Hinde & Stevenson-Hinde, 1987; Lollis, 2003). Each partner in the dyad interprets the others' behavior and creates expectancies, which are representations of themselves and the other in that relationship. These meanings become consolidated in representations of the relationship, including emotions, which then form the filter through which parent and child behaviors are experienced and predictions are made about the others' behavior. Similar conceptions of relational expectancies can be found in *cognitive expectancy models* of relationships (Levitt & Cici-Gokaltun, 2010) and *working models of attachment* (Bretherton & Munholland, 1999).

There is a growing appreciation of the distinctive nature of the parent-child relationship as a context for development. Maccoby (2000) argued that the parent-child relationship is unique and cannot be understood using concepts developed for adult personal relationships. The parent-child relationship is distinctive from other relationships because of the immense number and diversity of interactions that make up their history, the interdependence of the relationship and its involuntary nature. Power dynamics in parent-child relationships are also complex. Russell, Petit, and Mize (1998) argued that horizontal power in addition to vertical power is characteristic of parent-child relationships. This more complex view of parent-child relationships has been incorporated in *domain models* in which parents and children cycle through different domains within the relationship and the goals, functions, and power dynamics underlying parent-child interactions change throughout the day (Grusec & Davidov, 2010; Lollis & Kuczynski, 1997). Taken together, these ideas from the study of relationships provide the basis for a relational perspective on socialization that broadens the idea of what it means to parent a child beyond discipline and control strategies and beyond a focus on immediate contingencies between behaviors exchanged by parents and children during social interactions.

Figure 9.3 presents a *transactional model of parent-child relationships* that depicts the dynamic whole in social relational theory. The model is based on Lollis and Kuczynski (1997) who considered the implications of Hinde's (1979) theory for parent-child relationships. The present model is adapted to reflect changes in the theoretical and empirical literature. One change is the conceptualization of social interaction. In contemporary theory, Hinde's emphasis on the representational expectancies that agents form during interactions corresponds to the dialectical concept of transaction (Kuczynski & Parkin, 2007; Sameroff, 2009), rather than social interaction, which generally refers to exchanges of behavior. Thus, transactions are depicted as the building blocks of relationships. Parent-child interactions are transactional in nature because they involve mutual interpretations of each other's actions in the context of a previous history of social interactions. A single interaction between unfamiliar individuals does not constitute a relationship, but a relationship begins to be formed once individuals begin to predict each other's actions from their representation of what happened before.

The model as a whole represents just one child's working model of the relationship with one parent in a particular cultural context. Transactions between the parent and the child create a relationship context that incorporates the past history and anticipated future course of the relationship as well as experiences of the diverse relationship domains in which they engage on a daily basis. For example, a parent-child relationship considered at Age 10 is based on a history of transactions, including emotions and cognition, occurring over 10 years, and a projected history of the relationship that continues across the life span of the parent and the child. The relationship itself occurs within a cultural context that contributes socially constructed meanings to the relationship as well as to the interactions occurring within the relationships.

Past and Future Dimensions of Relationships

Relationships are constructed over time and are expected to endure. Thus they have a past, a present, and a projected future. The transactions that contributed to the relationship occurred across diverse relational domains, including repeated confrontations with parental authority, situations where the child's attachment security was threatened and was met by parental responsiveness or unresponsiveness, and moments of parent-child intimacy. Expectancies from past transactions, transactions in different relational contexts, and anticipations of the future are sources of relational information that the parent and the child use in interactions occurring in the present.

The intersection of the horizontal and vertical rectangles in Figure 9.3 represents the *relational present*.

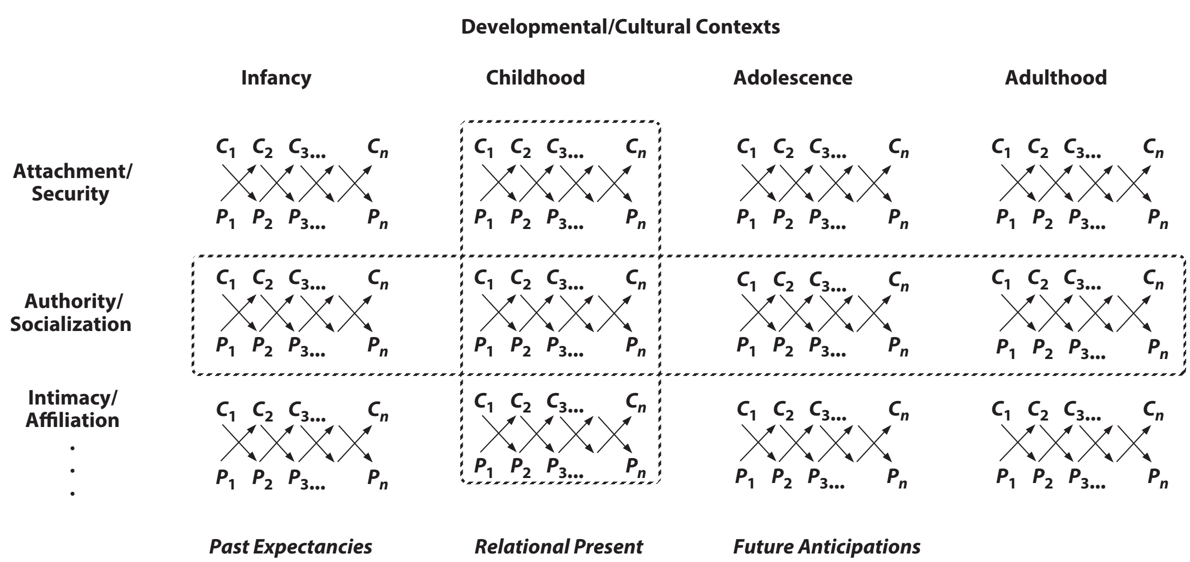

Figure 9.3 The transactional model of parent-child relationships embedded in culture.

In the relational present, parents and children interact with representations of the past and the future of the relationship not just with behaviors that are objectively present. As discussed by Abbey (2012), transactions occur in a boundary zone in irreversible time where, on the one hand, an individual's consciousness is colored by a rich accumulation of past experiences and, on the other hand, an individual's consciousness is anticipating and preadapting to an unknown future. The past and future cannot directly affect the present but interpretations of the meaning of past transactions (Lollis, 2003) and assumptions about what could be the case in the future can guide one's actions (Abbey, 2012).

It is readily apparent to any investigator who has interviewed parents about their childrearing practices that parents think about and reflect on their relationships with children. Transcripts of open-ended interviews generally reveal that participants rarely give a straightforward behavioral description of what they do. When given the chance, parents contextualize their behaviors and strategies in lengthy "digressions" concerning past interactions, felt emotions, personality, and comparisons with the sibling of the target child. Relationship cognitions have also been demonstrated in "own versus other" research designs that compare a parent or a child's reaction to people who vary in their relationship with the informant. For example, Dawber and Kuczynski (1999) found that parents use different influence strategies in their relationships with their own children than they do with unfamiliar children. These parents justify their differential actions by referring to relational knowledge of their own child's personality, past behavior, as well as predictions of their child's responses.

The projected future of the relationship contributes anticipations, conceptualized as goals to interactions occurring in the present. Knowing that the relationship will persist beyond the present may result in parents acting in a way that promotes future, rather than immediate, goals for a child during disciplinary interactions. The finding of Dawber and Kuczynski (1999) of a higher frequency of future goals for parents' interactions with their own children than with unfamiliar children lends support to the argument that the presence of future goals for the other is a relational phenomenon. Such goals include long-term socialization goals (Kuczynski, 1984), child-oriented goals (Dix, 1992), and relationship goals (Hastings & Grusec, 1998) designed to promote and maintain the mutual relationship context.

Multiple Domains

The presence of multiple relationship domains (Grusec & Davidov, 2010; Lollis & Kuczynski, 1997) adds to the complex nature of the expectancies that each person forms as they integrate information from diverse contexts. The parent-child relationship is not a monolithic relationship of vertical power. Instead, parents and children routinely interact in different domains of the relationship that are engaged in different contexts.

Three domains provide a foundation for understanding parent-child relationships: authority, attachment, and intimacy. Each domain has different underlying dynamics that are the result of the parents and children's varying perspectives and goals during everyday situations.

1. The *authority domain* engages the parental role of socialization agent and bidirectional ←→ dynamics occur in a context of interdependent power asymmetry. In this authority domain parents attempt to exercise their greater power in relation to a child who may or may not wish to accommodate the parent's expectations.
2. The *attachment domain* engages the parental role of caregiver and bidirectional ←→ dynamics occur in a complementary power relationship. In the attachment domain the child seeks, and the parent responsively provides, protection and security (Bretherton, Golby, & Cho, 1997).
3. The *intimacy domain* was proposed by Oliphant and Kuczynski (2011) as a specific conception of interactions in the horizontal or reciprocal power domain of relationships during middle childhood. Other conceptions of this domain focusing on infancy and early childhood include MacDonald's (1992) conception of the evolutionary significance pleasurable interactions; mutual attunement (Grusec & Davidov, 2010) and shared positive affect or mutually responsive orientation (Kochanska, 2002). Weingarten (1991) conceptualized parent-child intimacy as transient interactions in which parents and children share or cocreate meaning. Empirical examples of such intimate interactions were reported by Oliphant and Kuczynski (2011) and include perceptions of shared thoughts, ideas, emotion, and activities that are experienced as moments of mutuality during routine activities such as mealtime, bedtime, car trips, and chores, as well as intentional, idiosyncratic intimacy rituals set up to create the opportunity for mutual pleasure. Harach and Kuczynski (2005) found that

intimacy is the primary way parents describe desired relationships during middle childhood. Conceptually it is the principal domain in the relationship that benefits parents as well as children. According to Oliphant and Kuczynski (2011) parent-child intimacy is an inherently equal power domain of relationships that requires that parents and children coordinate their actions to achieve mutuality

Lollis and Kuczynski (1997) argued that transactions taking place within one domain influence the dynamics of interactions that take place within other domains. Examples include findings that children's compliance in the authority domain is associated with secure attachment relationships (Matas, Arend, & Sroufe, 1978) or an experience of responsive interaction (Parpal & Maccoby, 1985). Harach and Kuczynski (2005) reported findings that suggest that a desire to maintain an enjoyable intimate relationship may constrain parents' use of coercive power when disciplining children. Adolescents have been found to avoid aversive confrontational strategies in order to avoid damaging positive aspects of their relationships with parents (Lundell, Grusec, McShane, & Davidov, 2008; Parkin & Kuczynski, Wojciechowska, Dawczyk, & Pitman, 2012). The context created by interactions in the intimacy domain can also advance broader socialization or caregiving goals in the authority domain. For example, Kuczynski, Wojciechowska, Dawczyk, and Pitman (2012) found that parents create relationship contexts such as routine intimate interactions where children spontaneously disclose information that enable parents to gain knowledge about their activities, friendships, and internal states. Important questions for future research are how expectancies developed in different domains of the relationship are represented in present interactions as well as how parents maintain an optimal balance between conflicting domains in their relationships with children.

Relational Representations

Another symbolic product of social interactions is that people construct meanings about their relationship with the other partner. Watzlawick, Beavin, and Jackson (1967) argued that every interpersonal communication is not only an exchange of information about some topic, but also simultaneously a message regarding the relationship between the interacting partners. Thus partners in a relationship respond not only to the objective content of the interaction but also create and communicate meanings about the relationship. Emery (1992), for example, argued that family conflicts can be analyzed according to their surface (interactional) meanings and deep (relational) meanings. The surface meaning refers to the topic of disagreement. However recurrent conflicts may reveal a metacommunication about what its process of resolution or its outcome conveys about the broader structure of the relationship. According to Emery the deep meaning of conflict concern the functions of asserting (or testing) and changing (or resisting change) in the intimacy or power structure of family relationships. Thus, the dynamics of conflicts may reflect relational meanings beyond the immediate situation.

Transactions within the specific domains of authority, attachment, and intimacy may have metacognitive implications for the interacting partners representations of the relationship as a whole. For example, Cavell and Strand (2003) speculate that children develop a *sense of containment*, which is the expectancy that adults have the capacity to impose firm limits and prevail if goals conflict and cannot be negotiated. This suggests a relational reinterpretation of what is accomplished by parent-management strategies such as *time out*, which have been interpreted behaviorally as a form of punishment that weakens a response (MacMahon & Forehand, 2003). Successfully implementing time out for the first time is a long drawn-out process in which the parent is coached to stand firm in the face of child resistance until the child complies. A relational interpretation is that successful experiences of time out changes the child's representation of the power relationship with the parent such that the child learns that the parents' power will prevail when there is conflict. Similarly, in the attachment domain, experiences of parental responsiveness or nonresponsiveness in stressful situations has implications for the child's interpretation of the relationship as secure or insecure as well as the child's sense of agency in the relationship (Cummings & Schermerhorn, 2003). Finally, in the intimacy domain, experiences that one can participate in constructing a moment of mutuality in the relationship may have implications for one's sense of closeness or compatibility in that relationship as well as one's sense of *mattering* in the relationship (Marshall, 2001). Marshall and Lambert (2006) found that parents experienced that they mattered to children during interactions when children responded to their initiations during intimate interactions.

Distinctiveness

Each relationship in the family has a distinct history of transactions. A mother's relationship with one child will be different from her relationship with a second child because their relationship developed in a different bioecological context (Bronfenbrenner & Morris, 1998). The parent and child may have different perspectives on the relationship based on their different experiences as well as their different ways of perceiving and understanding interactions. In the case of a newly reconstituted family after divorce, a child may have few expectancies from the sparse history of the new relationship to guide their interactions with a stepparent and so the relationship and the stepparent's role in it may be tenuous until a history is allowed to accumulate. Similar scenarios can be constructed for stepparent–child relationships, children's transitions into foster homes, or reconnecting transnational families after long separations.

Culturally Embedded Relationships

Hinde's (1979) relationship theory stressed the reciprocal influences among the various levels of human complexity, that is, individuals, relationships, groups, and the sociocultural structure. Each level has to be understood as context and meaning constructor for another level. The embedding of relationships within culture has implications for the specific persons who form the proximal context for children's development. In many cultures the nuclear family is not the norm as a context for children's socialization and development. For example, Goh and Kuczynski (2009, 2010) argue that the appropriate unit of analysis for families in contemporary China is the intergenerational parenting coalition, consisting of grandparents, the parents, and one child who generally live in one household. Thus, the dynamics that need to be considered for Chinese families include the child's bidirectional ←→ relationships with the grandparent, the mother, the father, and the caregiving coalition considered as a whole.

Culture is a semiotic context (Moscovici, 1988) that provides social representations or meanings about values, ideas, and practices that enable individuals to orient themselves and communicate in their social worlds. Trommsdorff and Kornadt (2003) argued, for example, that cultures differ in their ideas about the relative roles of mothers, fathers, and grandparents in parent-child relationships, the appropriate power relations and patterns of intimacy, and communication in parent-child relationships, and the desired balance of autonomy and interdependence in the relationship and these cultural meanings affect the nature of bidirectional influence in different cultures. Kuczynski et al. (2003) discussed how social representations apparent in aphorisms about childrearing and the natural language used to describe parent and child behaviors affect how direction of influence between parents and children is perceived and how parents and children's actions are evaluated. Moreover, Peterson and Bush (2012) suggest that cultural ethnotheories regarding the meaning of parental authority in a given culture, may affect adolescents' evaluations of their parents' wisdom, competence, or trustworthiness and, thereby, affect their inclination to be influenced or not to be influenced by their parents. The implication from a social relational perspective is that although bidirectional ←→ influence is a universal assumption for parent-child relationships, the cultural meanings associated with the relationship may influence how agency is experienced in the relationship and how partners coact in their social relationships.

The Relational Origins of Socialization

Contemporary research diverges along two principal pathways to socialization: one emphasizing the *primacy of parental discipline and control*, and one emphasizing the *primacy of relationships*. The discipline and control pathway emphasizes parents' use of power assertion to elicit compliance and to suppress noncompliance with parental requests. Failure to suppress early noncompliance is assumed to place parents and children on a trajectory driven by negative cycles of bidirectionality. The most influential model is coercive process theory (Patterson et al., 1992) whereby, noncompliance, conceptualized as coercion, elicits coercive responses from the parent by a process of mutual negative reinforcement. These processes of mutual coercion escalate and become consolidated into habitual patterns of interacting that spread to relationships with teachers, peers, and, eventually, romantic partners as children age. Consistent with this mechanistic conception of causality, behavioral clinical interventions traditionally give priority to behavior management over relationship enhancement on the assumption that good relationships are a consequence of children's compliance rather than set the stage for compliance (Patterson, 1997).

The relational pathway emphasizes the causal role of relationships as the foundation of positive trajectories of socialization experiences driven by positive cycles of bidirectionality (Kochanska, 2002; Kuczynski & Hildebrandt, 1997). In the relational perspective a disposition of receptivity to parental influence emerges from history of mutual responsive interactions. Two veins of research support the relational trajectory. Stayton, Hogan, and Ainsworth (1971) argued that maternal behaviors that promote attachment, such as responsiveness to children's distress, also promote children's cooperation with mothers' commands. Research by Matas, Arend, and Sroufe (1978) found that early compliance was predicted by secure attachment as assessed using the Strange Situation. Research (e.g., Leerkes, Blankson, & O'Brian, 2009) found that maternal sensitivity to distress, rather than nondistress predicted fewer behavior problems and greater social competence in toddlerhood.

Maccoby and Martin (1983) argued that a more general relational process underlies the associations between compliance and attachment. Namely, children acquire a disposition to be receptive to parental requests by learning habits of reciprocity from a relationship history characterized by mutual compliance and responsiveness. This relational perspective has received substantial support from research indicating that children's tendency to comply is enhanced by brief experiences of responsive play with mothers (Parpal & Maccoby, 1985) as well as a substantial body of research by Kochanska and colleagues (see, e.g., Kochanska, 2002) indicating the mutually positive interactions and shared positive affect predict a willingness to comply and a mutually positive orientation during social interactions. Although there is a current debate regarding the ability of responsiveness to distress versus responsiveness to nondistress to predict various outcomes (see Grusec & Davidov, 2010; Leerkes, Weaver, & O'Brien, 2012), both forms of responsiveness highlight the importance of relationship processes.

Kochanska and Kim (2012) reported longitudinal research indicating that in the context of insecure or unresponsive relationships parent-child dyads engage in negative cycles of reactivity such that temperamentally difficult children elicit parental punitive behavior, which leads to further negative escalations and behavioral problems. But in the context of relationships that are secure and responsive, the maladaptive cycle is defused. Even if the child has a difficult temperament, the parent does not become more coercive and parental confrontation is not toxic in its effects. Moreover, positive discipline, and the development of a willing, cooperative receptivity work better when relationships are responsive and secure.

Relationship Construction and Maintenance

The relational perspective broadens the focus on socialization practices to include parents' actions that create and maintain the relationship context, which is the foundation for children's receptiveness to parental efforts. Relationship maintenance has been a topic of research in the literature on friendship and romantic relationships (Dindia, 2003) but it has not received much research with respect to parent-child relationships where the continuing existence or stability of the relationship appears to be taken for granted. An explanation for the dearth of studies on the process of constructing and maintaining parent-child relationships may be the traditional mechanistic orientation of the socialization literature where the relationship is viewed unimportant, except as a variable that may mediate the effects of direct control strategies.

A basic issue in the process of maintaining the parent-child relationship concerns parents' initial decisions to engage in the relationship. Palkovitz et al. (2003) raised the question of parent engagement in the context of father-child relationship, especially after divorce, when the decision to be involved in children's lives appears to be an active choice. Palkovitz's suggestion draws attention to the more general possibility that there is an intentional component in parents' choice to engage in their relationship with their children. At least one aspect to engaging in the relationship is the choice to be responsive to the child. The choice to be responsive means consciously opening up oneself to the child's influence, thereby engaging in a bidirectional ←→ process in which parents and children build a mutually responsive relationship.

Studies have explored parents' perceptions of their efforts to maintain an intimate relationship with children (Harach & Kuczynski, 2005; Oliphant & Kuczynski, 2011). Parental strategies include making time for mutually enjoyable interactions, managing their power in relationship to the child, communicating at the child's level and refraining from overpowering the child by imposing meaning, or making relational repairs through communication and apology. Parents report that children engage in analogous behaviors as their part in creating intimate interactions.

Relationship as Context for Agency

Social contexts have long been understood as constraining human agency by guiding meaning making and placing limits on individual choices. However, social contexts have also been constructed by collective and individual actions for the purpose of enabling and supporting agency (Giddens, 1984). The relationship context may constrain parental actions, during conflict. For instance, the desire to maintain an intimate relationship may prevent parents from employing coercive tactics that are damaging to the relationship. This dynamic has been observed in contexts in which children attempt to protect the relationship even when they resist parental demands (Parkin & Kuczynski, 2012). Adolescents report that even when they transgress against parental rules, or use their own judgment when engaging in prohibited behaviors with peers, they keep their experimentation with autonomy within bounds so as not to damage their relationship with parents or their parents' good opinion of them. In addition, they are guarded in their disclosures to parents or conceal the full extent of their autonomous actions not merely to avoid aversive consequences, but also to maintain positive relationships and protect their parents' feelings. Relational constraint can also be found in adolescents' overt resistance strategies such as negotiation and argument where adolescent attempt to accommodate parental perspectives while at the same time pursuing their own goals (Parkin & Kuczynski, 2012). Although negotiation and argument can be experienced as aversive by parents, these may constitute healthy forms of resistance because adolescents continue to engage in the relationship, thus indicating that the relationship matters to them.

The relationship context may enable children's exercise of agency by affording children leeway to negotiate the nature of the constraints placed upon them. The phenomenon of *leeway* was proposed by Goodnow (1997) to explain flexibility in parental expectations for children. Parents communicate a variety of positions with regard acceptable, tolerable, or "out of the question." Children, in turn, discover how much value-stretch their parents' position affords and how much leeway there is for their own creative interpretation. Goodnow (1997) proposed three forms of leeway: (1) The first lies in the nature of parental expectations. Not all values are of equal importance with some considered essential and others as trivial. This allows leeway in options for children to behave, from the parents' perspective, with "acceptable ignorance" or "acceptable incompetence." (2) The second form of leeway is related to a time frame when children are allowed flexibility to delay or explore alternative values before carrying out an expectation. (3) The third form of leeway concerns domains of decision making where children are specifically encouraged to express their creativity. Goodnow (1997) suggested that parents begin with certain expectations of their child, such as high achievement, and then their values undergo "stretch" as they come to realize their original expectations may have been too ambitious. Thus, leeway for children's agency is afforded by the parents' changing expectations based on their experiences with their child.

Parents may most often signal areas of negotiability and grant or cede leeway in the personal domain, which is generally considered to be under the child's jurisdiction, as well as trivial instances of social conventions where parents may have less investment (Smetana, 2011). However, children play a larger role in detecting and creating leeway in areas of ambiguity such as in mixed domains, where there is a struggle over definitions of what is conventional and what is personal. Children may also exploit leeway when the bottom lines of parental values are ambiguous or parents are adjusting their expectations to changing circumstances. For example, Parkin & Kuczynski (2012) found that beyond some bottom lines (which, nevertheless could be worked around) adolescents find it difficult to identify rules that are rigidly expressed or enforced. Instead, most rules are perceived to be coconstructed between the parent and the child and there is considerable flexibility that allowed room for negotiation. Children's agency and children's effectiveness as agents is enabled by the relationship, and as argued by Kuczynski and Hildebrandt (1997) the competent expression of agency involves accommodating to the mutual constraints of a reciprocal relationship.

Relationship Dynamics

The principal dynamics considered by the traditional social interactional perspectives (Patterson et al., 1992) concern the immediate contingencies between the behaviors of the participants in dyadic social interactions. In contrast, a relational perspective provides new dynamics that stem from the relationship context of social interactions (Table 9.1). Each of the dynamics listed in Table 9.1

TABLE 9.1 Relational Dynamics: Implications of Acting as if the Other Was a Partner in a Close Relationship

Level of Dynamic	Relationship Principles
Interdependence	Act as if the others' responses, actions mattered
Relational representations	Interpret interactions for meaning of self and other in relationship
Past expectancies	Act as if there was a past: others' personality, strengths, vulnerabilities, habitual ways of responding, one's own history
Future anticipations	Act as if there will be a future: socialization goals, proactive behavior, relationship goals
Domain complexity	Act as if what happens in one domain will affect another domain
Distinctiveness	Each relationship has a distinct history and dynamics
Cultural embeddedness	Cultural meanings of interactions and relationships

considers parents interacting in the relational present (i.e., they act "as if" they were in a relationship, not just an interaction between unconnected individuals). Dynamics of *interdependence* consider that the actions of relationship partners not only involve bidirectional ←→ influence but also that each partner draws meaning from the other's responses. What parents and children do and do not do is always meaningful to the other at an emotional level, making each receptive and vulnerable to the others' influence. Relationship-specific meanings relevant to socialization processes include *relational representations* of parents or children in relationship to the other, *past expectancies* from the history of the relationship and *future anticipations* of the relationship's continuance that give rise to future-oriented goals. The dynamics of *domain complexity* considers the causal relations between subdomains of the whole relationship (e.g., authority, attachment, intimacy). The dynamics of *distinctiveness* raises the possibility that the processes of socialization interactions are not only situation specific (Grusec & Goodnow, 1994; Grusec & Kuczynski, 1980; Kuczynski, 1984), they are also specific to relationships. Steinberg (1987), for example, found that mother-adolescent relationships have more frequent conflicts and are also more intimate than father-adolescent relationships. One possible explanation for this finding is that mothers may allow greater leeway for the expression of dissent and tolerate resistance or different points of view because they are more focused on maintaining a positive parent-child relationship. The dynamics of *cultural embeddedness* of relationships imply that the caregiver-child relationships that are most relevant as proximal contexts of development as well as the meanings generated by social transactions are specific to larger cultural contexts.

CONTRADICTION: THE SOURCE OF CHANGE

The dialectical principle of *contradiction* asserts that all phenomena consist of opposing components (thesis and antithesis) as an inherent aspect of their makeup. The nature of the contradictions depends on the physical, biological, or psychological system under investigation. Riegel (1976) identified inner dialectics and outer dialectics as two general kinds of contradictions of psychological systems. *Inner dialectics* are contradictions within a person such as simultaneously held opposing ideas. *Outer dialectics* are contradictions between an individual and another person or between an individual and some aspect of the environment. Because these opposites coexist and coact as a part of a whole, dialectical researchers tend to use a "both/and" rather than an "either/or" logic when studying and describing phenomena (Baxter & Montgomery, 1996; Holquist, 1990; Overton, 2006, Chapter 2, this *Handbook*, this volume). An either/or logic considers differences between components as mutually exclusive. This is the logic underlying unidirectional interpretations of socialization in which the effects or agency of the parent are emphasized, whereas the agency and contribution of the child are ignored or downplayed. The logic of both/and reasoning accepts that one component simultaneously coexists in a dynamic tension with an opposing component and outcomes will be a novel reflection of the action of both components. Conceptualizations such as coactions, coregulation, coconstruction, coevolution, mutuality, intersubjectivity, joint activity, dialogue, and shared meaning (Kuczynski et al., 2003) indicate a both/and logic. In each of these conceptions, adaptive processes are conceived as the coordination of potentially opposing active agents so as to achieve a joint goal. However, for phenomena that the contradictory components more clearly opposed, contradictions may still be generative. Using the example of the inherent contradictions of living in close relationships, Baxter and Montgomery (1996) argue that a healthy relationship is not one in which contradictions are resolved or prevented but one in which each partner manages to satisfy conflicting perspectives or goals.

For researchers who take a contextualist perspective on dialectics (e.g., Baxter & Montgomery, 1996) identifying contradictions is important principally as a way of describing the structure of phenomena, but for researchers who take an organismic-contextualist perspective, including the present authors, contradictions are also important because of their role as the source of change (see Overton, Chapter 2, this *Handbook*, this volume, for a further elaboration of this distinction). Any system will have aspects that are harmonious as well as aspects that are dissonant. The potential for change exists in the unstable "goodness of misfit" (Valsiner & Cairns, 1992) of the coacting components that has the potential for generating novel outcomes. Dialectical researchers focus on the contradictory aspects of systems because the tension that emerges from contradiction provides opportunities for change whereas harmony and consensus serve to maintain stability and continuity (Riegel, 1976). Although harmony is a pleasant and desirable state, in dialectics, it still requires active coordination to create and maintain.

Valsiner (2000) developed the ideas of *systemic causality* and *catalytic causality* to reframe contradiction as a relation between components in dynamic systems. "In the case of systemic causality, the given outcome (B) is a result of mutually interdependent relations of the parts of the causal system (for example, system A {Z < > X <> Y} . . . None of the parts (Z, X, Y) taken separately causes B, but their systemic interaction leads to B" (p. 75). *Catalytic causality* refers to the capacity of contexts to change the nature of the causal relations of living systems. Using the metaphor of chemical reactions, catalyzed refers to a set of conditions that need to be present for a particular causal linkage to occur, and the absence of which does not allow the causal process to lead to an outcome. According to Valsiner (2012), a given system of meanings may be maintained on a narrow or conservative trajectory of thesis/antithesis/synthesis where the prevailing meanings inhibit breaking away from that trajectory. Each system is always in a potential tension-filled state of transformation that is held in check as long as the external context remains the same. However, a change in context introduces new conflicting meanings to the system that may create the conditions for a new interpretation or create a space that enables new flexibility for exploring various meanings. An outcome of a catalyzing event could be the resolution of a contradiction, which may lead to a new qualitatively different trajectory, or it may lead to a failure of resolution, which leads to a path of continued tension, at least temporarily.

Contradiction in Social Relational Theory

Figure 9.4 is the general model of contradiction and its role as a causal process that informs social relational theory. The process begins with a catalyst—an event, a change in the environment, or a developmental or life-course transition—that creates patterns of behavior that are unexpected or clash with the parent or child's current understanding (thesis). The catalyst may also bring into awareness problematic patterns of behavior that may have occurred without reflection in the past. In making sense of the change the parent or child recognizes a contradiction (antithesis), which may be experienced in various forms including conflict, expectancy violations, ambivalence, and ambiguity. These experiences have in common that they entail uncertainty and create an affective state of tension. In other theories, these tensions have been conceptualized such as ruptures, turning points, critical events, crisis, perturbation, and disequilibration (see Witherington, Chapter 3, this *Handbook*, this volume).

In seeking a resolution to the contradiction the parent or child may engage in a process of problem solving, which may be resolved by a temporary qualitatively new understanding of the situation sending the parent, the child, or the relationship on new trajectories. Alternatively, the individuals may attempt to ignore or live with the contradiction, in which case the tension continues to be a factor in their lives. In the analysis that follows, the nature of contradictions is described first, followed by processes by which contradictions relate to causality. The nature of trajectories, conceptualized as syntheses, are discussed in the subsequent section.

Parent-child relationships constantly create both external and internal contradictions that feed into the dialectical process. Parents and children, considered as agents, have separate and potentially conflicting needs, perspectives, and goals. However, they are also continually embedded within the unity and interdependence of their shared relationship. Because the relationship is involuntary or individuals are invested in the relationship, the tensions must be managed in some way.

Parenting inherently involves constant adaptation to a rapidly changing organism (Holden & Ritchie, 1988). Children change continually as they develop from infancy to young adulthood. From the perspective of the parent, the child is a constantly moving target and strategies that worked previously may no longer work in the present. Holden and Ritchie (1988) used the concept of outer dialectics and inner dialectics (Riegel, 1976) as a starting point

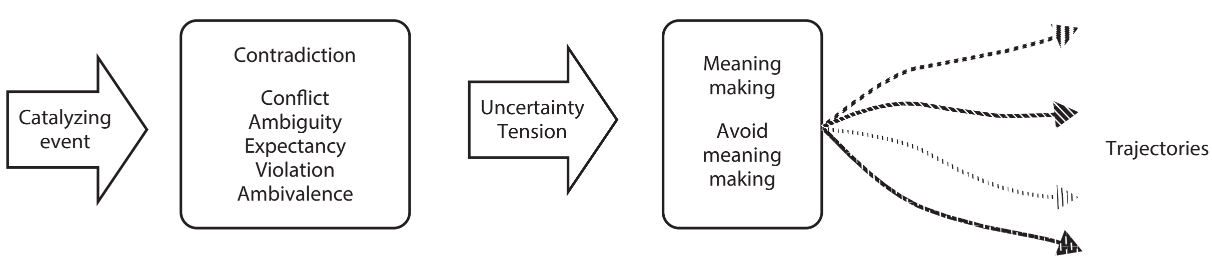

Figure 9.4 Psychological processes underlying causality in dialectical systems.

for identifying the contradictions that parents encounter in the competing roles of childrearing. Their examples of outer dialectics included contradictions between the parents' needs and the child's needs or between the parents' experience of childrearing and competing child advice from the culture, experts, and other caregivers. Holden and Ritchie devoted most of their analysis to inner dialectics, namely internal debates within the parent about how to carry out the different childrearing roles of caregiving, managing, and nurturing.

In the caregiving role, inner contradictions included competing goals such as allowing exploration but guarding against danger; being receptive to the child's requests but not spoiling the child and being warm but not seductive. In the managing role, contradictions included seeking obedience and respect but allowing assertion and questioning of authority; being firm and consistent versus flexible; being honest and open with the child versus protecting the child from harsh realities. In the nurturing role, contradictions included being involved but not intrusive; granting independence but maintaining dependence; encouraging mature behavior versus allowing children to be children; teaching versus allowing children to discover on their own; and changing the child versus accepting the child's shortcomings. In addition to the contradictions noted by Holden and Ritchie (1988) there may be contradiction between the parents' needs and those of the child. Parents may feel tensions between the responsibility of parenting and the impact of rearing children on their own well-being, careers, and aspirations.

Other contradictions arise from managing close personal relationships. In families reconstituted after divorce there may be contradictions specific to the stepparent-stepchild relationship. Particularly when the family is reconstituted after middle childhood, the child's relationship with the stepparent initially does not have the same rich history of interaction compared to biological parent-child relationships to provide a foundation for the new parent's roles. Baxter, Braithwaite, Bryant, and Wagner (2004) found that stepchildren reported that they often appreciate closeness with and involvement by the stepparent, but experience distance and discretion, and resist granting the stepparent full parental status in the relationship. Cissna, Cox, and Bochner (1990) demonstrated that parents also experience tension between the time and effort devoted to establish the newly formed marital relationship and the time and effort required to construct the stepparent relationship.

Contradictions in relationships are always contextually dependent and must be studied with regard to particular relationships or relationship types. Dialectical analyses of communications in close personal relationships, such as friendships and romantic partners, have found that there is a dynamic interplay between the tendency for connection and integration and the competing tendency of separation and autonomy (Baxter & Montgomery, 1996). These are expressed as three basic contradictions: autonomy-connection (the desire to be connected versus the desire to be a unique individual), openness-closeness (the desire for self-disclosure versus privacy and discretion), and certainty-uncertainty (the desire for stability and predictability versus spontaneity and novelty in the relationship).

There is growing awareness that even professional relationships have a horizontal power aspect that is the source of tensions between various domains of relationships with clients. Investigators who study professional relationships such as in social work (Alexander & Charles, 2009), nursing (McGuire, Dougherty, & Atkinson, 2006), psychotherapy (Wampold, 2001), and teaching (Manning-Morton, 2006) have argued for the recognition of the therapeutic role of a personal relationship domain in interactions between clients and professionals. Service providers are aware of the mutuality and reciprocity in their relationships with clients as well as the tension between their lived experience and the undermining restrictions placed on them by professional norms of their disciplines. For example, researchers studying early childhood education teachers' relationships with young children have conceptualized teaching in a way that recognizes the inherent complexity of the teacher-child relationship, which involves participating in an affective interpersonal relationship while simultaneously carrying out teaching and attachment or caregiving functions (Howes, 1999; Manning-Morton, 2006). The relationship domain of professional teacher, with norms for objective distance, has been found to coexist in a relationship system with an attachment/caregiver domain and a personal relationship/intimacy domain (Quan-McGimpsey, Kuczynski, & Brophy, 2011). Three principal contradictions have been found for early childhood education teachers when relating to individual children; these included interacting with one child versus the entire class, exclusive versus shared closeness, and engaging in a parental role versus the role of early childhood education teacher (Quan-McGimpsey et al., 2011).

Psychological Processes Underlying Contradiction

Contradictions can be further analyzed by considering underlying psychological processes. Kuczynski and colleagues have interpreted contradiction as occurring in four recurring phenomenona of daily experience: conflict, expectancy violations, ambivalence, and ambiguity (Kuczynski et al., 2009; Kuczynski & Parkin, 2009).

Conflict

Conflict occurs during interactions that pit the parents' needs, goals, will, or interpretations of events against those of the child. These external contradictions may be manifested in overt conflict. During the 1980s, parent-child conflict began to be viewed as an inevitable and mutually tolerated aspect of living in close relationships. Moreover, a dialectical interpretation emerged that conflict is a necessary condition for change and may have positive functions for the individual or for the relationship (see Shantz & Hartup, 1992, for a review of this perspective).

Expectancy Violations

Expectancy violations occur when one receives information that violates previously established ways of understanding. Sameroff (1975b) used an example of expectancy violation to illustrate the transactional process where contradictions between the parent's initial model of the child as pliant object and the parent's actual experience lead to a qualitatively different image of the child as a separate agent who exists independently of the parent.

Collins and Madsen (2003) proposed the *expectancy violation realignment model* as an explanation for how families adapt to change as children move through adolescence to adulthood. According to their model, developmental change may lead to new behaviors that contradict the representation of the child that the parent had previously formed. This contradiction initially creates conflict, puzzlement, or emotional upset, but a new basis for interaction will occur when the parent adapts to the new reality by reinterpreting the meaning of the child's behavior. The argument is that parents may initially interpret developmental changes in the child in a negative way as "attitude" or "defiance," but eventually adapt by interpreting the child's behavior as legitimate signs of adulthood, thus putting the relationship on a new, less conflictual trajectory.

Parental violations of children's expectations also create internal contradictions that children must reconcile or to which they must adapt. Youniss and Smollar (1985) documented how in early adolescence, children view parents as unilateral authority figures but eventually come to understand parents as individual personalities with unique strengths and weaknesses. Although this has been understood as an individual change in the adolescent's declining egocentrism, expectancy violations that occur as the adolescent becomes aware of parental vulnerabilities and strengths may also play a role.

The *social expectations model* of close relationships (Levitt & Cici-Gokaltun, 2010) is a model of relationship development continuity and change processes applicable across specific relationships and through the life span. According to this model, repeated transactions with a relationship partner build expectations about the partner's behavior that provide a basis for the development of close relationships. These relationship expectations, once established, are thought to provide the basis for continuity within relationships and generalization across relationships. However, relationships can change when individuals encounter circumstances that exceed or violate their expectations of, for example, trust, reciprocity, or a good image of the partner. The model suggests that relationship expectations that are untested will remain stable, expectations that are violated may lead to relationship change in a negative direction, and expectations that are surpassed may promote positive change in the relationship.

Ambivalence

Ambivalence is the experience of simultaneously positive and negative emotions, evaluations, or opposing directions for action. The construct of ambivalence has been used in a variety of ways in the social sciences. In sociocultural research, ambivalence has attracted attention for understanding the emergence of meaning. Abbey (2012) described the meaning-making process as the individual's attempt to overcome the ambivalence between their present understanding and the possibilities of an uncertain future. Many of the examples of parental contradictions described by Holden and Richie (1988) can theoretically be understood as ambivalence resulting from competing but equally desirable goals, which may come to mind when parents respond to a given childrearing situation. These include child-oriented goals for keeping the child happy, parent-oriented goals for the parents' convenience, socialization goals to foster the child's capacities (Dix, 1992), and relationship goals to maintain a satisfactory parent-child relationship (Hastings & Grusec, 1998). Each of these goals may also have short-term versus long-term considerations that may create ambivalence (Kuczynski, 1984).

Parent-child relationships also entail considerable ambivalences that are temporary or permanently irreconcilable. Family members frequently express mixed feelings toward each other, such that warmth and affection occur together with antagonism and irritation. Lüscher and Pillemer (1998) proposed a theory of intergenerational ambivalence as a tool for understanding how adult children and their aging parents experience and manage contradictory impulses and perceptions in their close relationships. Fingerman and Hay (2004) found ambivalence to be more characteristic of relationships involving romantic partners, mothers, fathers, sons and daughters, and siblings than those with extended family or friends. They argued that much of the tension between aging mothers and adult daughters is caused by their mutual struggle for independence and the older generation's desire and demand for more contact and involvement than the younger generation.

Methodologically, the phenomenon of ambivalence requires a both/and approach to measurement. For example, a parent may love a child but experience the child's behavior as aversive. A child may approve of the parent's socialization goals for achievement, but deplore the parent's methods. A child may reject the parent's beliefs or values but love and respect the parent's sacrifices on their behalf and resolve to care for them in old age (Kuczynski et al., 2009). These simultaneous strong positive and strong negative pulls are obscured in quantitative ratings of "somewhat close" on forced-choice global assessments of relationship dimensions.

Ambiguity

Ambiguity most directly corresponds to the idea that contradiction creates uncertainty, the state that drives the meaning-making process. Human goals and actions are future-oriented and because the future is unknowable, always involve some level of uncertainty. As described by Valsiner (2006), "Every next immediate moment in the life of an organism is ambiguous as a step between the already known and the still unknown. This state is the normal state of affairs during which an unexpected and unpredicted new phenomenon may emerge" (p. 118).

In addition, individuals may be required to act in the context of uncertainty when they have only partial knowledge about a catalyzing event. Rumsfeld (2002) described the many degrees of uncertainty from which politicians and bureaucrats must make their future-oriented policies. "As we know, there are known knowns, there are things we know that we know. There are known unknowns. That is to say, there are things that we now know we don't know. But there are also unknown unknowns. There are things we do not know we don't know" (February 12, 2002, press conference). Similarly, parenting is an ambiguous enterprise where parents act in the context of many shades of unknowns. There is often minimal information or clarity about the circumstances of the childrearing situations such as "what happened?" or "who started it?' or where children are, who they are with, or what they are up to, and whether or how to intervene.

Dawczyk and Kuczynski (2012) found all four forms of contradiction—ambiguity, ambivalence, parent-child conflict, and expectancy violations—in an interview of parents of 8- to 13-year-old children. Although no specific questions were asked regarding contradiction, parents spontaneously offered many digressions and incomplete or uncertain responses to the questions that were asked about their childrearing practices. These portions of interviews are normally regarded as a nuisance and are disregarded by the researcher who generally seeks for complete and unambiguous responses. However, viewed from the perspective of dialectics, these ambiguous portions of the interview may constitute an important reality of parental experience. Contradictions were found to stem from two sources: internal sources (originating from uncertainties within the parent) and external sources (originating in the child's unexpected behavior).

Contradiction is assumed to provide the motive force of dialectical tension, which drives individuals to work toward some resolution. The dialectical tension experienced by the individual can vary in intensity. Using the example of ambivalence, Abbey (2012) argued that tensions between opposing meanings is strong when ambivalences involve tension between opposing meanings where the meanings directly oppose each other with equal force. However, tension can be comparatively mild when one meaning is stronger than, and can overcome, the other. In social interactions and relationships, dialectical tension can be experienced as mild dissonance or as expressed emotion. Dawczyk and Kuczynski (2012) found that the majority of parents' descriptions of their experiences of contradictions were accompanied by expressions of emotions indicative of anxiety, stress, surprise, anger, and sadness. This finding suggests that dialectical tension may be manifested in uncomfortable emotional states that require resolution.

An important question is what agents *do* with dialectical tensions. An adaptive strategy is to seek some resolution to the contradiction either by taking action or reducing uncertainty by creating new meaning. Either of these approaches imply qualitative change. However, Abbey (2012) noted other possibilities. One is a prejudicial strategy where one adopts one meaning over another and creates artificial clarity by refusing to consider other options. This is an inflexible approach that does not reflect the changing reality. Another approach is to ignore the contradiction and disengage in the meaning-making process and living with the tension at least temporarily. Writing on ambivalence in intergenerational relationships, Lüscher (2011) argued:

> As a consequence of dealing with ambivalence, we may observe the confirmation of established, traditional patterns of action and of relationships. Or it may generate innovative, emancipatory actions and forms of relating. Or it may mean ending a situation or a relationship or being stuck in endless quarrels or in terminating a relationship by leaving a setting. Or, in the extreme, people may lose the ability to act and enter a stage in which their personality is completely divided. (p. 196)

An important question for the future is how to conceptualize contradiction as a central process in socialization. One approach is to explore how inherent contradictions in parent-child relationships are managed in daily life so as to keep damaging conflict between generations from arising. For example, there is evidence that parents tolerate or adjust to children's increasing resistance in middle childhood (Kuczynski, Burke, & Robson, 2013) as well as the ambiguity created by children's increasing engagement in unsanctioned peer activities that occur out of the parents sight (Kuczynski et al., 2012). It is possible that such parental toleration is moderated by a qualitative reframing of these contradictions as normal development of autonomy or "normal deviance" that parents remember being part of their own adolescent experience.

Another approach is to consider parenting as process of resolving contradictions or problem solving. Holden and Hawk's (2003) conception of metaparenting considers the intentional and reflective thought processes that parents use to evaluate and solve problems of childrearing. Metaparenting often takes place outside of immediate childrearing problems and consists of the processes of four interrelated forms of problem solving. *Anticipating* involves thinking about problematic situations before they occur. *Assessing* involves evaluating the reasons for a particular childrearing situation. *Problem solving* involves various activities such as recognizing the problem, identifying the source of the problem, and generating possible solutions, and testing and evaluating the success of the solution. *Reflecting* concerns longer-term evaluations of their behavior, their child's behavior, or parent-child interaction outcomes. Holden and Hawk (2003) argue that metaparenting plays an important role in mediating qualitative changes in the parent's attitudes, values, or goals, as well as their ability to act on and maintain new goals.

Dawczyk and Kuczynski (2012) found in their study of naturally occurring contradictions that many parental contradictions were not resolved but were at different stages in the problem-solving process. These included describing the contradiction, information gathering and reflection, and acting on the contradiction. *Describing the contradiction* implied that parents were aware of and acknowledged the contradiction, but they had not begun to process or manage the contradiction. *Information gathering and reflection* occurred when parents drew on their knowledge of the child, reflected on past experiences in the parent-child relationship, or engaged in self-reflection in an attempt to gain an understanding of the current situation causing the contradiction. *Acting on the contradiction* involved strategic efforts to manage contradictions through cognitive justification or reframing of their or their child's behavior, or plans to alter either the child's behavior or their own responses to the behavior.

The choices that parents and children make when confronted with contradiction determine the likelihood of change. Individuals could choose to ignore contradictory information, or avoid communication about contentious topics, or they may manage their state of uncertainty. In this case, the contradiction would remain unresolved, at least temporarily, thus maintaining their prior understanding and, therefore, stability, following a transaction. Choosing to confront contradiction, on the other hand, opens the possibility for constructing new meanings that can instigate qualitative change, for better or worse. Choosing to communicate so as to arrive at new solutions, reframing the meaning of emerging behaviors, or going into therapy all may result in qualitative changes in behaving, relating with others, or perceiving situations.

SYNTHESIS IN DIALECTICS: NONLINEAR OUTCOMES

A defining feature of dialectics is its focus on qualitative change or the emergence of novelty (see R. M. Lerner & Benson, 2013; Overton, 2006, Chapter 2, this *Handbook*, this volume). The dialectical leanings of a theory can be recognized by concepts such as transformation, working models, changed representations, bifurcations, phase shifts, and turning points (see Witherington, Chapter 3, this *Handbook*, this volume). These concepts represent the dialectical metaphor of temporary synthesis, the idea that the resolution of contradictions creates novel outcomes. The process of synthesis is unending because each new synthesis becomes the basis of a new contradiction.

Dialectical causality assumes a continuous process of change in a changing context where outcomes are always in process. The idea of qualitative change is often subverted by research questions and conceptualizations of outcome that turn dynamic processes into linear models (Sameroff & MacKenzie, 2003). These put a premium on findings of stability and continuity across time and regard findings of instability (insignificant correlations) as errors in measurement (Appelbaum & McCall, 1983). However, an exclusive focus on continuity is only possible from a mechanistic perspective of causality. Continuity and similarity are not the expected outcomes in dialectical approaches to human development. Valsiner (1989) provided a formal description of synthesis in the dialectical process.

> The relations between X and Y is *contradictory* (a basic assumption of the dialectical perspective) in the sense that the two parts (X and Y) are opposing each other while remaining mutually necessary parts of the system. As a result of the opposition of the subparts of the whole, the whole system "leaps" to a novel state of being (incorporating a new part (Z)). (p. 67)

Conceptualizing nonlinear change is a major focus of various systems approaches to development, and approaching nonlinearity using the dialectical idea of synthesis is a focus of sociocultural theory (Valsiner, 2012). Most dialectically inspired empirical research has stopped at the point of listing contradictions in a phenomenon but does not go on to analyze the potential of dialectical tensions to create new syntheses. A current challenge is to develop concepts about what synthesis looks like. Valsiner (2012) has critiqued a number of conceptualizations of synthesis. For example, synthesis should not be considered as a selection of alternatives where considering the pros and cons of conflicting arguments lead to one opposite dominating the other. Also unsatisfactory are ideas of synthesis as optimal blends of the oppositional components. According to Valsiner, neither selection nor optimization of conflicting alternatives adequately capture synthesis as the construction of truly novel forms as the organism moves unpredictably from the known and unknown.

Synthesis in Social Relational Theory

The idea of synthesis alerts researchers that the outcomes of socialization processes must be more than conformity or the mere transmission of similarity from the older generation to the younger generation. Change and the emergence of novel syntheses are also the expected outcomes of socialization and development. There are several directions that may lead to advances in the conceptualization of synthesis in research on socialization. These are a dialectical reformulation of interpersonal influence, the concept of synthetic outcomes, and the concept of nonlinear trajectory.

Relational Influence

In the socialization literature parental influence is often conceptualized as parental control. *Parental control* has been conceptualized as a parenting dimension, a parental practice, a process, and an outcome. What is not clear is the meaning of *control*. Baumrind (2012) argued that parental control ideally should be conceptualized as confrontative power assertion rather than as coercion. However, confrontative power assertion itself was defined in a deterministic way. Confrontative power assertion was operationalized as "confronts when child disobeys, cannot be coerced by the child, successfully exerts force or influence, enforces after initial noncompliance, exercises power unambivalently, uses negative sanctions freely, and discourages defiant stance" (p. 37). For example, in the authoritative parenting style (Baumrind, 2012), the parent considers children's attempts to negotiate, but in the end, the parent decides, exercises control to enforce compliance.

From a dialectical perspective the concept of control is problematic because it raises a distinction between linear deterministic models of causality and dialectical models of causality. The term *control* may be appropriate if it means no more than a power-assertive pattern of behavior; however, it is problematic from a dialectical perspective when *control* refers to the process of influence or the outcomes of a control attempt. Control as an outcome or causal process implies an underlying mechanistic model of linear cause and effect, which is inappropriate for conceptualizing influence between human agents.

Bateson (1972) used Lewis Carroll's famous account of flamingo croquet in *Alice in Wonderland* to illustrate the difficulty of applying traditional notions of linear causality to interactions among biological organisms. In this game (Figure 9.5), Alice must play croquet using a live flamingo as a mallet with the goal of propelling a live hedgehog as if it were a ball through wickets formed of doubled-up soldiers. The game proved difficult because the flamingo and the other components of the game were not inanimate objects but active agents with goals of their own and capacities to act and to think ahead. Alice's control of the flamingo was illusory because the poor mechanical coupling of Alice to the flamingo made it difficult for her to "control" the flamingo or determine the hedgehog's trajectory in any predicable way.

Playing the game with living organisms requires dialectical ground rules. First, the idea of control needs to be abandoned and replaced with a concept of relational influence compatible with influence between active agents. For example, Alice's influence in the game may improve if she assumed that the components of the game are agents and use strategies adapted to the agentic nature of the participants and perhaps her relationship with them. Second, Alice may have to adjust her expectations so that they anticipate that the outcomes will be something different than exact compliance to her wishes.

Figure 9.5 Flamingo croquet: Metaphor of linear causality when applied to agents.

In the literature on close relationships, the term *influence* is used instead of *control* to denote causal processes whereby relationship partners affect each other's thoughts, behaviors, and emotions (Huston, 2002). Building on this usage, we propose the construct of *relational influence* as a dialectical model of causality for understanding transactions between human agents in a relationship context (Figure 9.6). In the process of relational influence, outcomes of influence attempts are dynamically constructed in bidirectional ←→ transactions as individuals construct new meanings from each other's verbal and nonverbal communication. The model of relational influence is useful for understanding how differences are created between the intention of a parental attempt to "control" a child's behavior and the child's response.

The model of relational influence in Figure 9.6 is an elaboration of Sameroff's (1975a, 1975b) transactional model of development, which depicts parents and children engaging in qualitative change as they respond to each other over time. However, as discussed by Sameroff (2009), transaction also occurs at the micro level when parents and children interpret each other's behavior during social interactions. The process of transaction in relational influence depicted in Figure 9.6 is elaborated by Lawrence and Valsiner's (1993, 2003) conception of the internal processing that occurs between the input from the external environmental and the person's output back into the external social world. They argue that there are two internal processes to consider, internalization and externalization. *Internalization* refers to the cognitive processing (internalization transaction) that takes place as individuals make personal sense of messages from the environment. Internalization may consist of interpreting events based on their existing knowledge, evaluating the message along with competing messages from the environment, and reconstructing the message for their own use (Kuczynski et al., 1997). *Externalization* refers to the further processing that takes place as they manifest or act on what they know (externalization transaction).

The latter relation takes the form of externalization of one's "personal culture"—organization of one's environment and external appearance in ways that fit the person's

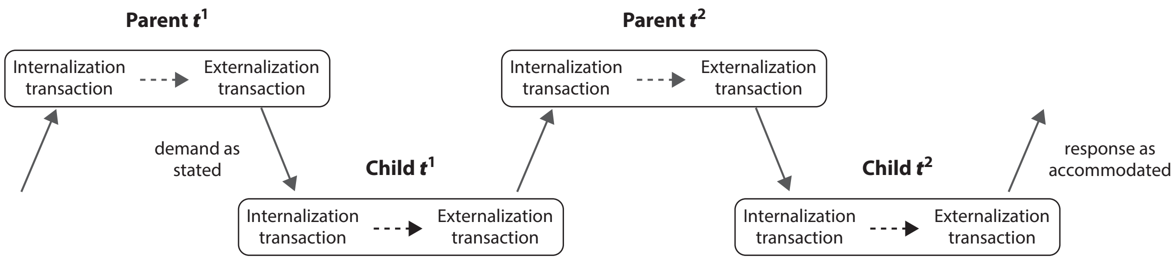

Figure 9.6 Relational model of influence: Construction of novelty, impossibility of control.

internalized psychological "needs." The externalization of the person's (previously) internalized psychological processes reintroduces the products of internalization into the sphere of social transaction (Lawrence & Valsiner, 1993, p. 288).

As depicted in Figure 9.6, a command that initiates an influence attempt by a parent is embedded in a previous history of parent-child transactions such that the parent's choice of influence strategy has already been preadapted (internalization transaction) to the child. In the parent's externalization transaction the parent may consider usefulness of the proposed action for achieving their goals for the child, predictions of the child's responses on the basis of expectancies developed in the past, or consider the consequences for the parent-child relationship. Similarly, the child interprets and evaluates, cognitively and emotionally, the parents' communication (internalization transaction) and chooses a response that accommodates or resists the parents' communication (externalization transaction). Thus, in the process of a control attempt messages may repeatedly undergo one process of transformation as they are internalized and another process of transformation as they are externalized back into the social world.

The argument is that relational influence always contains a qualitative transformation or synthesis. There may be the appearance of control in the sense of the child's externalized cooperative behavior; but children can interject creative components into a cooperative response. Also, one can never know if the other has accepted the message or in what way the individual has transformed it. Thus whatever intentions-goals-strategies the parent or the child may have or use, for his or her effect on the other the parent or child is dependent on the other. Parents or children may *want* to control but the best they can hope for is relational influence.

Other venues of nondeterministic parental influence may occur when the purpose is not to directly influence the child's behavior but to influence the holistic contexts that may beneficially guide the child's choices. Examples of such holistic indirect influences may include contributing to a responsive relationship context to which the child has a stake, or managing the child's ecological environments such as the child's neighborhood, school, and network of peer relationships (Parke et al., 2003). Managing these proximal and distal contexts may serve to constrain the child's agency but in a nondeterministic way that allows the child scope for action.

Synthetic Outcomes

The dialectical conception of relational influence implies a dialectical conception of *synthetic outcomes* that reflect the coregulated nature of outcomes in close relationships. Two conceptions of outcomes that are iconic in unidirectional models of socialization are the constructs of *compliance* (Kuczynski & Hildebrandt, 1997) and *intergenerational transmission* (Kuczynski et al., 1997). Both of these conceptions connote an expectation that outcomes in the younger generation are linear reflections of the input of the older generation. A way forward is to reconceptualize compliance as the synthetic outcome of accommodation and negotiation and intergenerational transmission as the construction of working models.

Accommodation and Negotiation

A deterministic conception of outcomes is most explicit in behavioral perspectives on compliance to parental demands. According to researchers who take a behavioral perspective (e.g., MacMahon & Forehand, 2003; Patterson, 1982), the operational definition of an appropriate child response is immediate compliance within seconds after a parental command. Ideally, children should comply immediately, completely, and without complaint, a definition that implies an expectation of an exact match between the child's response and the parent's command. Moreover, Patterson (1982) defines alternative child responses as noncompliance, which is considered to be a form of coercion. This does not allow possibilities of considering as legitimate the novelty that emerges from the transactions between human agents.

Grusec, Goodnow, and Kuczynski (2000) argue that although there are situations in which parents do expect immediate or strict compliance, such as when there are issues of safety or morality, such situations are relatively infrequent in daily life. Thus, Goodnow (1994) suggests that parents communicate a variety of positions with regard to their acceptance of children's behaviors ranging from what is ideal to what is acceptable, tolerable, or "out of the question." Similarly, Kuczynski and Hildebrandt (1997) argue that in close relationships the goal is less often to obtain exact compliance than it is to obtain conflict resolution or a compromise of the original desires of the participants. During the history of their relationship, parents and children evolve shared understandings of what will pass for compliance in different situations. It is only rarely that the shared understanding approximates the complete, immediate submission that is implied by immediate compliance. Accordingly, they proposed that the constructs of accommodation and negotiation as dialectical reformulations of compliance and noncompliance for children's cooperative and noncooperative responses in close relationship contexts. The idea is that these terms convey the synthetic nature of the process and outcomes of many episodes of socialization. They are synthetic outcomes because they incorporate novelty that results from a dialogic engagement of the opposing perspectives of parents and children.

Accommodation conveys both a cooperative response, and also that the form of the cooperative response will be chosen by the recipient rather than by the sender of a request. Thus, an accommodating response by children may acknowledge that the parent has been heard, that children will attempt to coordinate the parent's wishes with their own plans or that children are willing to negotiate an alternative course of action. Children's responses, even when cooperative will contain a novel component creatively constructed by their actions and interpretations. For example, a child who is disposed to cooperate may wish to do so at a time or in a manner (e.g., whistle while working, listening to music while studying) of their own choosing, thus infusing creative agency into their accommodative action. Similarly, *negotiation* is a synthetic outcome of two opposing causal forces, the parents' demand and the child's resistance to the demand, as constrained by the relationship context. Just as children must regulate their cooperative behaviors in a social context, they must also regulate their autonomous behaviors within a context that contains other individuals, including parents, whose choices clash with their own. Consequently, the main argument is that socially competent children display a coregulated but nonexact form of cooperation or resistance—a synthesis—that represents their expression of agency within the constraints of a close parent-child relationship.

Working Models

The idea that children internalize the values of the parents or that culture is transmitted from one generation to the next also has deterministic connotations. Strauss (1992) described the construct of *intergenerational transmission* of values or culture as incorporating FAX metaphor that implies that parents directly and faithfully transmit a copy of their own values to their children. The idea of transmission not only discounts the agency of children but also implicitly discounted the agency of parents who were considered to be passive conduits of their own socialization experiences (De Mol, Lemmens,Verhofstadt, & Kuczynski, 2013; Kuczynski et al., 1997). The transmission idea also does not incorporate the possibility of intergenerational change in social values or that members of each generation actively construct their own values in the process of internalization. The flip side of intergenerational continuity is cultural and social change. Since the 1970s there have been vast changes in values concerning gender equality, racial, cultural, family, and sexual diversity, and the rights of children. There is a new concern for the impact of human activities on the environment. The role of media and globalization of knowledge drives increasingly rapid change occurring in the present. Yet the socialization literature has not had the conceptual tools to study the developmental implications of these phenomena.

Kuczynski et al. (1997) maintain that the concept of *working models* can appropriately replace the deterministic conception of internalization as a static transmission of similarity, with a conception that internalization is an ongoing process of synthesis where beliefs and values are continuously being constructed and challenged throughout life. The model in Figure 9.7 considers the ecological context of socialization and internalization, reframed as a dialectic between parents and children's engagement with the social world at the macro level, processing of information at the individual level, and transactions occurring between the parent and the child in the proximal context of the family.

The macro contexts of the parents' internalization (which may differ for the mother and the father) and the macro context of the child's internalization are depicted

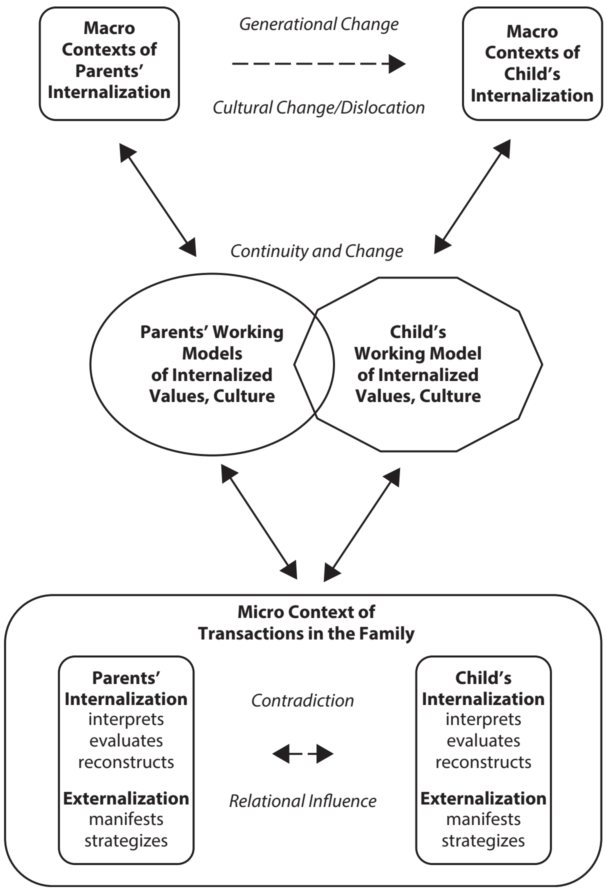

Figure 9.7 Dialectical model of intergenerational transmission.

at the top of Figure 9.7, conceptualized as culture and generation. The concept of *generation* is concerned with continuity and change produced through the agency of people born and learning at succeeding periods of historical time. Generational change comes about through external forces and collective actions such as immigration, war, economic changes, new technology, and the introduction of new ideas by individuals and groups. According to Mannheim (1928/1952) young people form a generation by being exposed to specific social, historical, and political events and ideas of a particular time period. They develop shared ways of interpreting and evaluating situations, and may form generational groups that react to issues in similar ways. The different generations of parents and children form the context of external ideas to which parents and children are exposed. The parent generation and the child generation are separated by the historical time in which they were growing up. Many families also may experience abrupt change in culture due to immigration. For immigrant parents and children, therefore, there are differences in the external influences of direct socialization such as schools and other institutions as well as differences in to their exposure the process enculturation, or emersion in the everyday practices of the encompassing culture.

The micro context of transactions within the family is depicted at the bottom of Figure 9.7. Parents and children are depicted as engaging in transactional processes of internalization and externalization (Lawrence & Valsiner, 1993, 2003) as they face contradictions that emerge from their separate perspectives within the constraining influences of a valued, interdependent, long-term relationship. Parents and children must reconcile the different sources of information from their surrounding ecology as well as their interactions from each other to affirm or reconstruct their own ideas and to decide how to interact with each other. Kuczynski and colleagues (Kuczynski et al., 1997; Kuczynski & Knafo, 2013; Kuczynski, Navara, & Boiger, 2011) suggest that studying the acculturation of immigrant families in a new culture offers new insights into the process of creating the syntheses that are the working models of parents and children. Thus, family acculturation involves not only processes such as teaching, modeling, and discipline that have been studied in within-culture socialization, but also processes that are unique to the problem of fostering aspects of the parents culture of origin to children in the new cultural context. Their reviews of the literature included novel strategies such as cocooning, prearming, intentional enculturation, guided participation, on the part of parents; cultural brokering, negotiation, resistance, and accommodation on the part of children; as well as relationship management so as to protect the relationship despite differences in perspective on the part of both parents and children.

At the center is the expected dialectical outcome of internalization, a synthesis that incorporates both similarity and change. Because of the different life experiences, different transactions with each other, and their different exposure, loyalty, and susceptibility to ideas of generational peers, media or other institutions in their ecological contexts, each member of the family develops different personal working models of their values.

Nonlinear Trajectories

Socialization is often conceived of preparing the child for future success in society. However, there is little conceptualization of the future as an outcome. The idea of a nonlinear trajectory consisting of a general orientation with a wide range of possibilities as outcomes offers a nonlinear conception of progress toward the future. The idea of trajectories was depicted earlier in Figure 9.6, as possible syntheses that result from the processing of contradictions. The *trajectory equifinality model* proposed by Sato, Hikada, and Fukuda (2009) conceptualizes trajectories as a continuing process of development that entails further contradictions and syntheses along the way to an uncertain future. The trajectory equifinality model assumes that individuals are agents who produce their own development (R. M. Lerner & Busch-Rossnagel, 1981). The model also builds on the principle of equifinality, which means that in open systems a given end state can be reached by many potential paths (McClelland et al., Chapter 13, this *Handbook*, this volume; Overton, 2010, Chapter 2, this *Handbook*, this volume; von Bertalanffy, 1968). However, the model adds a conception of the activity of the individual, the role of social forces, and a conception of a broad zone of possible endpoints.

The trajectory equifinality model begins with an individual's goals and vision of a possible future, which may be quite broad. Operating on the individual's progress toward the future are two social forces, *social direction* from cultural and external powers that keep an individual in line, and may be a barrier to individual choices, and, *social guidance*, which are the available social supports for the individual's goals. From these conflicting directions, the individual creates a *synthesized personal trajectory*. Along the way barriers and opportunities provide multiple bifurcations or choice points where decisions are made about deviations from the trajectory or alternate routes on the trajectory. The trajectory moves toward a *multifinality* where there is more than one concrete goal, or a *zone of finality* if the general direction but not the specific goals are clearly visualized.

Holden (2010) discusses the idea of trajectory from the perspective of the parent providing social guidance for children's progress toward the future. Parents initiate trajectories by selecting environments that expose children to experiences and invest resources in particular activities, such as music lessons that may or may not pan out. Parents may support trajectories through proactive and sustained efforts, including encouragement, time, and helpful messages and material assistance. Parents mediate trajectories that are chosen by the child by helping the child to interpret roadblocks and helping them to avoid problematic trajectories. Finally, parents provide guidance by reacting positively or negatively to child-initiated trajectories by supporting the child's choices of activities, education, and career, or using their power to attempt to redirect or create barriers to the child's choices. Holden's analysis is not a deterministic one because the child is also active in accepting, rejecting, or negotiating parent-initiated pathways. Children's own efforts determine progress on the trajectory and they may choose their own pathway with or without the parents' support.

A question for future research is whether parents take a dialectical perspective on their role as socializing agents. Parents do not always expect exact transmission of messages and exact conformity as outcomes (Goodnow, 1997) and it is possible that when parents give commands or hold forth on values, they have some expectation that their requests will be compromised or transformed through interpretation. In this view, parents who have an inflexible or deterministic conception of future goals may be on a trajectory that is problematic for both parents and children. Having precise goals such as insisting that children have specific beliefs, or that they achieve academically at an unrealistic level, or adopt a narrow range of professions (doctor or lawyer, but definitely not psychologist) may undermine children's confidence or promote resistance in children and a sense of failure in parents.

There is preliminary evidence that parents may have expectations and practices that are consistent with a dialectical perspective on influence. Robson and Kuczynski (2013) found that parents of 8- to 13-year-old children rarely conceived of or enforced their behavioral expectations of children in the sense of clear, inflexible "rules" determined solely by the parent. Instead, flexibility was built into the nature of parental expectations. Flexibility was evident in that parents adjusted their expectations according to the child's emotional state and situational circumstances and allowed leeway in the time frame for the child's cooperative response. Leeway was also inherent in the way parents perceived they implemented their expectations. Parents reported that rules were negotiated during interaction. For instance, parents adjusted their rules based on the child's resistance and the child's persuasive abilities. Resistance was anticipated and often interpreted as a legitimate sign of children's autonomy and parents granted greater leeway as children earned their autonomy by demonstrating responsibility. Thus, parents appeared to have an underlying dialectical conception of their influence both by incorporating leeway for the child's agency in their very conception of rules and in anticipating and accepting novel outcomes during interactions with their child.

APPLIED SOCIAL RELATIONAL THEORY

Although social relational theory is relevant to multiple practical applications concerning interventions in the family, the focus here is on applications in family therapy. When families enter the therapeutic setting, parents, who generally initiate the appointment, often present the problem as noncompliance or unmanageability of the child. Parents are frustrated, angry, powerless, defeated, and define for the therapist the desired outcome, which often is that the child must be changed or must be made to comply. However, the therapist sees other issues beyond the presenting problem of child noncompliance, in particular the therapist sees relational complexities in the dynamics of the family. The child is also frustrated, angry, powerless, and defeated, and other family members, the marital relationship, sibling relationships may also be troubled.

Depending on the therapist's theoretical orientation, there are different directions for choosing where to intervene in a dynamic parent-child relationship system. For the behaviorally (i.e., mechanistically) trained therapist the choice is often to begin with the child's noncompliance and its role in a mutually coercive cascade (McMahon & Forehand, 2003; Patterson et al., 1992). Noncompliance has been described as the foundation for the development of children's aggression and the parents are commonly given a child-management protocol to increase their control over the noncompliance. In this perspective the quality of the parent-child relationship is a secondary goal that, hopefully, will follow improvements in the child's behavior. Contemporary parenting programs that are focused on noncompliance often have a relationship-management component where efforts are made to improve the relationship by adjusting the ratio of positive to negative reinforcements or emotional communication skills (Kaminski, Valle, Filene, Cynthia, & Boyle, 2008). However, relationship management is often added on eclectically and pragmatically and does not stem from a theoretically integrated position on the role of relationships in the assessment of causality in the family.

Some cognitive-behavioral therapists have adopted a more comprehensive relational approach to intervention. Cavell challenged the tight focus on noncompliance, arguing that a strong stance against noncompliance could undermine the affective quality of their relationship (Cavell & Elledge, 2007; Cavell & Strand, 2003). Cavell advocated a broader focus on long-term socialization goals instead of immediate reduction of problem behavior. This approach includes constructing an accepting long-term relationship as a context for children's development and developing a sense of connection and containment within that relationship.

Family therapists, trained in a family systems perspective (Nichols, 2012) understand the family as an organized whole, beyond the individual and beyond the dyad, in which mutual influences between the family members feature the interdependent nature of the system. Family systems theory was influenced by cybernetics and general systems theory (Dallos & Draper, 2000). Both theories offered a comprehensive paradigm to understand the individual family member within the dynamics of the family context, but differed in their approach about the nature of the system. Cybernetics takes a mechanistic perspective in which families are approached as closed systems driven by basic principles as feedback, homeostasis, and circularity. In the mechanistic perspective, systems resist change and psychopathology of an individual family member is assumed to have the function of restoring homeostasis when the family equilibrium is upset. On the other hand, in the general systems perspective, systems are open and consist of living organisms that constantly coact with their environment (Overton, 1975; von Bertalanffy, 1968). Within this organismic perspective systems are also seen as self-organizing, self-regulating sets of processes that actively maintain internal stability, as well as creatively adapt to the external environment. In the organismic systems metaphor the psychopathology of an individual family member is considered to reflect the failure of the family as a system to adapt to internal and environmental changes (Minuchin & Fishman, 1981). Because of this holistic approach to humans' individual and relational functioning, the target of intervention is more often the relationship. However, family therapists are hampered by insufficient conceptual tools for understanding relationship dynamics and for intervening at the relationship level.

Social relational theory is not a psychotherapeutic model or protocol, but a theory about family dynamics offering ideas and concepts that focus on meaning construction within family relationships and other social contexts. The theory's dialectical assumptions has a potential to inform clinical practice with troubled families because it offers a reframing of troubled relationships that builds on strengths within the family. Its core examples from research on well-functioning, or nonclinic, families, indicating that child resistance, conflict and opposing perspectives, intimacy, flexibility, and uncertainty have positive functions in the family reframe similar ideas that have had an exclusive negative connotation in studies of clinic families. The focus on agency, the relationship context, and dialectical change suggests directions for a positive action-oriented approach that contrasts with the problem-focused interventions.

Concepts such as equal agency, which draws attention to the agency of not only the parent but also the child and the dialectical tensions between both agents, the relationship as context embedded within cultural contexts, and the dialectical nature of interpersonal influence, can help the clinician to understand (and do something with) the complexity of the process of reconnecting the agents to the relationship.

Addressing the agency of individuals is central to a strengths-focused approach in which the focus is on the positive capacities of parents and children, including positive goals and resources that they can develop, rather than on their problems and deficiencies (R. M. Lerner, Almerigi, Theokas, & Lerner, 2005; Saleebey, 2013). Focusing on strengths connects agents as a constructive future perspective on their relationship becomes more visible (Berg, 1994). Most psychotherapy models agree that progressive change can only be obtained by addressing constructive human dimensions, for example by encouraging parents to use positive reinforcement of appropriate behavior not just punishing noncompliance. However, although attention has been paid to the resilience of children in the family (Walsh, 2006), an agentic strength perspective is almost absent in research on child psychopathology. The traditional focus on children with ADHD, autism, obsessive-compulsive disorders, oppositional-defiant disorders, and conduct disorders is on the deficits of these children and how the environment, in particular the parents, have to deal with it. Almost no research has focused on what these children add to the relationship and how the environment can build on these constructive aspects in social interactions with these children. Instead, clinical concepts such as "noncompliance" infuse children's attempts to express their autonomy with the idea of defiance (Kuczynski & Hildebrandt, 1997). Similarly, constructs such as "parentified child" and "role reversal" attribute victimization and passivity to actions that alternatively may be viewed as the child acting as competent or resilient actor stepping up to promote mutual goals on behalf of the family (Chee, Goh, & Kuczynski, in press).

Focusing on the agency of the child is consistent with evolutions in family therapy in which the child is perceived as an agent of change (Wilson, 2012). Children bring novelty, unpredictability, and creativity into the family therapy session that the therapist can welcome to induce change. Wilson argues that the family therapist has to leave his safe position and move to a "zone of discomfort," a zone that is not controllable for the therapist due to the agency of the child in the therapy session. Treating parents and children respectfully and equally does not mean agreeing with them all the time. Change includes dialectical interventions from the clinician whereby the appropriateness of parents' and children's positions, beliefs, and goals are challenged. This active attitude includes the clinician not being able to know in advance which meanings and behaviors are appropriate for the system because these are coconstructed within the therapeutic process.

Isolated Versus Connected Agents

An implication of the social relational perspective is that the dialectical process of opposing forces between parent and child actions as agents can only be constructive for development when both feel connected to the relationship. The inevitable contradictions that exist between parents and children, which are necessary for development, become obstacles when parent and child agents no longer feel connectedness to the relationship. When contradictions can only be felt and understood as mutual rejections, positive moments of synthesis are impossible and parents and children become alienated from the relationship.

The basic therapeutic premise that follows from this perspective is that family members who visit clinical practice are feeling and behaving as *isolated agents* and not as *connected agents*: Family members have lost or are losing their connectedness to the relationship. At the beginning of a psychotherapeutic process, parents and children tell stories about their being hurt, misunderstood, rejected, teased, denigrated, and assaulted by others. They experience these feelings in an overpowering and undifferentiated way. The basic feeling is one of disadvantage or being badly treated by others. The core issue is that family members seem to have lost a sense that they have significance and make a difference in their relationships.

Children can be said to differ in their sense of connectedness in supportive relationships. Relationally connected children have a history of involved, responsive, and intimate relationships and have a relatively high stake in their relationships with parents and others in their social networks. As connected agents, they are more likely to have their expression of agency constrained by a desire to protect their valued relationship. They are more likely to have a mutually responsive orientation (Kochanska, 2002) and, when they resist, they are more likely to do so in a way that accommodates the relationship. In contrast, relationally isolated agents have a history of uninvolved, unresponsive and nonintimate relationships and a corresponding low stake in personal relationships with caregivers. This dynamic is likely for children in neglecting, abusive, and insecure relationships.

Baumrind (2012), citing Bakan (1966), argues that optimal development requires a balance within the individual of the competing drives of communion and agency:

> *Communion* is the drive to be connected and of service that manifests itself adaptively in pro-social conduct, including friendliness with peers, and cooperation with just authority; *agency* is the drive for independence, individuality, autonomy, and mastery that manifests itself adaptively in self-efficacy, initiative, assertiveness, and resistance to what are perceived as unjust demands. Agency unmitigated by communion is self-centered and exploitive resulting eventually in reciprocated harm; communion unmitigated by agency is self-abnegating and subservient, inviting exploitation. (p. 46)

Thus, Baumrind cautions against the extremes forms of both isolated and connected agency. Reinterpreting this from a relational perspective, what is required is a relationship context that fosters both autonomy and interdependence. This means a relationship where the agency of each member is acknowledged, where difference can coexist with connection, and each member recognizes existentially that they have influence in the relationship.

Reconnecting Agents to the Relationship

A direction for application is that any professional change agent, including the therapist can construct with the parent and the child moments of shared and cocreated meanings in their relationship. The therapist can begin to connect parents and children by pointing to the fact that they took the trouble to visit clinical practice as evidence that the relationship matters to them. Furthermore, the concept of the relationship as a systemic whole, including a past, a present, and a future can inspire parents, children, and the clinician in their joint search for moments of shared meaning (Oliphant & Kuczynski, 2011; Weingarten 1991). Joint recognition of moments of intimacy reconnects the isolated agents to the relationship. By identifying past and present moments of shared meaning the parent and the child can each recognize that the ability to engage in shared meaning belongs to their relationship and not just conflict. However, the construction of the relationship cannot be solely an individual activity. Mutual moments of intimacy are necessary to connect the agents and to create the possibility for constructive dialectics in the relationship. Moments of intimacy do not reflect fusion of the agents: Difference between the agents and acceptance of difference is necessary for positive development.

The agency of the family member reflects the meaning or significance of the family member within the relationship and consequently implies the existential nature of being an agent in the relationship. Because the sense of being an agent is constructed within the relationship, a family member is dependent on acts of recognition of other family members for the development and construction of his or her sense of agency. When the parent and the child can feel again that they make a difference toward each other, they can be reconnected to the history of their relationship.

Promoting the Idea of Dialectical Influence

The idea of "making a difference" in the relationship pertains to the dialectical construct of relational influence discussed earlier. An important goal in reconnecting isolated family members to the relationship is that family members develop a concept of interpersonal influence that is appropriate to interactions among human agents. There are two potential issues, loss of a sense of relational efficacy, and an inappropriate linear conception of the nature of influence in social interactions between human agents.

Relational efficacy is a dialectical elaboration of the existing concept of *self-efficacy* (Bandura, 2006). Despite the importance of the self-efficacy construct for understanding human agency, the original definition of self-efficacy is based on an implicit linear conception of influence, namely, the belief that an agent has the capacity to exert personal control to produce a particular outcome. This sense of *control* is assumed to originate through the experience of contingencies among actions, intentions, and outcomes. However, relational efficacy, or the belief that one can influence another person in a relationship, distinguishes interpersonal outcomes from outcomes such as control over the nonsocial environment. The construct of relational efficacy includes both cognitive and experiential dimensions and stems from an individual's experience of making a difference in the relationship (De Mol & Buysse, 2008a). Relational influence captures the person's existential being in the relationship, where what the person does or does not do has consequences for the other person in the relationship.

A sense of relational efficacy develops from an individual's history of transactions in specific relationships. Children report that their sense of influence in the family derives from a mutually responsive parent-child relationship context (De Mol & Buysse, 2008b). Similarly, Cummings and Schermerhorn (2003) proposed that parental sensitivity and responsiveness promote children's beliefs that they can influence family interactions. For instance, Cummings and Schermerhorn argued that secure and insecure attachment patterns could be interpreted as children's beliefs that their bids for comfort in stressful situations will be met with success. De Mol and Buysse (2008a, 2008b) found that children recognize their influence on parents but often do not perceive this influence to be strategic or intentional. This suggests that children derive their sense of relational influence from the way their parents respond to their actions. The influence children have on their parents tells children something about their agency in the relationship. Because of their position in the relationship, which is less bounded by cultural obligations in comparison with the parents' position (e.g., parents have a social and financial responsibility, which children do not have), children can feel and describe the dialectical nature of interpersonal influence. This is much more difficult for parents because they may be constrained by illusions of control because of dominant unilateral discourses in our society.

Relational efficacy has two components. First, a sense of relational efficacy develops from the awareness that one's influence emerges from a history of transactions in the relationship and that one exerts one's own influence in a bidirectional ←→ context that includes the influence of the other. Second, a realistic sense of relational efficacy requires awareness that influence is dialectical in nature and that the outcome has the potential for novelty. Assessing the other's response always entails uncertainty because the other's response contains external behaviors that one can objectively see as well as internal responses that one cannot see. Grusec and Goodnow (1994) argue that the success of the parent's influence attempt depends, cognitively, on the child's accurate perception of the message and, motivationally, on the child's acceptance of the message. However, the parent never knows for certain if the message has been accurately perceived or accepted.

A sense of relational efficacy is built up of one's experience of both cooperation and resistance, formed during the history of the relationship. Because of the transformations that occur during transactions, an expectation of having a deterministic control over social outcomes is unrealistic and potentially maladaptive because the agency of each family member is ignored (White & Epston, 1990). However, even if a child does not comply, or comply exactly, to a parent's request, a sense of relational efficacy may emerge from perceptions that the parent has been heard, that they matter (Marshall & Lambert, 2006), or that they have made a difference in the relationship.

When agents lose their sense of relational efficacy, the relationship is no longer a constructive power resource that can support them as agents of influence. And when constructive power resources disappear, only coercive power remains (De Mol & Buysse, 2008a). Cummings and Schermerhorn (2003) argued that when children have little sense of agency in the relationship they tend to express their agency in extreme controlling ways or may act in an excessively self-reliant manner. Similarly, Bugental, Lyon, Krantz, and Cortez (1997) found that mothers who experience a loss of influence act in a threatened manner and resort to coercion to restore their power. The problem with coercive power is that coercion can never change the relationship in constructive way because individual agents become further alienated from the relationship.

Another implication for clinical practice is that isolated agents may have an inappropriate expectation that their influence in interpersonal relationships should be linear and direct. The assumption that parents and children are equally agents implies that one relationship partner cannot mold the other or cannot influence the other in a way that the other becomes a person as desired by the relationship partner who exerts influence.

To develop a sense of efficacy in the relationship, parents and children need a dialectical conception of what influence means. Namely, because of the meanings generated by each of the interacting partners during the processes of internalization and externalization, their effects include qualitative change or novelty (see previous discussion of relational influence). Without this dialectical conception of influence, the other's responses of nonexact accommodation, reinterpretations, and negotiations cannot be perceived as positive outcomes of influence. The metaphor of developing and *experiencing the inside* (as a result of internalization) and *dialoguing via the outside* (as a result of externalization) can be used to translate the abstract scientific metaphor of internalization and externalization into a form that can be used in clinical practice.

Each person in a transaction influences the other in a two-stage process: their inside private experience and their outside public communication. The inside consists of cognitions and felt emotions about the other and the relationship and what one would like the other to do. Individuals disclose their inside to others through their outside via overt behavior, verbal messages, and nonverbal communication such as facial expression, tone of voice, and body posture. Within social interactions individuals can see others' outside but not their inside. It is by means of their outside that individuals affect the other person, which means that the other person will interpret the individuals' outside. Based on these interpretations and inside experiences, the person will respond with their own outside. Each person in a social interaction interprets the other's behavior, attributes meaning to it and feels something about it, and ultimately responds or externalizes on the basis of that interpretation and feeling. Thus an influence transaction between two people is a dance with four steps: sender's outside to recipient's inside; recipient's outside to sender's inside. The outcome of actions between agents in the dance of relational influence should always be considered to generate something new that reflects the activity of both partners.

Within a clinical context, the child, as full and equal partner of the parents and the clinician can contradict the illusion of direct control and give insights in the complexities of interpersonal influence. Although agency includes strategic action and partners use strategic behavior to influence the other partner in the relationship, strategic action can never unilaterally change the other agent. Consequently, the therapeutic agent has to take this position explicitly, acknowledging the impossibility of imposing change on the parent and the child. However, therapeutic agents do have relational influence in the sense of making a difference in the relationship.

Acknowledging the Cultural Context of Agency

The recognition in social relational theory of cultural influences on the construction of the parent-child relationship also has important clinical implications. Cultural representations complicate the therapeutic scenario at a level beyond dyadic interactions. For example, a strong social representation in Western culture is the deterministic notion that the parent is causally responsible for the development of the child (De Mol & Buysse, 2008b). This social representation is problematic because meanings are constructed about the failing parent and about the child who is victim of the parental failure. The cultural representation that the parent-child relationship is necessarily hierarchical is a barrier to understanding that friendship qualities or intimate interactions that are possible in the relationship. The dominant representation that a real parent-child relationship is a biological relationship is problematic for stepparent-stepchild relationships where there are no cultural prescriptions available for the stepparent and child about how to act in the relationship. For children with ADHD the representation that education can only be accomplished if the child acts beyond their capacity and sits still and attentive for long periods of time is a barrier to understanding the child's limitations for acting agentically within these constraints.

The therapeutic agent can address the barriers posed by cultural representations by offering parent and child the broad cultural framework in which the constraints on their agency acquire meaning. This implies that parents and children cannot change cultural discourses, but by addressing them as full agents they can think how to cope with these complexities and recognize that they have an influence on these discourses, although without changing them linearly. Acknowledging cultural representations allow the clinician to address the reciprocal influences between the various levels of human complexity.

DIALECTICALLY INFORMED METHODOLOGY

The dialectical approach is partially an argument that a broader methodology of theory-driven research is needed for the study of socialization processes. Over the years there have been calls for a conception of science that recognizes a constitutive role of theory construction as an interpretative act in the process of generating scientific knowledge in psychology (e.g., Haig, 2005; Kuczynski & Daly, 2003; Overton, 2002, Chapter 2, this *Handbook*, this volume; Valsiner, 2000). This position means that the field needs to move beyond the neopositivist methodologies that have dominated research efforts. As an epistemology, neopositivism regarded scientific hypotheses as strict inductions drawn from pristine empirical observations and hypotheses were assessed in this same pristine field. This approach demanded that any theoretical concept or broad theory be ultimately reducible to the pristine observations from whence they derived (see Overton, 2006, for a critique of the history of neopositivism and instrumentalism as scientific methodologies). A consequence of neopositivism is that inductive and hypothetico-deductive methods, with an associated focus on the tools of statistics, aggregated variables, and objective measures, are viewed as the hallmarks of the scientific method, a position that marginalizes the role of theory construction (e.g., Haig, 2005; Overton, 2006; Valsiner, 2000).

Valsiner (2000; Branco & Valsiner, 1997) suggests that rather than viewing methodology as a toolbox of ready-made methods for gathering data (observations),

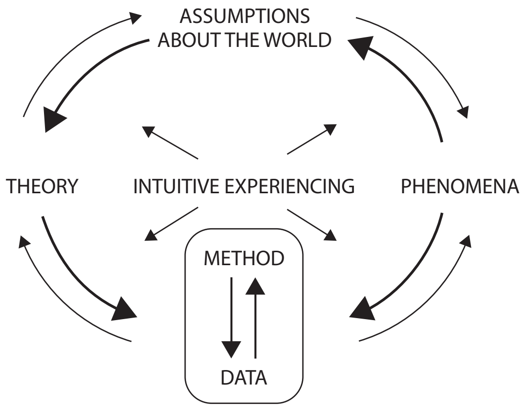

Figure 9.8 The methodology cycle.

Source: From "Changing Methodologies: A Co-Constructivist Study of Goal Orientations in Social Interactions," by A. U. Branco and J. Valsiner, 1997, *Psychology and Developing Societies*, *9*(1), 35–64. Reprinted with permission of Sage Publications.

methodology should be viewed more generally as the whole process of knowledge construction (Figure 9.8). "It entails mutually linked components of general assumptions about the world at large (axioms), specific constructed theories of the given target area, understanding of pertinent phenomena, and—finally—ways of constructing specific methods to transform some aspects of the phenomena into purposefully derived data" (Valsiner, 2000, p. 82). Explaining the phenomenon is the focus of the knowledge construction process and the researcher is the agent who will use whatever methods or concepts it takes to achieve understanding, mainstream or not. Worldviews, metatheory, theory, phenomena, and the production of data are interlinked in a system of ideas observations and procedures in which the researcher, on the basis of personal reasoning, experiences of the real world, and intuitions, makes productive or unproductive choices among various methods in relation to the emerging understanding of phenomena. The following examines the coacting components of the methodological cycle.

Focusing on the Phenomenon

The phenomenon is the central focus of the research endeavor. According to Haig (2005) phenomena are relatively stable, recurrent, general features of the world that researchers seek to explain. Haig distinguishes phenomena from data. Data are pliable and idiosyncratic to particular investigative contexts because data result from the interaction of a large number of factors.

> Phenomena have a stability and repeatability that is demonstrated through the use of different procedures that often engage different kinds of data. Data are recordings or reports that are perceptually accessible; they are observable and open to public inspection. Despite the popular view to the contrary, phenomena are not, in general, observable; they are abstractions wrought from the relevant data, frequently as a result of a reductive process of data analysis. (Haig, 2005, p. 374)

As was outlined earlier in this chapter, socialization, as a phenomenon, is more complex than once was assumed and involves intergenerational change, not just stability and continuity, active agency, not just passive reactivity. This is what needs to be understood. Theory, data, worldviews, experience, therefore, can be regarded as no more than conceptual and procedural tools that aid in understanding the phenomenon.

Worldviews

Worldviews generally refer to metatheoretical ideas regarding ontology, or assumptions about the nature of the world. Ontological assumptions guide the conceptualization of both the phenomenon and its constituent processes. It was argued in this chapter that a dialectical (organismic-contextual or relational developmental systems) ontology is better suited for understanding the phenomenon of socialization in the family than a mechanistic ontology. A dialectical ontology involves assumptions about the active nature of the coacting components, the context in which they coact, the relations between the components and the whole and the nature of outcomes. We also argue, that to make effective use of dialectics as a conceptual tool, one cannot adopt just one idea, such as accepting that children are agents, but retain other assumptions such as a mechanistic conception of influence or regarding context as a variable rather than a constituent process. Comprehensively adopting a dialectical model has implications for the whole system of ideas that are used to understand a phenomenon.

Adopting a dialectical framework is difficult because training in psychology continues to be influenced by a mechanistic ontology (see Overton, Chapter 2, this *Handbook*, this volume). According to Kuczynski et al. (2003) adapting a dialectical framework is especially difficult in the study of socialization because dialectics goes against the grain of "common sense" cultural understandings of the nature of parent-child relationships. Natural language, concepts, aphorisms, and metaphors, which are part of culture, guide the perception of childrearing and as a fundamentally unidirectional, deterministic process. There have been several proposals of steps to be undertaken by a researcher who wishes to take the qualitative shift to dialectically inspired research.

Toomela (2012) addressed the challenge of enabling researchers to abandon habits of partitioning what is a systemic causal whole into discrete linear causes and effects by providing steps for implementing the principle of holism. Citing the work of Vygotsky, Toomela argues that to understand any phenomenon in a system under investigation one needs to know: (a) the component parts that make up the whole; (b) the specific relations between the components or structure of the phenomenon; and (c) development, or how the phenomenon emerges and changes over time.

Overton (2002) outlined three steps that focus on the need to replace traditional epistemological dichotomies of observation versus interpretation, and, theory versus data, with relational bipolar dimensions:

Step 1, *relational analysis—synthesis* replaces split reductionism. This means that analysis must occur in the context of some integrated whole, and the integrated whole operates in the context of its analytic parts (see also Wagoner, 2011).

Step 2, *relational action pattern—conditions* explanation replaces split causes. This means a focus on the systemic conditions associated with change rather than direct causation between isolated elements. This idea invokes Aristotle's formal and final explanations and is similar to Valsiner's (2000) idea of catalytic or systemic causality rather than efficient or linear causality.

Step 3, *abductive logic* replaces split induction and deduction. *Abduction*, also referred to as *retroduction*, was originally described by the pragmatist philosopher Charles Sanders Pierce (1992) as a third mode of inference, along with deduction and induction, and the only mode of inference concerned with the discovery of new ideas. Modern revival of interest in abductive inference is attributable to Hanson (1958) and to Harman (1965), who introduced a conception of abduction known as *inference to best explanation*. The abductive process or abductive inference operates by arranging the observation under consideration and all background ideas (including specific theoretical and metatheoretical concepts) as two spheres of the dialectic relation. The question is then asked as to what must necessarily be assumed in order to have that observation. The inference to what *must,* in the context of background ideas, *necessarily be assumed* then comes to constitute the explanation (or abductive hypothesis) of the phenomenon (Overton, Chapter 2, this *Handbook*, this volume). Theory construction involves three general methodological phases: (1) theory generation entailing the abductive process to generate a system of hypotheses, (2) theory appraisal by assessing the abductively derived hypotheses in varied contexts beyond those used to generate them, and (3) theory development whereby the supported abductive hypotheses become a part of the system of hypotheses to be applied to other phenomena to generate further abductive hypotheses. Each phase requires inferential processes, the very processes that neopositivism disparaged as unscientific (Haig, 2005; Overton, Chapter 2, this *Handbook*, this volume).

Finally, Kuczynski and Parkin (2009) offered a third set of recommendations, this time for implementing a dialectical ontology for the study of parent-child relationships and socialization. First, stop thinking of parents and solely in terms of mindless behavioral reactivity or sets of variables; think of parent and child as equal agents. Second, stop thinking about parents and children as individuals or even individuals engaged in social interaction; think of parents and children as engaging in transactions in an interdependent, long-term relationship context. Third, actively search out processes within the parent, within the child, or between the parent and child that are most likely to be a source of contradiction and disequilibrium, for these are the source of changes in representations that are opportunities for qualitative change. Fourth, challenge linear thinking; think both/and and search for synthesis.

Theory

In the methodology cycle (Branco & Valsiner, 1997; Valsiner, 2000) the researchers' consideration of the phenomenon and the array of ideas concerning worldviews, experience, and data leads to the development of mid-range theory that conceptualizes current understanding of the phenomenon or some aspect of the phenomenon. As can be seen in list of constructs in Table 9.2, the conceptualization of many basic concepts in socialization research was guided explicitly or implicitly by the worldview metaphors of mechanical mechanism and linear causality. Adopting

TABLE 9.2 Socialization Concepts in Mechanistic and Dialectical Metatheoretical Frameworks

Constructs	Mechanistic-Deterministic →	Dialectical-Relational ←→
Bidirectional dynamics	Social interaction Exchange of behaviors Individual dynamics	Social transaction Mutual meaning making Relationship dynamics
Context	Decontextualized dyads	Close relationships
Agency	Unequal agents	Equal agents
Unequal power	Static asymmetry	Interdependent asymmetry
Agency constructs	Self-efficacy, sense of personal control	Relational efficacy, sense of interpersonal influence Isolated and connected agents
Interpersonal causality	Control	Relational influence
Antecedents of change	Control strategies	Contradiction: ambiguity, ambivalence, conflict, expectancy violations
Conformity	Compliance/noncompliance	Willing compliance, accommodation/negotiation
Internalization	Intergenerational Transmission	Construction of working models

a organismic-contextual or a relational developmental systems ontology (see Overton, Chapter 2, this *Handbook*, this volume; Witherington, Chapter 3, this *Handbook*, this volume) interpreted through dialectics provides a means of reinterpreting each of the basic concepts so that they are infused with interconnected assumptions of holism, contradiction, and synthesis. The dialectically reinterpreted concepts in Table 9.2 represent a continuation of the proliferation of new concepts and, indeed, new language, for parent-child relations and socialization processes that has been occurring in the literature on parent-child relations since the "discovery" of reciprocal relational bidirectionality ←→. Examples are "coconstruction," "coaction," "scaffolding," "coevolution," "coregulation," "collaboration," "intersubjectivity," "interpenetration," "shared meaning," "shared affect," "joint activity," "attunement," and "relational dialectics" (Kuczynski et al., 2003). These new concepts represent processes—not mechanical mechanisms—for which there are no natural language terms. Rather than thinking of interaction as a series of discrete turns, exchanges, reactions, or control techniques, the new concepts attempt to aid the perception of the thoughts and actions of one partner as intertwined with the thoughts and actions of the other. Actions of the parent and of the child may be mutually anticipated, interpreted, and adjusted to in a continuous fashion so that it is difficult to think of the products of parent←→child relations, whether they be meanings, childrearing strategies, or social relationships, as individual achievements.

Data ←→ Method

According to Valsiner (2000), methods and data are constructed by researchers on the basis of the way they have personally strategized their study of a phenomenon with regard to the methodology cycle. The data ←→ method process may feed back to the reconstruction of theory regarding the phenomenon. The methodology cycle encourages a flexible and strategic approach to method that defuses debates between quantitative and qualitative research. "Neither quantitative nor qualitative methods per se can be labeled 'objective' or 'scientific' as their status in these valued roles is determined only through their fit with the methodology cycle" (Valsiner, 2000, p. 82).

Given that so much data has been derived from mechanistic, neopositivist approaches, it would seem that there should be more investment in deriving data from an organismic-contextual perspective. In this endeavor, there is a special place for a theoretically guided mixed-methods approach that includes qualitative methods (see Tolan & Deutsch, Chapter 19, this *Handbook*, this volume, for an extended discussion of mixed methods). Qualitative research, including naturalistic observation and its cognitive counterpart, qualitative interviewing, is an interpretive, naturalistic method for identifying, describing, and understanding phenomena. Several features of qualitative research makes it well-suited for the identification and analysis of phenomena from a dialectical perspective. First, the dialectical conceptions of processes, contexts, and outcomes, described in this chapter, entail cognitive, bidirectional ←→ transactions, and qualitative research is directly concerned with data having to do with the research participants' cognitive and emotional experience. Second, qualitative methods are naturalistic methods and have the goal of discovering natural categories (themes) that are grounded in the participants' experiences of the phenomenon. This contrasts with dominant quantitative approaches in which meanings are predetermined, and operationalized beforehand (e.g., preestablished coding systems, rating scales) and imposed on the research participant. Although such methods have their place in testing selected hypotheses derived from existing theory, they do not generate new concepts and theoretical innovation. The most important outcome of qualitative research is to identify and describe new concepts as well as theory about phenomena that takes into account the contextualized and transactional nature of socialization. Qualitative research is also useful for exploring underlying micro processes that underlie measured variables or statistical associations between variables. Finally, naturalistic qualitative research may lead to the construction of new measured variables that derive ecological validity from the extent to which they reflect the natural cognitive experiences of parents and children.

Qualitative research maximally involves the interpretive capacities of researchers in the process of making sense of the data they collect. Kuczynski and Daly (2003) outlined an abductive approach to qualitative analysis of narratives that is designed to promote the discovery of new phenomena from naturalistic data. The strategy requires that the researcher enters the analysis of naturalistic data by first arranging background ideas as *sensitizing concepts*. For example, sensitizing concepts may be the competing behavioral and dialectical models for a phenomenon that are available in the literature as well as ideas available from experience. These sensitizing ideas initially serve to guide the interpretation of data. Thus, sensitizing ideas are analogous to hypotheses, which may or may not be confirmed by the analyses of the data. However, the researcher's ideas are sensitizing and do not determine the final identification or interpretation of themes because the researcher is also alert to ideas in the narratives that contradict or cannot be understood with reference to the background of existing theory. These contradictions are the surprising observations for which a new explanation must be abductively generated. The new inference of a best explanation for a phenomenon can then be assessed against competing ones. Essentially, the approach is a deliberate search for puzzles in the data that fuels the abductive interpretive process in the search for new discoveries.

CONCLUSIONS

It has long been recognized that theories of socialization often provided inadequate models for understanding the phenomenon of socialization. An important advance has been made since the 1970s in the move from unidirectional to bidirectional ←→ models of socialization to capture the inherent bidirectionality that is evident in the phenomenon of socialization. A second advance has been the increasing focus on human agency (Bandura, 2006; Kuczynski, 2003; Sokol et al., Chapter 8, this *Handbook*, this volume; Witherington, Chapter 3, this *Handbook*, this volume) in the complex causal structure of socialization phenomena. The new challenge is consider the larger framework of dialectical systemic assumptions in which relational bidirectionality and agency are embedded. Individual concepts within dialectics—activity, context, qualitative change, contradiction—have long been a source of key metaphors that have fueled theory development in psychology. However, this has often been a piecemeal approach that essentially reduced the various aspects of the dialectical framework to elements rather than components of a whole system of thinking and perceiving phenomena.

The dialectical framework outlined in this chapter is incomplete because the construction of dynamic systems metatheories for developmental psychology is ongoing (Molenaar & Nesselroade, Chapter 17, this *Handbook*, this volume; Overton, Chapter 2, this *Handbook*, this volume; Valsiner, 2012; Witherington, Chapter 3, this *Handbook*, this volume). Moreover, the process of translating between metatheoretical to substantive theory levels of analysis as well as the implications for practice is in its early stages. In any case, conclusions, in dialectics, are always in process.

The transactional model originally proposed by Sameroff (1975a, 1975b) is also an unfinished project. Although the idea of reciprocal relational bidirectionality has taken hold, the dialectical conception of transaction has not. One reason has to do with compromises that result when rich theoretical concepts are subjected to statistical testing. "Although the transactional model originates from a strongly dialectic, organismic orientation, any operationalization requires a mechanistic measurement model, in which dynamic processes are reduced to static scores that can be entered into statistical analyses" (Sameroff & MacKenzie, 2003, p. 617).

Social relational theory builds on the transactional model in two ways: First, when the purpose is to predict selected key hypotheses, improvements can be made in the creation of variables that capture dimensions of parent and child behavior in a more dynamic way and in formulating outcomes so that they reflect the idea of synthesis. Qualitative changes are difficult to detect when measures of outcomes themselves are conceptualized in a deterministic way.

Second, social relational theory provides guidance for exploring underlying micro processes of social transactions. A micro-process model of dialectical causality together with a macro model of transactional nature of human development (Sameroff, 2009) may jointly address the tension between complementary goals of research: prediction, on the one hand, and understanding intervening processes, on the other.

A further challenge concerns application in clinical and other interventions. Advances in applying a dialectical systems perspective requires a new generation of science practitioners who are equally informed in dialectical theory and immersed in the reality of the family lives of their clients and knowledge of what it takes to help them. The promise of an organismic-dynamic-contextual framework for systems is that it offers theory to grasp the continuously more complex nature of families in current society because it embraces complexity and does not try to resolve it using mechanistic concepts.
